# ANNALS OF THE MISSOURI BOTANICAL GARDEN

VOLUME 80
1993

## *Colophon*

This volume of the ANNALS of the Missouri Botanical Garden has been set in APS Bodoni. The text is set in 9 point type while the figure legends and literature cited sections are set in 8 point type.

The volume has been printed on 70# Vintage Gloss. This is an acid-free paper designed to have a shelf-life of over 100 years. Vintage Gloss is manufactured by the Potlatch Paper Company.

Photographs used in the ANNALS are reproduced using 300 line screen halftones. The binding used in the production of the ANNALS is a proprietary method known as Permanent Binding.

The ANNALS is printed and distributed by Allen Press, Inc. of Lawrence, Kansas 66044, U.S.A.

Annals of the
Missouri Botanical Garden

---

**The Annals,** published quarterly, contains papers, primarily in systematic botany, contributed from the Missouri Botanical Garden, St. Louis. Papers originating outside the Garden will also be accepted. Authors should write the Managing Editor for information concerning arrangements for publishing in the ANNALS. Instructions to Authors are printed in the back of the last issue of each volume.

# MONOGRAPH OF THE NEOTROPICAL SPECIES OF *ASPLENIUM* SECT. *HYMENASPLENIUM* (ASPLENIACEAE)[1]

*Noriaki Murakami*[2] *and*
*Robbin C. Moran*[3]

## Abstract

*Asplenium* sect. *Hymenasplenium* is one of the best defined groups of *Asplenium*, being characterized by creeping rhizomes, dorsiventrally symmetrical steles, swollen petiole bases, unique rachis-costae structure, and chromosome base numbers of $x = 38$ or 39. In the Neotropics, the section has ten species and three hybrids. The species are *A. delitescens*, *A. hoffmannii*, *A. laetum*, *A. obtusifolium*, *A. ortegae*, *A. purpurascens*, *A. repandulum*, *A. riparium*, *A. triquetrum*, and *A. volubile*. The hybrids are *A.* ×*papyraceum* (of unknown parentage), *A. delitescens* × *A. laetum*, and *A.* ×*incisoserratum* (= *A. hoffmannii* × *A. laetum*). All the aforementioned species and hybrids are endemic to the Neotropics. Central America and the Andes harbor the most species and endemics. A cladistic analysis was not done because the neotropical species of the section apparently do not form a monophyletic group separate from the paleotropical ones.

Section *Hymenasplenium* is one of the best defined groups within *Asplenium*, distinguished by the following synapomorphies: creeping rhizomes, dorsiventrally symmetrical steles, swollen petiole bases, unique rachis-costae structure and chromosome base numbers of $x = 38$ or 39. All other *Asplenium* species have erect or ascending rhizomes, radially symmetrical steles, nonswollen petiole bases, and $n = 36$ or multiples thereof (rare exceptions differ in only one of these characteristics).

*Hymenasplenium* was first described by Hayata

[1] We thank the curators of the following herbaria for making loans available: A, AAU, B, BM, BR, COL, CR, F, G, GH, K, L, M, MICH, NY, PORT, QCNE, S, U, UC, Z. We also thank the following botanists who helped one or both of us with fieldwork in Latin America: George Anger, Gerardo Aymard, Mireya Correa, Lisa and Larry Dorr, Michael Grayum, Hiroshi Kidono, María Morrello, David Neill, Benjamin Øllgaard, Francisco Ortega, and Pablo Sánchez. We also thank the Smithsonian Tropical Research Institute for the use of its Fortuna Dam facilities when we worked in Panama, and UNELLEZ in Guanare, Venezuela, for the use of its facilities. The research for this paper was done while the first author worked at the Missouri Botanical Garden supported by a grant from The Japanese Society for the Promotion of Science. He thanks Peter H. Raven, who served as his official host. Finally, we thank our wives, Misaki Murakami, who did the illustrations, and Cirri K. R. Moran, who helped with the computer-related aspects of the research.

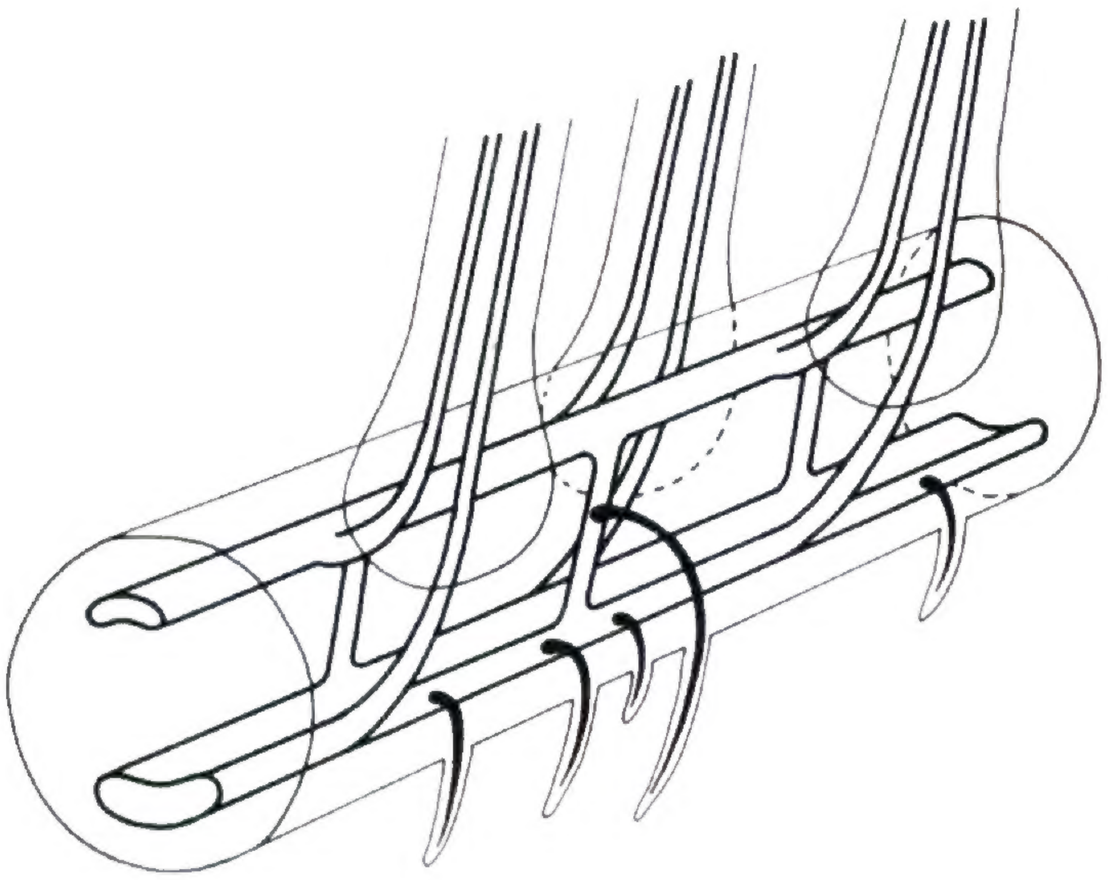

FIGURE 1. Creeping rhizome, dorsiventral stele, and swollen leaf bases—characteristics of *Asplenium* sect. *Hymenasplenium*.

(1927) as a monotypic genus based on *A. unilaterale* Lam. and distinguished entirely by the stelar structure of the long-creeping rhizome (Fig. 1). Hayata was greatly influenced by stelar structure and described several genera based solely upon this character (e.g., *Diploblechnum*, *Monachosorella*, *Boniniella*, *Pentarhizidium*, and *Hymenasplenium*). Iwatsuki (1975) revised the species of *Hymenasplenium*, which were then thought to occur primarily in the Old World, and reduced the genus to a section of *Asplenium*. This ranking has been followed by nearly all pteridologists, including us.

The present monograph treats 10 neotropical species that clearly belong to section *Hymenasplenium* alongside the Old World species. (The Old World species of the section are *A. apogamum* Murakami & Hatanaka, *A. cardiophyllum* (Hance) Baker, *A. cataractarum* Rosenstock, *A. cheilosorum* Kunze, *A. excisum* C. Presl, *A. hondoense* Murakami & Hatanaka, *A. obliquissimum* (Hayata) Sugimoto & Kurata, *A. obscurum* Blume, *A. subnormale* Copel., and *A. unilaterale* Lam.) We have not done a cladistic study of the neotropical species because they are not a monophyletic group distinct from the paleotropical species. The first author plans to do a cladistic study of all the species in the section worldwide using evidence from morphology, anatomy, chloroplast DNA, and nuclear gene sequencing of the small subunit of ribulose-bis phosphate carboxylase. The only difference we have seen between the Old and New World species is that the New World ones have proliferous roots, whereas the Old World ones do not. Proliferous roots do not correlate with any other character (besides geography) and therefore cannot be used to define a natural group.

Previous workers, studying only the Old World species of section *Hymenasplenium*, have surveyed anatomy (Iwatsuki & Kato, 1975; Misuta et al., 1980), reproductive patterns and morphological variation (Murakami & Iwatsuki, 1983), phytochemistry and chemotaxonomy (Murakami & Hatanaka, 1983, 1985, 1988a; Murakami et al., 1985), ecology and morphological variation (Kato & Iwatsuki, 1985, 1986), genetic diversity (Watano & Iwatsuki, 1988), taxonomy (Murakami & Hatanaka, 1988b), and chromosome numbers (Mitui et al., 1989).

The New World species are much more poorly studied. For a long time, workers in the Old World thought that the only New World species that belonged to section *Hymenasplenium* was *A. obtusifolium*. Smith (1976) was the first to point out that the New World species *A. delitescens*, *A. melanopus* (= *A. purpurascens*), *A. laetum*, *A. hoffmannii*, and *A. repandulum* also belonged to the section. He did not, however, study the group in detail.

## SPORES

We examined the spores of all the neotropical species of section *Hymenasplenium* and found that perispore morphology was useful in defining two groups. The first group has five species, which we informally refer to as the "*repandulum* group." It comprises *A. obtusifolium*, *A. repandulum*, *A. riparium*, *A. triquetrum*, and *A. volubile*. All have spiny spores (Fig. 2A–C) or, in the case of *A. obtusifolium*, papillate spores (Fig. 2G, H). The second group comprises the rest of the neotropical species, which all have cristate spores (Fig. 2D–F). The eight paleotropical species of section *Hymenasplenium* examined by Kato et al. (1990)

had cristate spores and would therefore belong to this second group. Because most species of *Asplenium* outside of section *Hymenasplenium* have cristate spores (Tryon & Lugardon, 1991), the spiny and papillate character states should be considered apomorphic.

## GEOGRAPHY

The neotropical species of section *Hymenasplenium* are all endemic to the Neotropics. They range from southern Mexico to Panama, the Antilles, and South America from Venezuela to southeastern Brazil, forming a wide arc around most of Amazonian Brazil (Map 1).

The Andes from Venezuela to Bolivia harbor the most species (8) and this is the only region with endemics (i.e., *Asplenium ortegae*, *A. repandulum*, *A. volubile*). Costa Rica and Panama are also species-rich, containing six species. The Antilles and extreme western Amazonian Brazil both have two species, and the Guianas, southeastern Brazil, and Paraguay all have one species. The Serra do Mar region of southeastern Brazil, which is a center of species richness and endemism for ferns (Tryon, 1972), has played a minor role in the diversification of the section. Only one species (*A. triquetrum*) occurs there and it is nearly endemic (Map 9).

*Asplenium obtusifolium* is notable for its nearly circum-Caribbean distribution (Map 5) and its correlation with geography of the 32- and 64-spored races.

## PRINCIPAL COMPONENTS ANALYSIS

Our recognition of 10 neotropical species of *Asplenium* sect. *Hymenasplenium* is based primarily upon qualitative characters as shown in the key. In order to check the validity of our species circumscriptions, we decided to do a Principal Com-

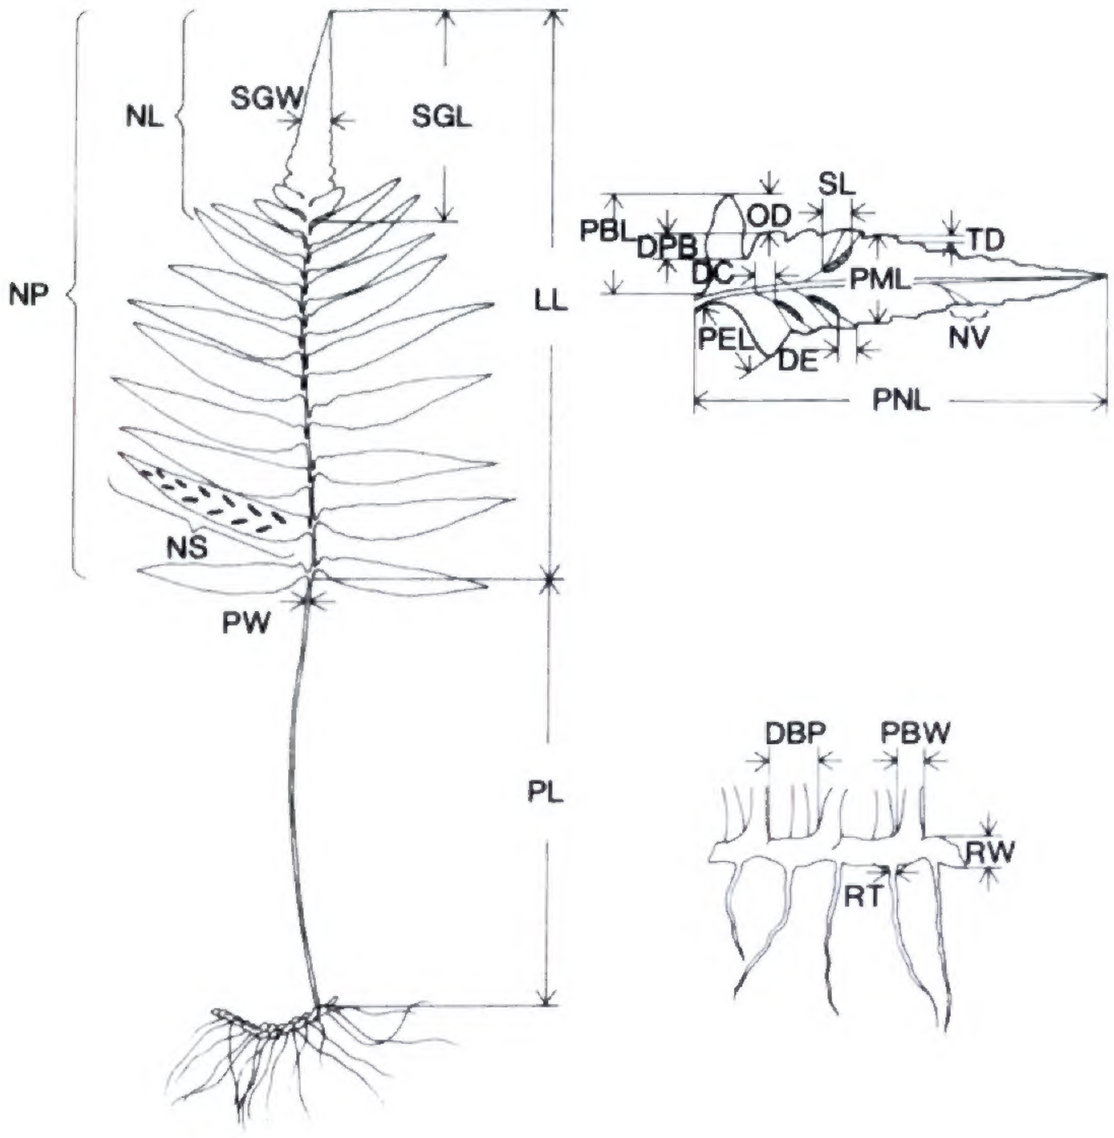

FIGURE 3. Parts of the plants measured for the Principal Components Analyses (Figs. 4, 5). Lamina length (LL), petiole length (PL), petiole width (PW), number of pinna pairs (NP), pinna length (PNL), pinna base length (PBL), pinna width at middle (PML), pinna excised portion length (PEL), number of veins (NV), depth at pinna base (DPB), auricle length (OD), serration depth at tip (TD), number of sori (NS), sorus length (SL), distance to sorus from edge of pinna (DE), distance from costa (DC), segment length (SGL), segment width (SGW), number of lobes (NL), rhizome width (RW), petiole base width (PBW), distance between two petioles (DBP), root width (RT).

ponents Analysis (PCA) of certain quantitative characters (Fig. 3) measured on herbarium specimens throughout the range of each species. We separated the species into two groups according to their separation in the first couplet of the key. The first group, which is identified under lead 1b in the key, contained *A. hoffmannii*, *A. laetum*, *A. delitescens*, *A. purpurascens*, and *A. ortegae*. The second group, which we believe to comprise a closely related group of species and which is identified under lead 1a of the key, contained *A. obtusifolium*, *A. repandulum*, *A. riparium*, *A. volubile*, and *A. triquetrum*. Then, we did a PCA on each group using computer program NTSYS version 1.40 (Rohlf, 1988). The data set for each herbarium specimen was projected on three principal component axes for the first group (Fig. 4) and two axes for the second group (Fig. 5; the third axis accounted for little variation in the second group). Tables 1 and 2 show the Eigen values and Eigen vectors of the Principal Components.

The result for the first group was that all species were separated from each other (Fig. 4). This result supports our circumscriptions of the species.

The result for the second group was not as clear (Fig. 5). Although *A. obtusifolium*, *A. riparium*, and *A. volubile* were separated from each other, *A. repandulum* completely overlapped *A. triquetrum* and *A. volubile*. *Asplenium repandulum*,

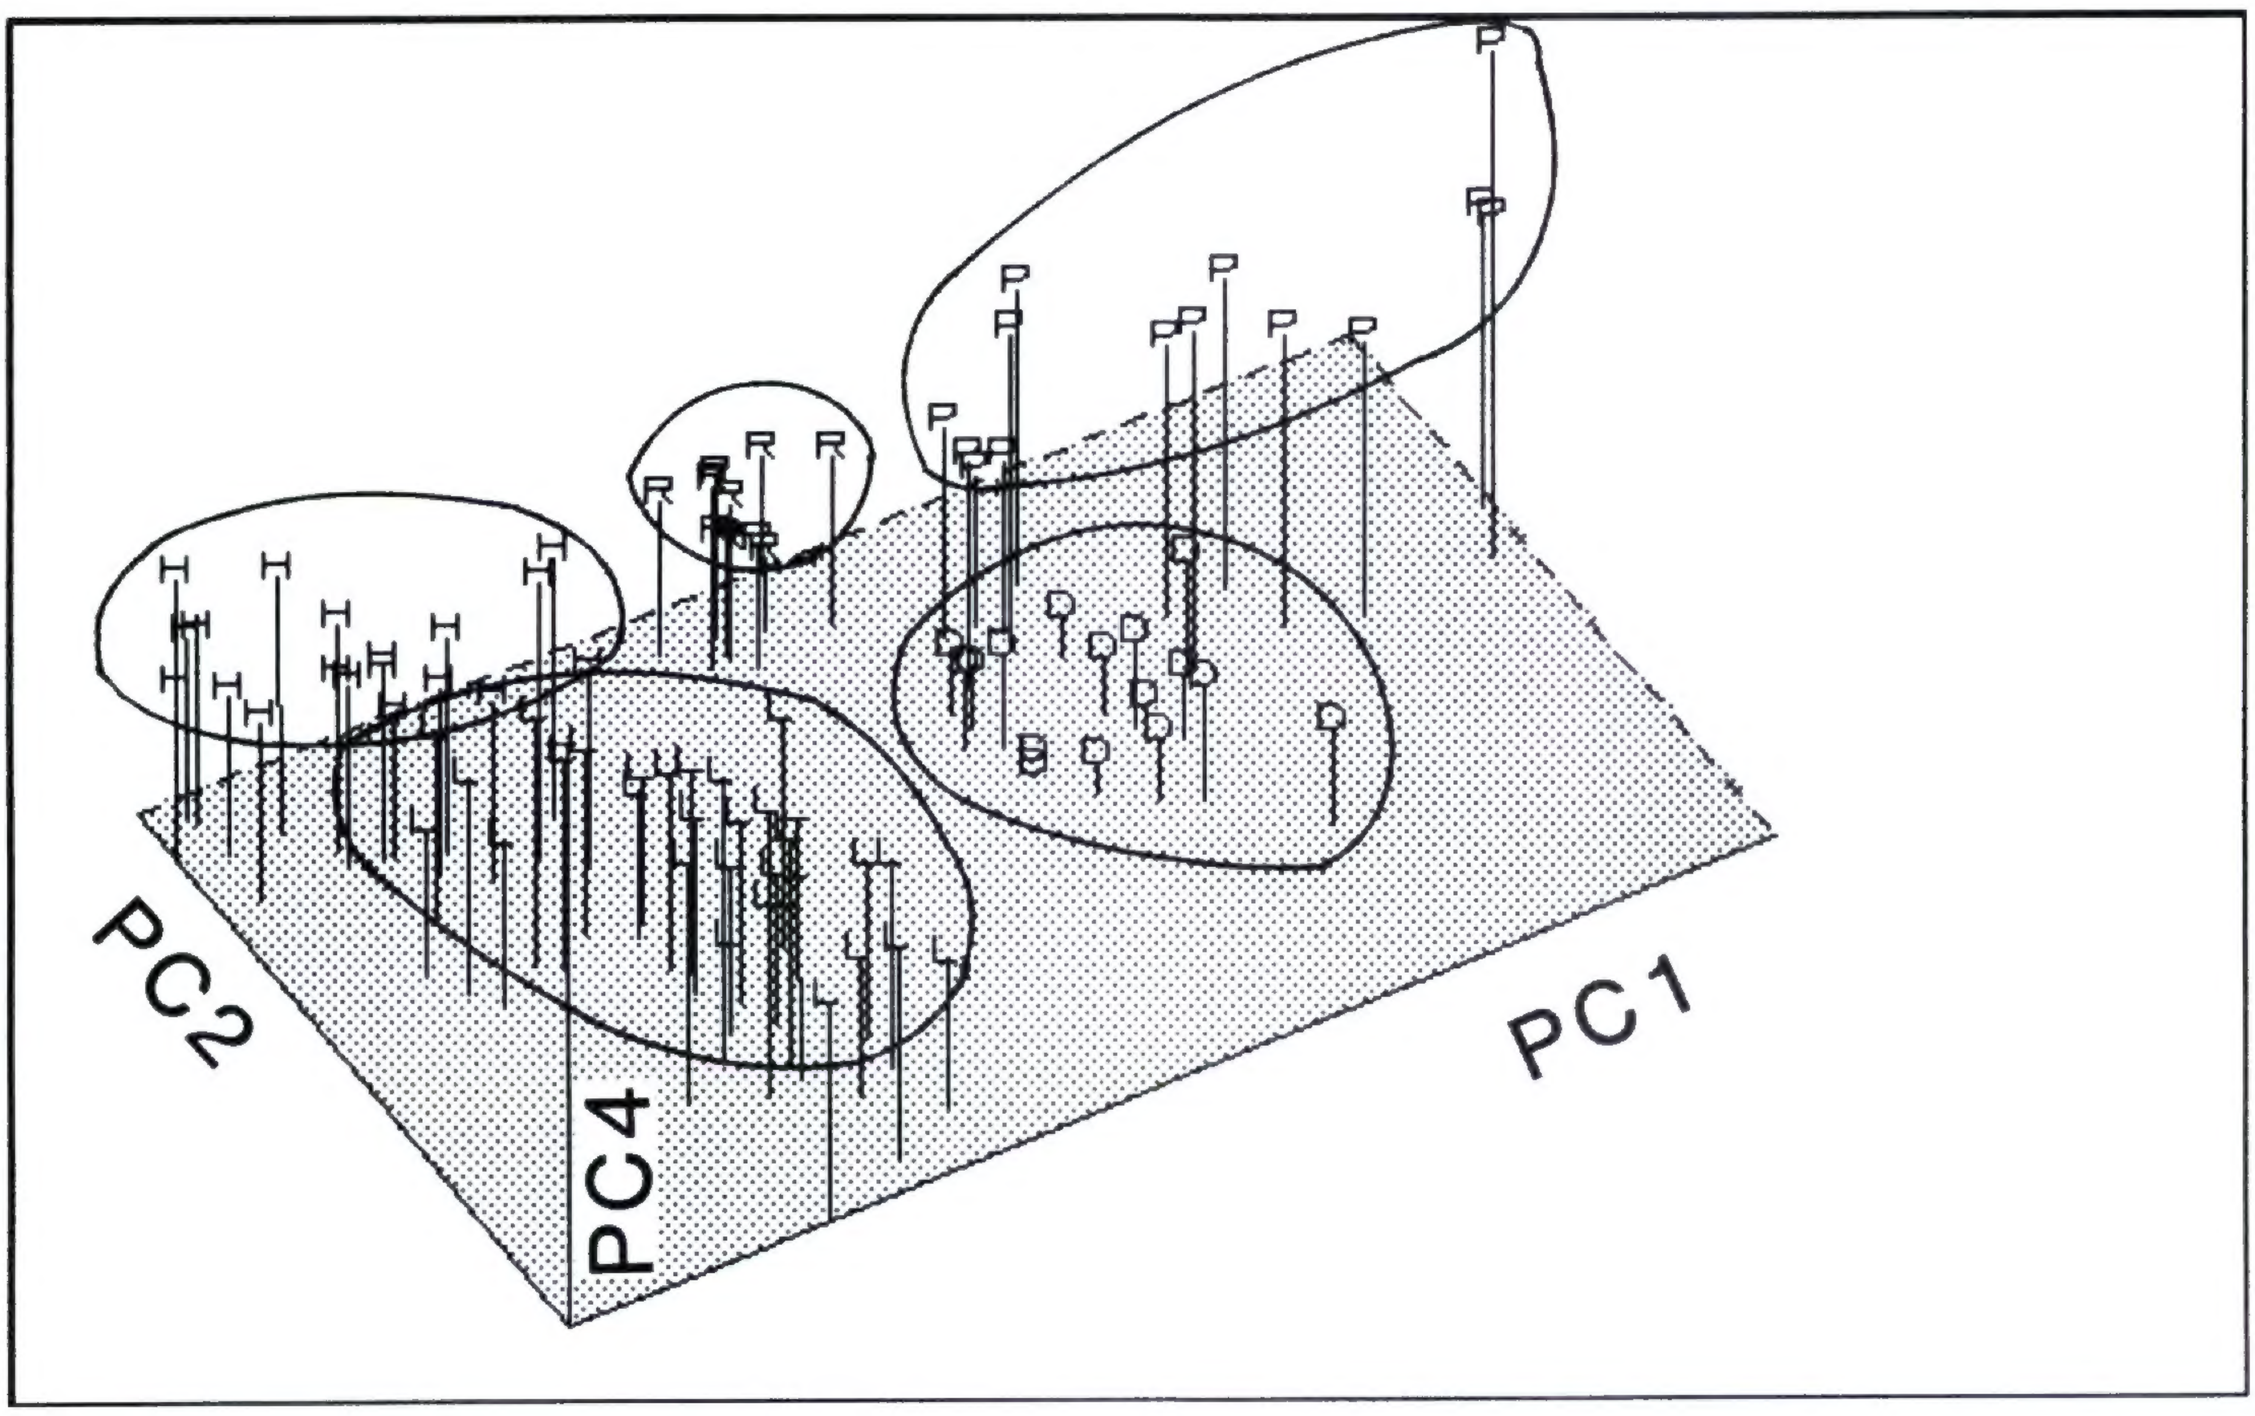

FIGURE 4. Principal Components Analysis of 23 characters of *A. delitescens* (D), *A. hoffmannii* (H), *A. laetum* (L), *A. ortegae* (R), and *A. purpurascens* (P). The three Principal Component axes account for 62% of the measured variation.

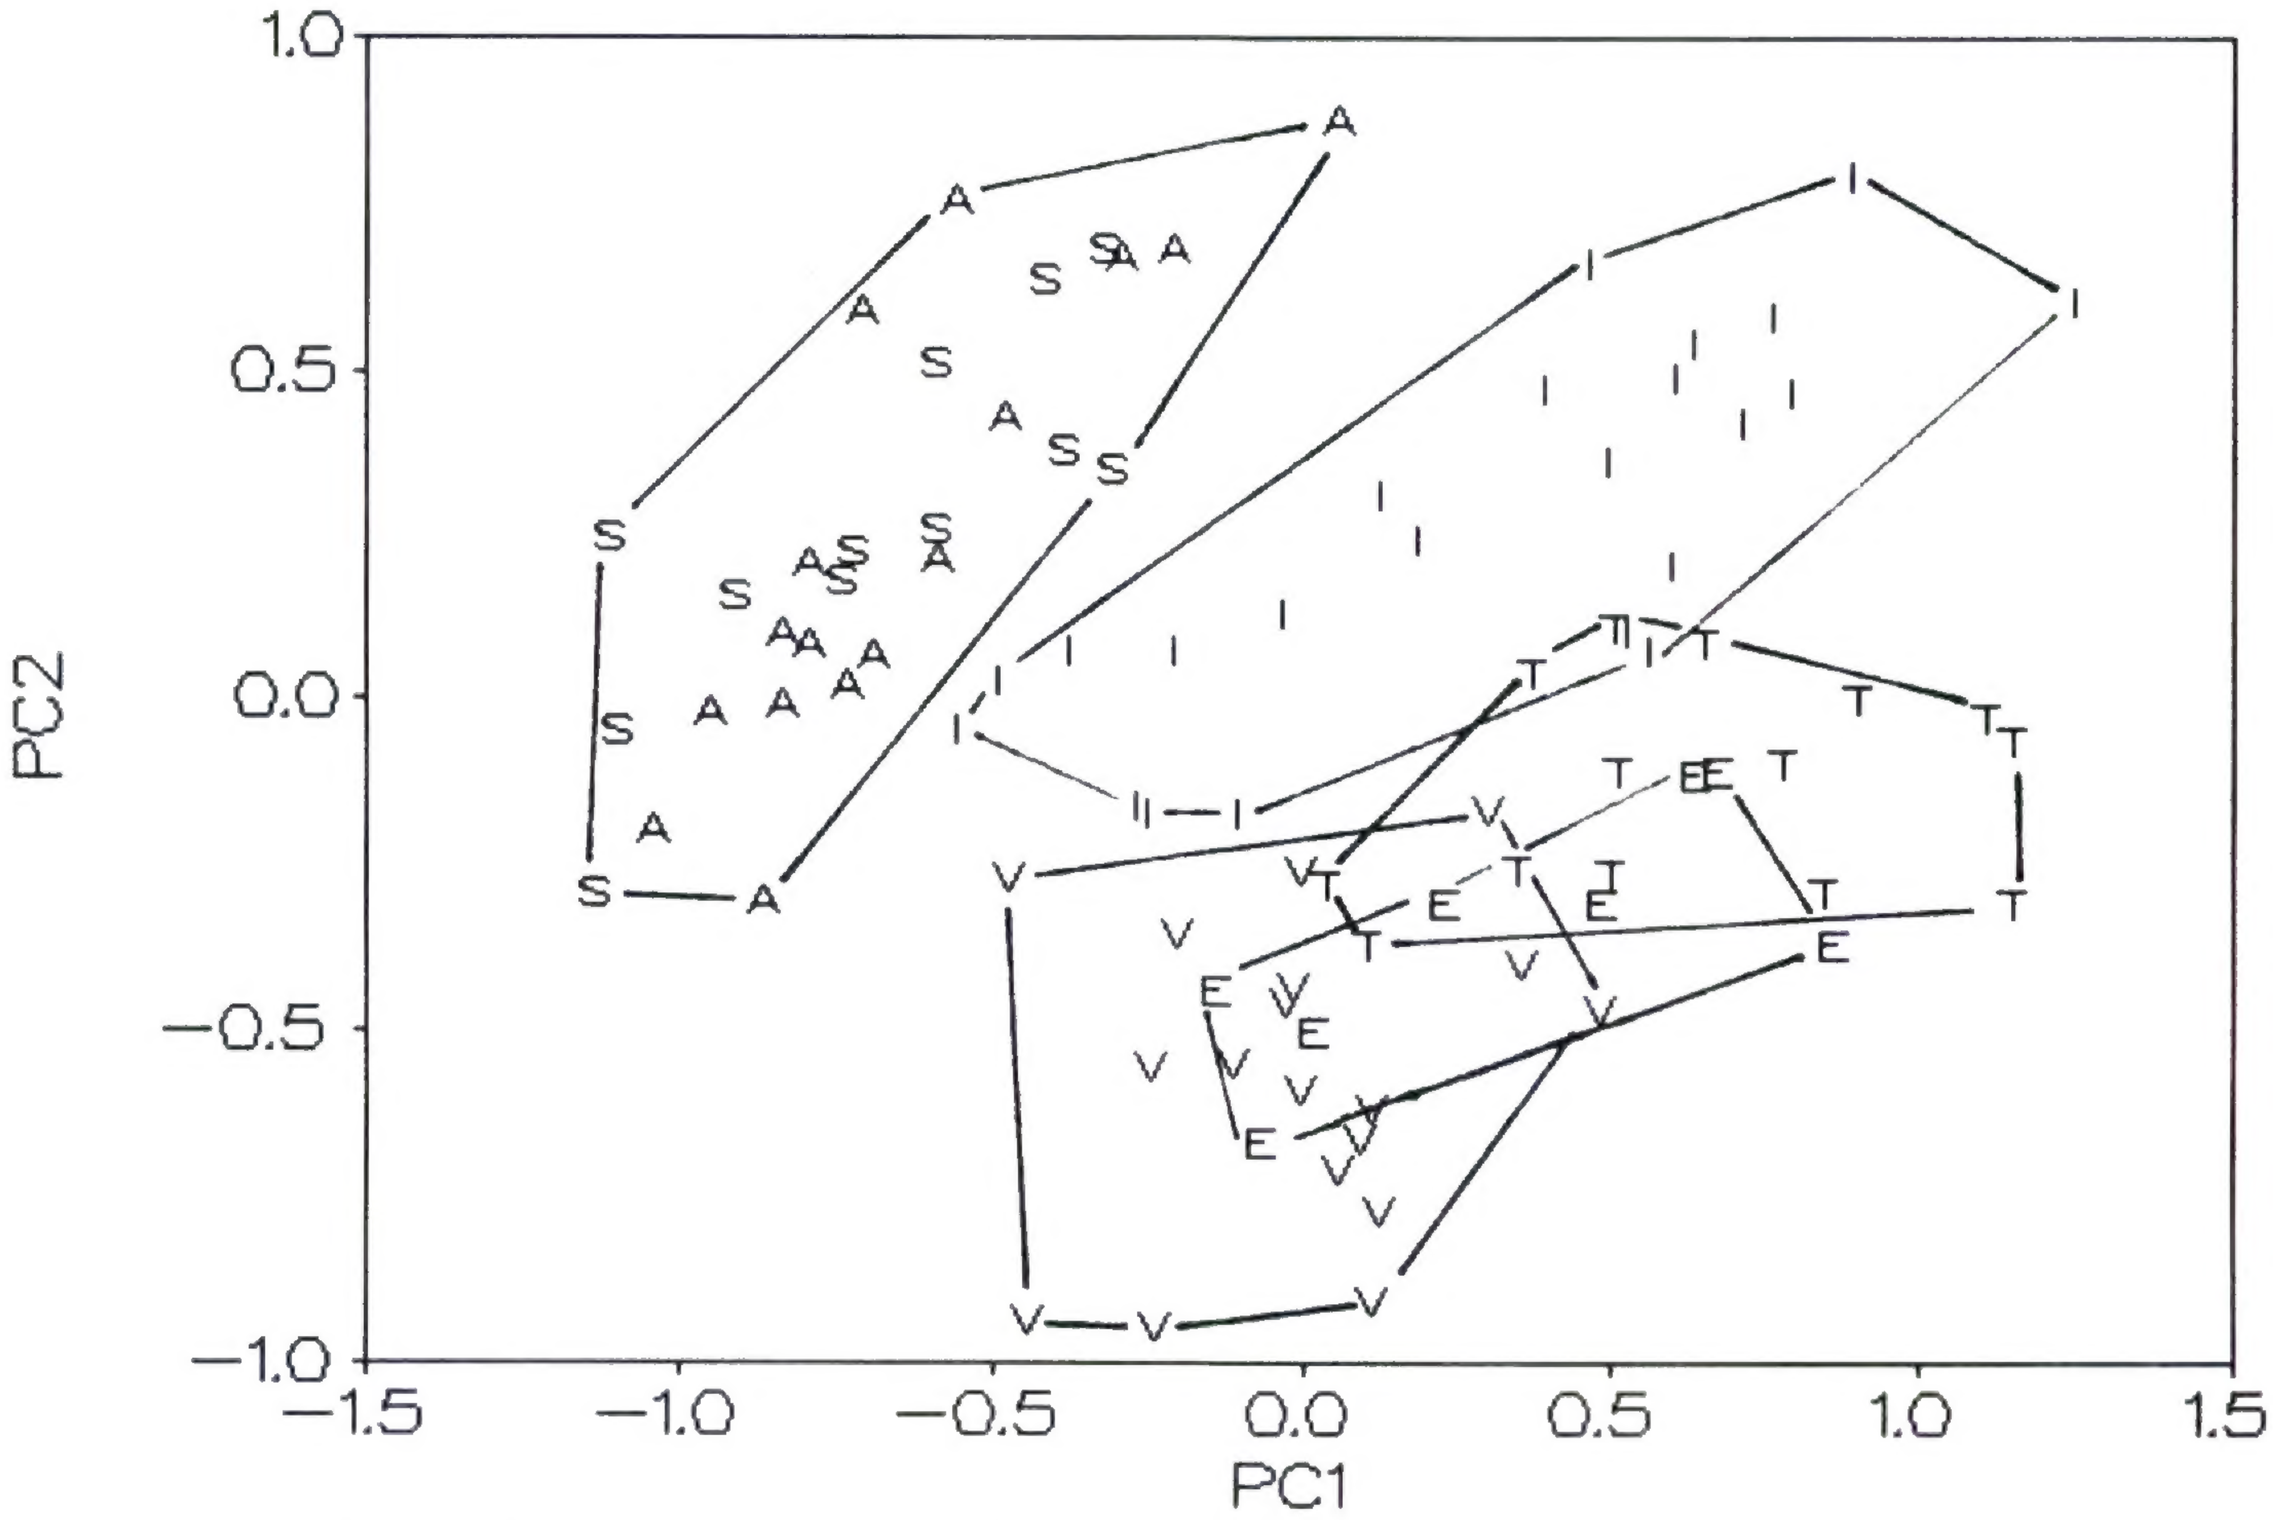

FIGURE 5. Principal Components Analysis of 20 characters of *A. obtusifolium* (A, 32-spored race; S, 64-spored race), *A. repandulum* (E), *A. riparium* (I), *A. volubile* (V), and *A. triquetrum* (T). The two Principal Component axes account for 54% of the measured variation.

however, can be distinguished from *A. triquetrum* by petiole length relative to the lamina, habitat, and range (see key, couplet 4), and from *A. volubile* by the carinate rachis and rachidial wings parallel to the plane of the lamina. These characteristics were not included in the measurements used for the PCA. Another result was that the two spore-races of *A. obtusifolium* could not be separated by the morphological characteristics measured (Fig. 5).

## Relationship to Other Groups of *Asplenium*

We are not sure what group of species within *Asplenium* is most closely related to section *Hymenasplenium*. Several species of *Asplenium* (*A. abscissum* Willd., *A. argentinum* Hieron., *A. hostmannii* Hieron., and *A. otites* Link) greatly resemble certain species in section *Hymenasplenium* in leaf form. Consequently, they are often misidentified as a species in section *Hymenasplenium*, especially *A. laetum* (which see for comparison). These species, which can be immediately distinguished from section *Hymenasplenium* by their erect rhizomes and rachis-costa architecture, may be the closest group in *Asplenium* related to section *Hymenasplenium*. This suggestion is based only on similarities in leaf form and is therefore tentative.

## Taxonomic Treatment

**Asplenium** sect. **Hymenasplenium** (Hayata) Iwatsuki, Acta Phytotax. Geobot. 27: 44. 1975. Basionym: *Hymenasplenium* Hayata, Bot. Mag. (Tokyo) 41: 712. 1927. TYPE: *Asplenium unilaterale* Lam.

Plants terrestrial, epipetric, or epiphytic; rhizome creeping, green to blackish, with two rows of alternately arranged petioles on the dorsal surface, scaly near the apex; rhizome stele dorsiventral, composed of two unequal meristeles connected by lateral strands, the ventral meristele wider and the dorsal one narrower, bearing roots from either the ventral, dorsal, or connecting meristeles; petiole terete, scaly at base, glabrous distally, greenish to atropurpureous, the base swollen and often persisting after the leaf has fallen and decayed; lamina usually 1-pinnate or (in *A. cardiophyllum*) simple and cordate; rachis not or very shallowly grooved, with or without perpendicular or flat green wings, lacking buds; costae bordered by a flange of green

tissue that is decurrent on the adaxial surface of the rachis; decurrent margins of the pinnae not thickened; veins free or (in *A. cardiophyllum*) anastomosing; spores bilateral, ellipsoid to subglobose, the perispore commonly cristate, but occasionally spiny or papillose; $x = 38$ or 39.

**1. Asplenium delitescens** (Maxon) L. D. Gómez, Brenesia 8: 52. 1976. *Diplazium delitescens* Maxon, Contr. U.S. Natl. Herb. 10: 497, t. 56, fig. 1. 1908. TYPE: Cuba. Oriente: vic. of San Luis, 18 Feb. 1902, *Pollard & Palmer 348* (holotype, US; isotypes, F, MO). Figure 6A; Map 2.

Plants terrestrial; roots 1–1.5 mm wide; rhizome 3.5–7 mm wide, nearly naked; scales 2–2.5 mm × 0.25–0.35 mm, black-brown, narrowly lanceolate, toothed; petiole bases 2.8–4.5 mm wide, swollen, 1–2 mm distant from each other on the same row; petiole 15–25 × 0.15–0.2 cm, ca. ½ the

KEY TO THE NEOTROPICAL SPECIES OF *ASPLENIUM* SECT. *HYMENASPLENIUM*

1a. Leaf apex conform, subconform, or hastate; spores spiny or papillose; rhizome greenish when living (sometimes turning blackish upon drying).
  2a. Pinna apices obtuse or rarely acute; pinna pairs 3–10, usually with a free basal acroscopic lobe; spores papillose; plants rheophytic, usually under or near waterfalls; Costa Rica, Panama, Colombia, Venezuela, Antilles ..... 4. *A. obtusifolium* L.
  2b. Pinna apices acute or rarely obtuse; pinna pairs 8–18, usually without a free basal acroscopic lobe; spores spiny; plants epiphytic or epilithic and (usually) on rocks along streams.
    3a. Rachis strongly carinate abaxially, triangular in cross section, with adaxial green wings in the same plane as the lamina (these wings are difficult to distinguish in dried material); Ecuador, Peru, Bolivia, Paraguay, southern Brazil.
      4a. Plants epilithic; petiole ca. ½ as long as the lamina length; Bolivia, Paraguay, southern Brazil ..... 9. *A. triquetrum* Murakami & R. C. Moran
      4b. Plants epiphytic; petiole ¼–½ as long as the lamina; Amazonian Ecuador and Peru ..... 7. *A. repandulum* Kunze
    3b. Rachis rounded abaxially, terete or semi-terete in cross section, with adaxial green wings perpen-

dicular to the plane of the lamina (the wings difficult to see in dried specimens); southern Mexico to western Venezuela and Ecuador.

5a. Petioles ¼–½ as long as the lamina; plants twining around small trees or saplings; rhizome internodes 1–2.5 cm long; Costa Rica, Panama, western Colombia, western Ecuador ..... 10. *A. volubile* Murakami & R. C. Moran

5b. Petioles ½ to equaling the lamina; plants usually on boulders along streams; rhizome internodes 0.2–0.6 cm long; Mexico to western Venezuela and Ecuador ..... 8. *A. riparium* Liebm.

1b. Leaf apex nonconform, pinnatifid; spores cristate; rhizome brown or blackish when living.

6a. Free pinna pairs 2–6(–8); rachis green; Mexico to Panama, Trinidad, Venezuela, Colombia ..... 2. *A. hoffmannii* Hieron.

6b. Free pinna pairs 6–25; rachis atropurpureous to castaneous.

7a. Veins (in the middle of the pinnae) 2–4-forked; rachis grooved, with an adaxial green wing perpendicular to the plane of the lamina; western Venezuela, and Ecuador and Peru on the eastern side of the Andes ..... 5. *A. ortegae* Murakami & R. C. Moran

7b. Veins (in the middle of the pinnae) 1–2-forked; rachis grooved but without adaxial green wings.

8a. Pinnae pinnatifid throughout their length, usually lobed ¼–½ to the costae; Ecuador ..... 6. *A. purpurascens* Mett. ex Kuhn

8b. Pinnae entire to serrate, sometimes with a basal auricle on the acroscopic side and/or basiscopic side.

9a. Pinnae 7–11 × 1.2–2 cm, 6–9 pairs; petiole and rachis stramineous to greenish brown; southern Mexico to Venezuela and Peru, Cuba ..... 1. *A. delitescens* (Maxon) L. D. Gómez

9b. Pinnae 2–6 × 0.6–1.2 cm, 10–25 pairs; petiole and rachis atropurpureous; Mexico to southern Brazil ..... 3. *A. laetum* Sw.

leaf length, stramineous to green-brown, occasionally partly purplish, glabrous; lamina 20–30 cm long, green, 1-pinnate, deltate with an abruptly reduced, pinnatifid apex; rachis like the petiole, grooved and with herbaceous green wings; lateral pinnae 7–11 × 1.2–2 cm in the middle of the leaf, 6–9 pairs, lanceolate to linear-lanceolate, long-acuminate, the margin slightly toothed, the teeth 0.5–1 mm deep, excavate on the basal basiscopic side ⅙–¼ of the total length, acroscopic base truncate, auricle 1–4 mm long; veins 2-forked; sori 5–10 mm long, occasionally diplazioid in the abruptly reduced pinnae near the apex; spores 33–38 μm long, 64 per sporangium, perispore cristate.

*Additional specimens examined.* MEXICO. CHIAPAS: Mpio. de Ocosingo, ruins of Yaxchilán on the banks of the Río Usumacinta, 300 m, *Breedlove 29935* (F, MO, NY); Mpio. de Las Margaritas, W side of Laguna Miramar E of San Quintin, 350 m, *Breedlove 33123* (F, MICH, NY); Mpio. of Las Margaritas, low ridges at the confluence of the Río Ixcan with the Río Lacantum (Río Jatate) on the Guatemala border, 300 m, *Breedlove & McClintock 34140* (MO); Palenque, in rocky streamside forest by the ruins, 170 m, *Chater et al. 128* (BM, MO); Mpio. *Asplenium delitescens* occurs from Mexico to Peru and east-central Brazil, and Cuba (Map 2). It grows terrestrially in wet forests from 0 to 800(–1,400) m. Rarely, it grows on rocks.

The species is characterized by stramineous or greenish petioles, few (6–9) pinna pairs, and deltate laminae with abruptly reduced apices (Fig. 6A). Where the lamina abruptly contracts to the narrowed apical segment, the pinnae and lobes are often retuse. Occasional specimens are intermediate between *A. delitescens* and *A. laetum* (Fig. 6B). These are treated in the hybrid section of this monograph.

*Asplenium delitescens* closely resembles *A. abscissum* Willd. (which is not a member of section *Hymenasplenium*) in leaf cutting and outline. To the naked eye, *A. abscissum* differs from *A. delitescens* by its erect (rather than creeping) rhizome and the obovate, evenly serrate (rather than quadrangular-truncate, and irregularly serrate) pinnae that are immediately beneath the apical segment. Two microscopic characters also distinguish the species. Both species are sparsely scaly abaxially where the pinnae join the rachis. In *A. abscissum*, the scales are 0.2–0.6 mm long, reddish, and uniseriate. In *A. delitescens*, the scales are 0.5–1.5 mm long, blackish, and uni- to triseriate. The structure of the pinna and rachis is also diagnostic. *Asplenium abscissum* has a slightly raised costa and a thickened pinna margin decurrent on the side of the rachis (Fig. 16C). In contrast, *A. delitescens* has a slightly sunken costa bordered by a green flange of tissue that is decurrent on the adaxial surface of the rachis (Fig. 16D). The decurrent margin of the pinna is not thickened (this form of the rachis and costa juncture is constant throughout section *Hymenasplenium*).

Smith (1976) first pointed out that *A. delitescens* and several other neotropical *Asplenia* belonged to section *Hymenasplenium*. He also realized that this species belonged to *Asplenium*, rather than *Diplazium* where it was originally placed, and gave an excellent discussion on the characteristics that distinguish the two genera.

**2. Asplenium hoffmannii** Hieron., Hedwigia 60: 258. 1919. TYPE: Costa Rica. Alajuela: Aguacate, Aug. 1857, *Hoffmann 836* (holo-

COLOMBIA. BOLIVAR: Torrecilla, near Turbaco, 150–300 m, *Killip & Smith 14658* (K, NY).

*Asplenium hoffmannii* occurs from southern Mexico to Colombia, Venezuela, and Trinidad (Map 4). It grows on rocks along deeply shaded streams in wet forests. Rarely, it grows on old walls or terrestrially. The elevation ranges from 0 to 500(–900) m.

The species is characterized by membranaceous laminae, few (1–3) leaves per rhizome, deeply and evenly serrate pinnae, and few (usually 2–6) pinna pairs (Fig. 7). It hybridizes with *A. laetum* to produce *A.* ×*incisoserratum* (which see; Fig. 16). The hybrid differs from *A. hoffmannii* by having more pinna pairs (6–14), more than three leaves per rhizome, basally darkened petioles (especially in large leaves), and aborted spores.

**3. Asplenium laetum** Sw., Syn. Fil. 79, 271. 1806. NEOTYPE (designated by Proctor, 1985): Schkuhr, Krypt. Gew. 1: 65, t. 70. 1809. Figure 8A; Map 4.

*Asplenium virens* Desv., Mém. Soc. Linn. Paris 6: 273. 1827, not C. Presl, 1825. TYPE: "America," *collector unknown* (P-Herb. Desv.; photos GH, US ex P).

*Asplenium schkuhrianum* C. Presl, Tent. Pterid. 107. 1836, nom. superfl. for *A. laetum* Sw. LECTOTYPE (designated by Morton & Lellinger, 1966): Venezuela. Distrito Federal: Caracas, *Bredemeyer s.n.* (W-Herb. Jacquin). This is probably the specimen used by Schkuhr (1809) in drawing his t. 70, which has been designated as the neotype of *A. laetum* (see above).

*Asplenium lugubre* Liebm., Mexic. bregn. 243 (seors. 91). 1849. LECTOTYPE (designated by A. R. Smith, 1981): Mexico. Veracruz: Baranca de Mirador, *Liebmann* [Fl. Mex. 322] (lectotype, C not seen; isolectotypes, B, K).

Plants terrestrial or epilithic; roots 0.5–0.8 mm wide; rhizome 2.5–6.5 mm wide, sparsely scaly; scales 2–3.3 × 0.23–0.33 mm, black-brown, linear-attenuate; petiole base 1.5–3.5 mm wide, swollen, 0.4–2.5 mm distant from each other on the same row; petiole 4–20 × 0.09–0.15 cm, ⅛–½ the leaf length, blackish reddish purple, sometimes green, grooved, sparsely scaly at base; lamina 15–40 cm long, 1-pinnate, lanceolate to oblong with attenuate apex; rachis like petiole, grooved and with green, perpendicular, herbaceous wings; lateral pinnae 2–6 × 0.6–1.2 cm in the middle of the leaf, 10–25 pairs, subquadrangular, the margin slightly to strongly toothed, the teeth 0.5–2 mm deep, the basiscopic side excavate basally for ca. ½ the pinna length, the apex acute, the base broadly cuneate and almost sessile to stalked, auricle 0–3 mm long; veins 1-forked; sori 2.5–7.5 mm long; spores about 27–38 μm, 64 per sporangium, perispore cristate.

*Additional specimens examined.* MEXICO. *Asplenium laetum* grows terrestrially in deeply shaded forests or on boulders along streams. It is the most common and widely distributed species of section *Hymenasplenium* in the New World (Map 4), ranging from Mexico to northern Argentina, but absent from most of Amazonia. The species has sometimes been reported from Africa and Madagascar, but these reports are based on specimens of *A. inaequilaterale* Willd., a species that does not belong to section *Hymenasplenium*.

The species is characterized by dark petioles and rachises, short-creeping rhizomes, and attenuate lamina apices (Fig. 8A). In other characters it is extremely variable. Some single-character variation is correlated with geography. For example, plants from the Canal Area in Panama usually have obtuse or retuse pinnae with nearly entire or shallowly serrate margins (e.g., *Croat 7008*, *Kennedy 2673*, *Béliz 150*). Plants from Bolivia and Peru have attenuate pinna apices with sharply and obliquely serrate margins (e.g., *Croat 51271*, *Klug 4253*, *Schunke V. 3261*). We have not, however, subdivided the species because no other characteristics correlate with this variation, nor are there any suites of quantitative characteristics that correlate with geography (Fig. 9). Future studies, especially of isozymes and chromosomes, may show that *A. laetum* as circumscribed here actually consists of several species.

Occasional specimens will key to *A. laetum* that are actually intermediate between *A. delitescens* and *A. laetum* (Fig. 6B). Such intermediate specimens are treated in the hybrid section of this monograph.

Several species of *Asplenium* that do not belong

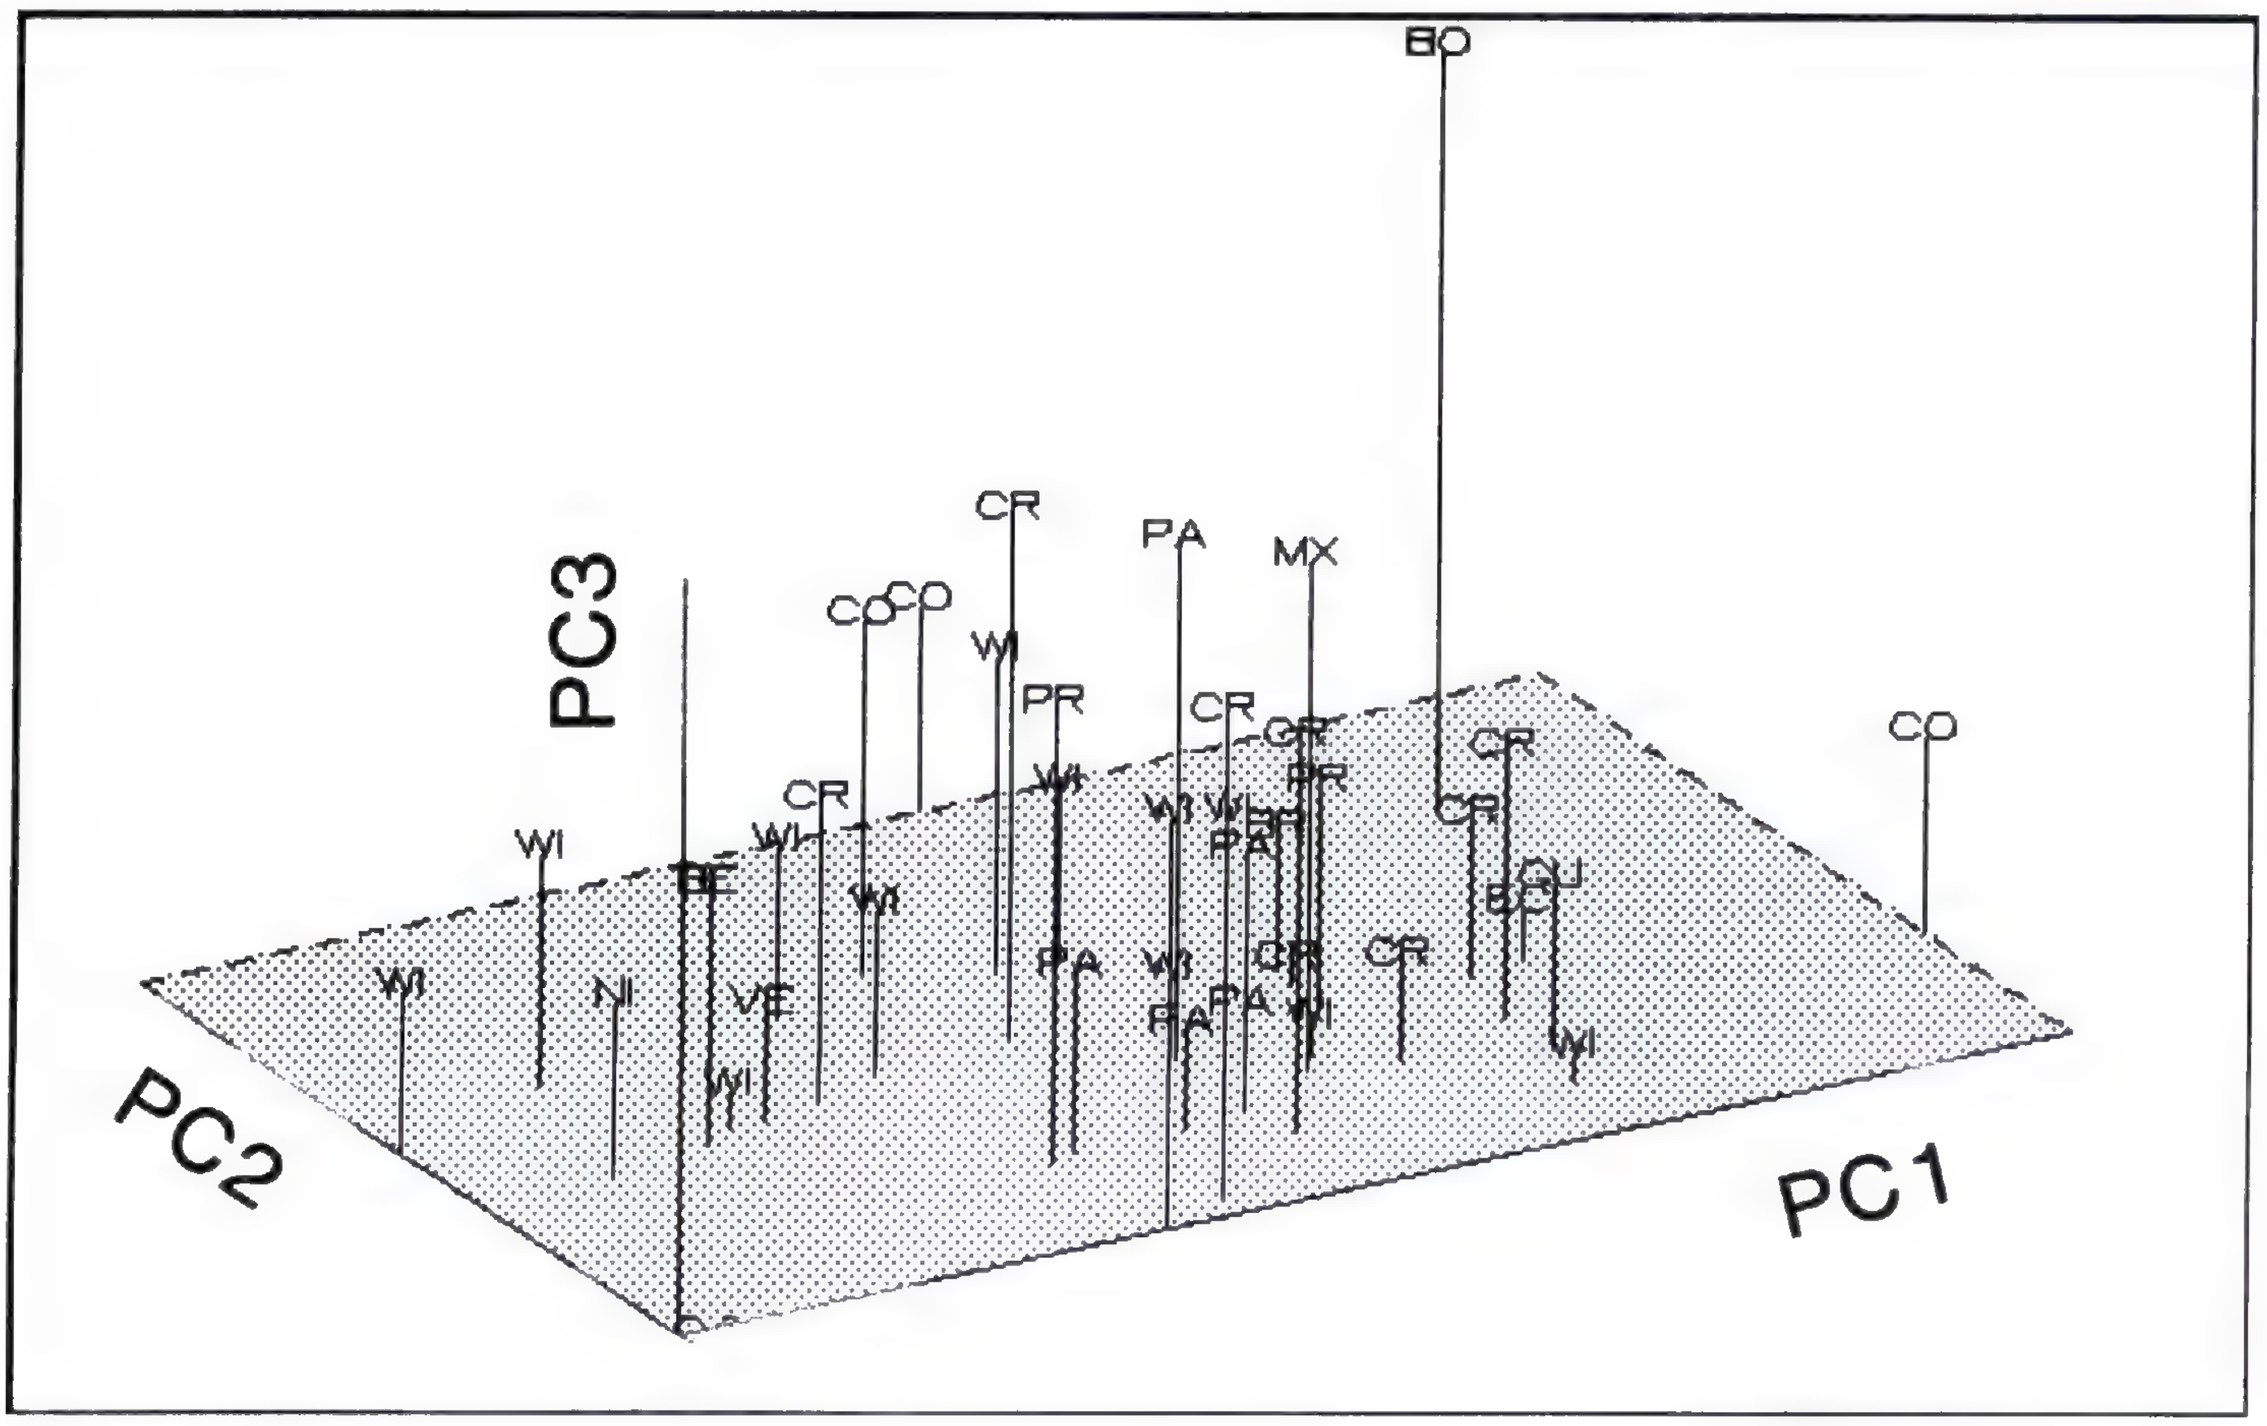

FIGURE 9. Principal Components Analysis of 30 characters of *Asplenium laetum*. BE, Belize. BR, Brazil. BO, Bolivia. CO, Colombia. CR, Costa Rica. EC, Ecuador. GU, Guatemala. NI, Nicaragua. PA, Panama. PR, Peru. VE, Venezuela. WI, West Indies.

to section *Hymenasplenium* are frequently misidentified as *A. laetum* because of their similarity in leaf cutting and outline (i.e., *A. argentinum* Hieron., *A. hostmannii* Hieron., and *A. otites* Link). These species can be distinguished from *A. laetum* by their erect rhizomes and greenish petioles. Besides these characteristics, they also differ from *A. laetum* in the form of the rachis and costa junctures. *Asplenium laetum* has the form typical of section *Hymenasplenium*: the costa is slightly sunken and bordered by a flange of green tissue that is decurrent on the adaxial surface of the rachis, and the decurrent margin of the pinna is not thickened (Fig. 16D). In contrast, the other *Asplenium* species mentioned above have prominulous costae not bordered by a flap of green tissue, and the decurrent margins of the pinnae are thickened and often a lighter color than the rest of the laminar tissue (Fig. 16C).

**4. Asplenium obtusifolium** L., Sp. Pl. 1080. 1753. *Asplenium riparium* Liebm. var. *obtusifolium* (Klotzsch & Karsten) Hook., Sp. Fil. 3: 119. 1860. TYPE: Petiver, Pter. Amer. 117, t. 2, fig. 14 (erroneously cited by Linnaeus as f. 4). [= Plumier, Traité Foug. Amér. t. 67. 1705.] Based on a plant from Morne de la Calebasse, Martinique. Figure 10; Map 5.

*Asplenium aquaticum* Klotzsch & Karsten, Linnaea 20: 354. 1847. *Asplenium obtusifolium* var. *aquaticum* (Klotzsch & Karsten) Giesenhagen, Flora 76: 172, fig. 1. 1892. TYPE: Colombia. "In locis paludosis," *Karsten s.n.* (holotype, B; photo, GH ex B).

Plants epilithic; roots 0.6–1 mm wide; rhizome 2.5–4.5 mm wide, nearly naked, the projecting apex sparsely scaly; scales 0.9–1.3 × 0.15–0.4 mm, brown, deltate-acuminate; petiole base 1.5–3.5 mm wide, swollen, 1.5–5 mm distant from each other on the same row; petiole 4–10.5 × 0.1–0.25 cm, ⅓–½ the leaf length, terete, greenish, fleshy and dull, glabrous; lamina 8–20 cm long, dark green, translucent, 1–2-pinnate (lowest pair of pinnae usually lobed or divided basally), deltate to oblong with subconform apex; rachis like petiole, narrowly marginate adaxially; lateral pinnae 2.5–4.5 × 0.8–1.5 cm in the middle of the leaf, 3–10 pairs, slightly to strongly ascending, obliquely oblong to oblong-lanceolate, often laciniate basally into 1–3 segments, simply toothed, the teeth 0.5–1.5 mm long, the basiscopic margin excavate ca. ½ the pinna length, the apex usually obtuse, rarely acute, auricle 1–2.5 mm long; veins 1-forked at middle part of pinnae; sori 4.5–9 mm long; spores papillate, 27–33 μm long for race with 64 spores per sporangium, 42–47 μm long for race with 32 spores per sporangium.

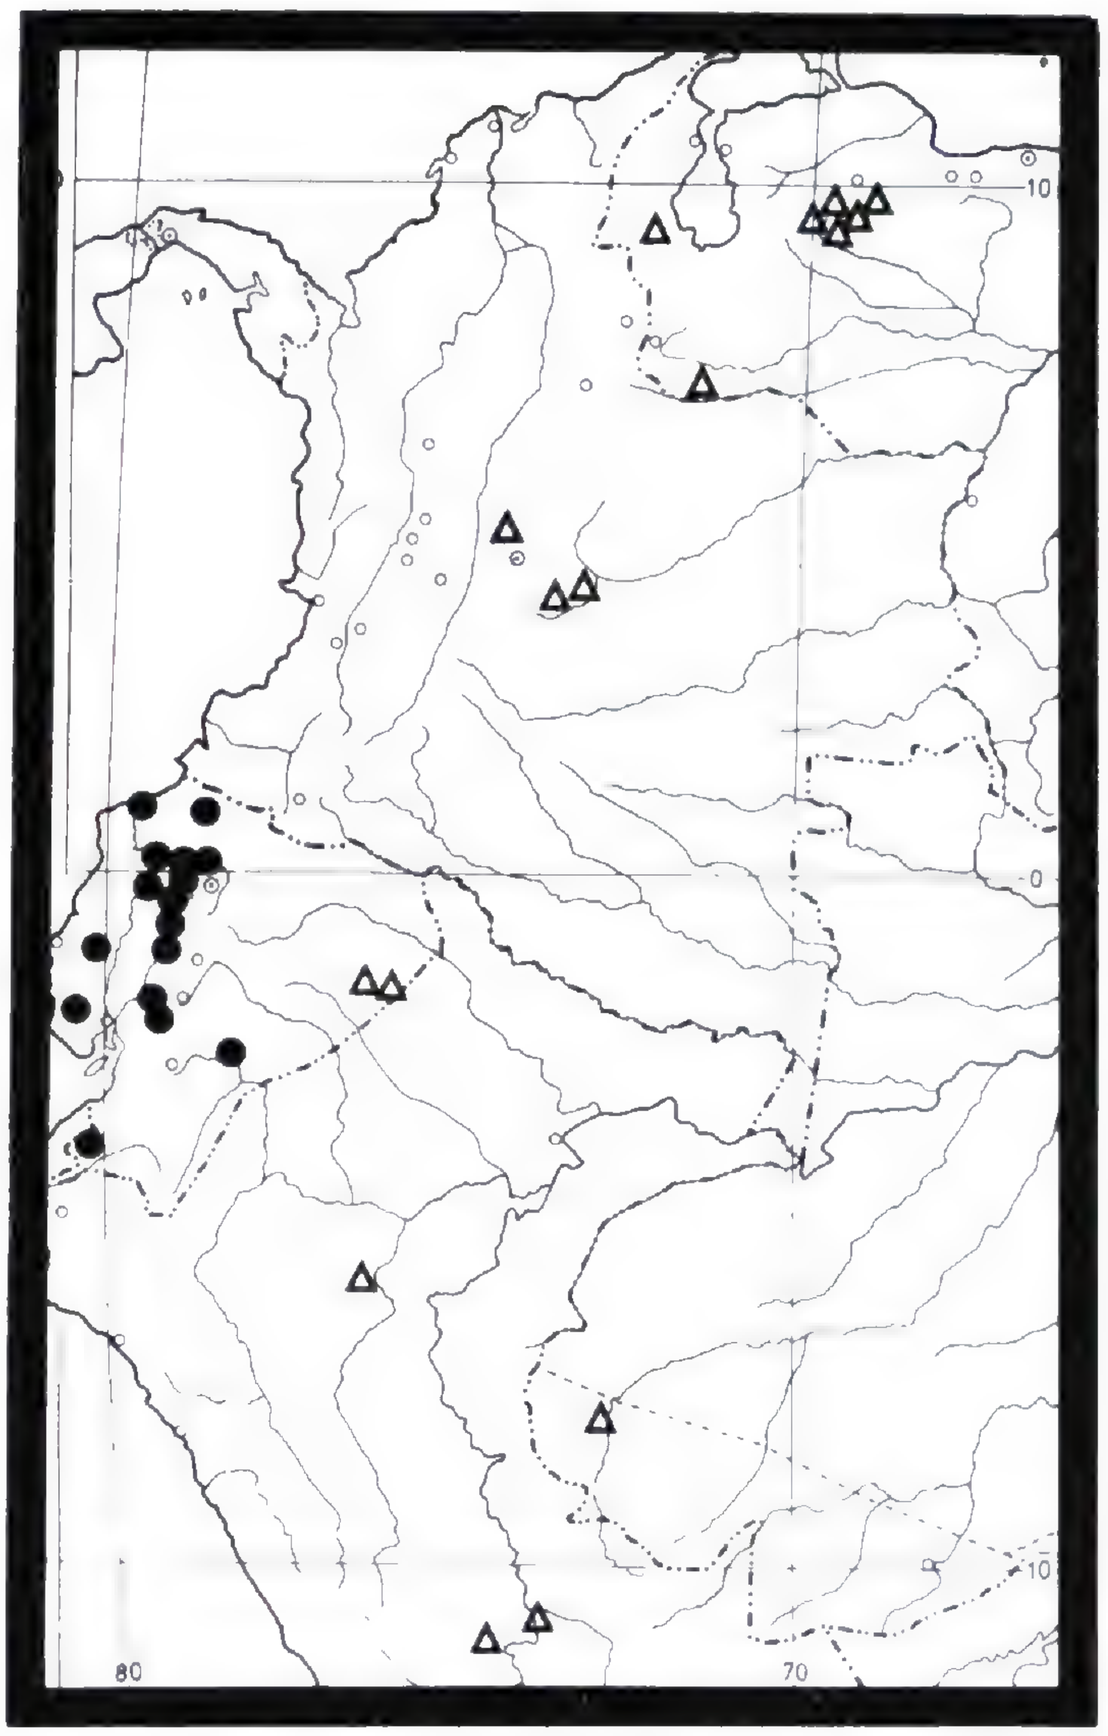
H. Smith 1126* (B, BM, BR, COL, G, GH, L, MICH, MO, NY, S, UC). NORTE DE SANTANDER: Ocaña, 1,600 m, *Schlim 653* (B, BR, G, K, L). SANTANDER: Tequendame, 1,200 m, *Kalbreyer 951b* (B).

*Asplenium obtusifolium* has a circum-Caribbean distribution (Map 5). It grows in the spray of, or underneath, waterfalls and on wet rocks along shaded streams. Its elevational range is 200 to 1,200 m.

This species is characterized by greenish petioles, fleshy leaves, small (8–20-cm-long) laminae, and few (3–10) pinna pairs. The pinnae are usually obtuse and the basal pairs lobed or divided basally (Fig. 10).

*Asplenium obtusifolium* is remarkable by having two races: one with 32 spores per sporangium, the other with 64 spores. The sporophytes of the two races appear indistinguishable and could not be distinguished by a Principal Component Analysis of 20 quantitative morphological characters (Fig. 5). The two spore races differ geographically, with the 32-spored race occurring only in the western portion of the range and the 64-spored race occurring only in the eastern portion (Map 5).

The 32-spored race is presumably apogamous, but this idea needs to be investigated. In the Old World, *A. apogamum* Murakami & Hatanaka, *A. cheilosorum* Kunze, and *A. hondoense* Murakami & Hatanaka have been shown to have both a sexual race with 64 spores per sporangium and an apogamous race with 32 spores per sporangium (Mitui et al., 1989). Therefore, it seems likely that the 32-spored race of *A. obtusifolium* is apogamous.



MAP 6. The distribution of *Asplenium purpurascens* (solid dots) and *A. ortegae* (open triangles).

**5. Asplenium ortegae** Murakami & R. C. Moran, sp. nov. TYPE: Venezuela. Apure: Dtto. Paéz, along Río Arauca at Colombian border, *van der Werff & González 4599* (holotype, MO; isotype, NY). Figure 11B, C; Map 6.

Plantae terrestres. Rhizoma 3.5–5.2 mm latum, internodiis approximatis, squamis 0.5–1.9 mm longis, ca. 0.2 mm latis, lanceolatis, clathratis, brunneis vel nigriscentibus, 3–6-cellulas latis. Petioli 6–21 cm longi, atrobrunnei, nitidi, sparse squamulosi; laminae 11–25 cm longae, 9–18 cm latae, deltatae vel late oblongae, ad apicem abrupte angustatae, segmento terminali lobato, elongato; pinnae plerumque 4.5–9 cm longae, 1.1–1.7 cm latae (pinnae basales interdum profunde lobatae et usque ad 3 cm latae), 6–10-jugatae, breviter petiolatae vel sessiles, latere acroscopico basali truncato, rotundato vel (in Amazonia occidentali) cuneato, nunquam auriculato, latere basiscopico basali cuneato vel excavato, marginibus typice serratis vel serrate lobulatis, interdum in foliis maximis usque ad costas, apice longe attenuatis. Rhachis basaliter atrobrunnea vel nitida, distaliter viridula, infra sparse squamulosa vel glabrata. Venae (2 )3–4-furcatae. Sori 3–7 mm longi.

Plants terrestrial; roots 1.1–1.7 mm wide; rhizome 3.5–5.2 mm wide, nearly naked; scales 0.5–1.9 × 0.23–0.29 mm, black-brown, lanceolate; petiole base 2.2–5.5 mm wide, swollen, 0.5–1.1 mm distant from each other on the same row; petiole 6–21 × 0.09–0.15 cm, ⅓–½ the leaf length, atropurpureous, sparsely scaly at base; lamina 11–25 cm long, light green, herbaceous, 1-pinnate, deltate to oblong with acuminate apex, apex pinnatifid, abruptly reduced or evenly tapered; rachis green to dark reddish purple, grooved with green herbaceous wings perpendicular to the plane of the lamina; lateral pinnae 5–9 × 0.9–1.7 cm in the middle of the leaf, 6–10 pairs, lanceolate to linear-lanceolate, the margin slightly double-toothed, 0.5–1.3 mm deep, the basiscopic side excavate for 1/10–1/5 the length of the pinnae, stalked at lower pinnae, auricle absent; veins 3–4 times forked; sori 3–7 mm long; spores about 30 μm, 64 per sporangium, perispore cristate.

*Paratypes.* VENEZUELA. PORTUGUESA: Dtto. Ospino, Quebrada Honda, en el caserio La Cristobera, *Ortega et al. 3093* (BM); Dtto. Guanare, Mpio. ACRE: Cruzeiro do Sul, Rio Juruá and Rio Moa, between Mundurucus and Tatajuba, Rio Juruá, *Maas et al. P12902* (F).

*Asplenium ortegae* is named for Francisco Ortega, prominent Venezuelan pteridologist, who has given us much hospitality and assistance during fieldwork in Venezuela.

From Colombia to Bolivia, the species occurs on the eastern side of the Andes; in Venezuela, it occurs on both sides (Map 6). It grows on shaded forest floors in wet forests from 0 to 500(–800) m.

*Asplenium ortegae* is characterized by short-creeping rhizomes, atropurpureous petioles, truncately serrate-lobed pinna margins, and usually 3- or 4-forked veins (Fig. 11B, C). Rarely, the basal pinnae become pinnatifid, and the plants then resemble *A. purpurascens* (which also has atropurpureous petioles). The two species may be separated by the characteristics given in the key.

Despite the resemblance to *A. purpurascens*, evidence from chloroplast DNA supports a close relationship of *A. ortegae* with *A. delitescens* (this evidence will be presented in a future paper by the first author). Morphological characteristics also support this relationship. Both species have deltate laminae, relatively few (6–10) pinna pairs, and similarly shaped laminar apices. *Asplenium delitescens*, however, differs by having stramineous petioles, less serrate pinna margins, and twice-forked veins (Fig. 6A). It may eventually be shown that *A. ortegae* is of hybrid origin involving *A. delitescens* as one of its parents.

**6. Asplenium purpurascens** Mett. ex Kuhn, Linnaea 36: 102. 1869. TYPE: Ecuador. Chimborazo: "ad pedem montis Chimborazo," *Spruce 5697* (holotype, B not seen; fragment, B). Figure 11A; Map 6.

*Asplenium melanopus* Sodiro, Anal. Univ. Quito 9: 88. 1893 [= Crypt. Vasc. Quit. 189. 1897]. *Diplazium melanopus* (Sodiro) Hieron., Bot. Jahrb. Syst. 34: 456. 1904. SYNTYPES: Ecuador. Pichincha: "Crece en la región tropical, en los bosques de los Colorados," *Sodiro s.n.* (isosyntype, K); "en el valle de Pallatanga cerca de Puente de Chimbo," *Sodiro s.n.* (isosyntype, K).

Plants terrestrial; roots 1.5–2 mm wide; rhizome 4.2–6.5 mm wide, sparsely scaly; scales 1.6–2.3 × 0.35–0.55 mm, black to dark brown, lanceolate; petiole base 2–5 mm wide, swollen, 2–4 mm distant from each other on the same row; petiole 17–27 × 0.15–0.2 cm, about ½ the leaf length, dark reddish purple, scaly at base; lamina 20–30 cm long, dark green, firm-herbaceous, 1-pinnate, deltate, the apex attenuate, pinnatifid; rachis like the

petiole, grooved, with herbaceous green wings; lateral pinnae 6.5–12 × 1.3–2.5 cm in the middle of the leaf, 8–11 pairs, lanceolate to linear-lanceolate, long-acuminate, the basiscopic side excavate for ⅐–⅕ the length of the pinna, stalked at the lower pinnae, auricle absent, the margin lobed to pinnatifid, the tip of each lobe with rounded teeth, about 1 mm deep; veins 3–4 times forked; sori 4–8 mm long, often diplazioid; spores 27–33 μm, 64 per sporangium, perispore cristate.

*Additional specimens examined.* ECUADOR. CHIMBORAZO: vic. of Sacramento, on E side of Río Sacramento, 1,200–2,000 m, *Wiggins 11095* (NY, UC). COTOPAXI: Tenefuerste, Río Pilalo, km 52–53, Quevedo–Latacunga, 750–1,300 m, *Dodson & Gentry 12275* (MO, QCNE); 20 km NW of Corazón, Río Guapara, 250 m, *Sparre 17173* (S); in confiano Columbiae, *Buchwald 43* (UC); El Recreo, *Eggers 15214* (B, BM, L). *Asplenium purpurascens* is largely restricted to the western side of the Andes of Ecuador (Map 6). It grows in wet forests from 80 to 1,400 m.

The species is characterized by short-creeping rhizomes, atropurpureous petioles and rachises, and pinnatifid pinnae (Fig. 11A). No other neotropical species of section *Hymenasplenium* has regularly pinnatifid pinnae.

The holotype of *A. purpurascens* was not among the specimens we received on loan from B. There were two very small fragments on a sheet at B, but these were not enough to identify the species. We feel confident that we are applying the name correctly because it is possible to distinguish the species based on Mettenius's original description. According to his description, *A. purpurascens* has creeping rhizomes, lustrous purple petioles, and pinnatisect pinnae. The provenance of the type also agrees with applying the name to the above-cited plants.

**7. Asplenium repandulum** Kunze, Linnaea 9: 65. 1834. TYPE: Peru. Huánuco: Pampayaco, in sylvis montosis ad arborum truncos, July 1829, *Poeppig s.n.* (holotype, B not seen; isotype, NY (fragment) not seen). Figure 12; Map 7.

Plants epiphytic; roots 0.6–1.5 mm wide; rhizome 2.5–7 mm wide, nearly naked; scales 0.5–2.5 × 0.2–0.5 mm, black, ovate-lanceolate, clathrate; petiole base 2.5–4 mm wide, swollen, 1–2 cm distant from each other on the same row; petiole 4–15 × 0.15–0.3 cm, about ⅐–⅓ the leaf length, dark green-brown, fleshy and dull, terete, glabrous; lamina 22–40 cm long, dull green, 1-pinnate, lanceolate to oblong with subconform apex; rachis like petiole, with adaxial green wings in the same plane as the lamina, strongly carinate abaxially; lateral pinnae 4–6 × 1.1–1.8 cm in the middle of the leaf, 12–17 pairs, obliquely oblong to oblong-lanceolate, margin almost entire to only slightly toothed, the basal basiscopic side excavate for ⅐–¼ the pinna length, acute at apex, broadly cuneate and almost sessile at base, auricle 2–6 mm long; veins 1-forked; sori 4–10 mm long; spores 40–48 μm, 64 per sporangium, spiny.

*Additional specimens examined.* ECUADOR. MORONA-SANTIAGO: Macuma, on the Macuma River, S of Chiquaza, 700 m, *van der Werff 660* (GH, MO). PASTAZA: Baños—aut Jivaria de Pintuc, excurs. nach Canelos, 1,200–1,300 m, *Stübel 878* (B). PICHINCHA: prope Sto. Domingo, Aug. 1875, *Sodiro s.n.* (K). PERU. AMAZONAS: ca. 12 km E of La Peca, Serranía de Bagua, 1,650–1,800 m, *Gentry et al. 23073* (MO, UC). HUANUCO: Leoncio Prado, Dtto. Hermilio Valdizan, road from Pumaguasi to La Cumbre, La Divisoria, 1,600 m, *Plowman & Schunke V. 7363* (F). JUNIN: Chanchamayo, Chanchamayo Valley, 1924–1927, *C. FIGURE 12. *Asplenium repandulum*. A, B. Ecuador, *van der Werff 660* (MO). Cross section of rachis shown in A.—C. Peru, *Hutchison 1196* (G).

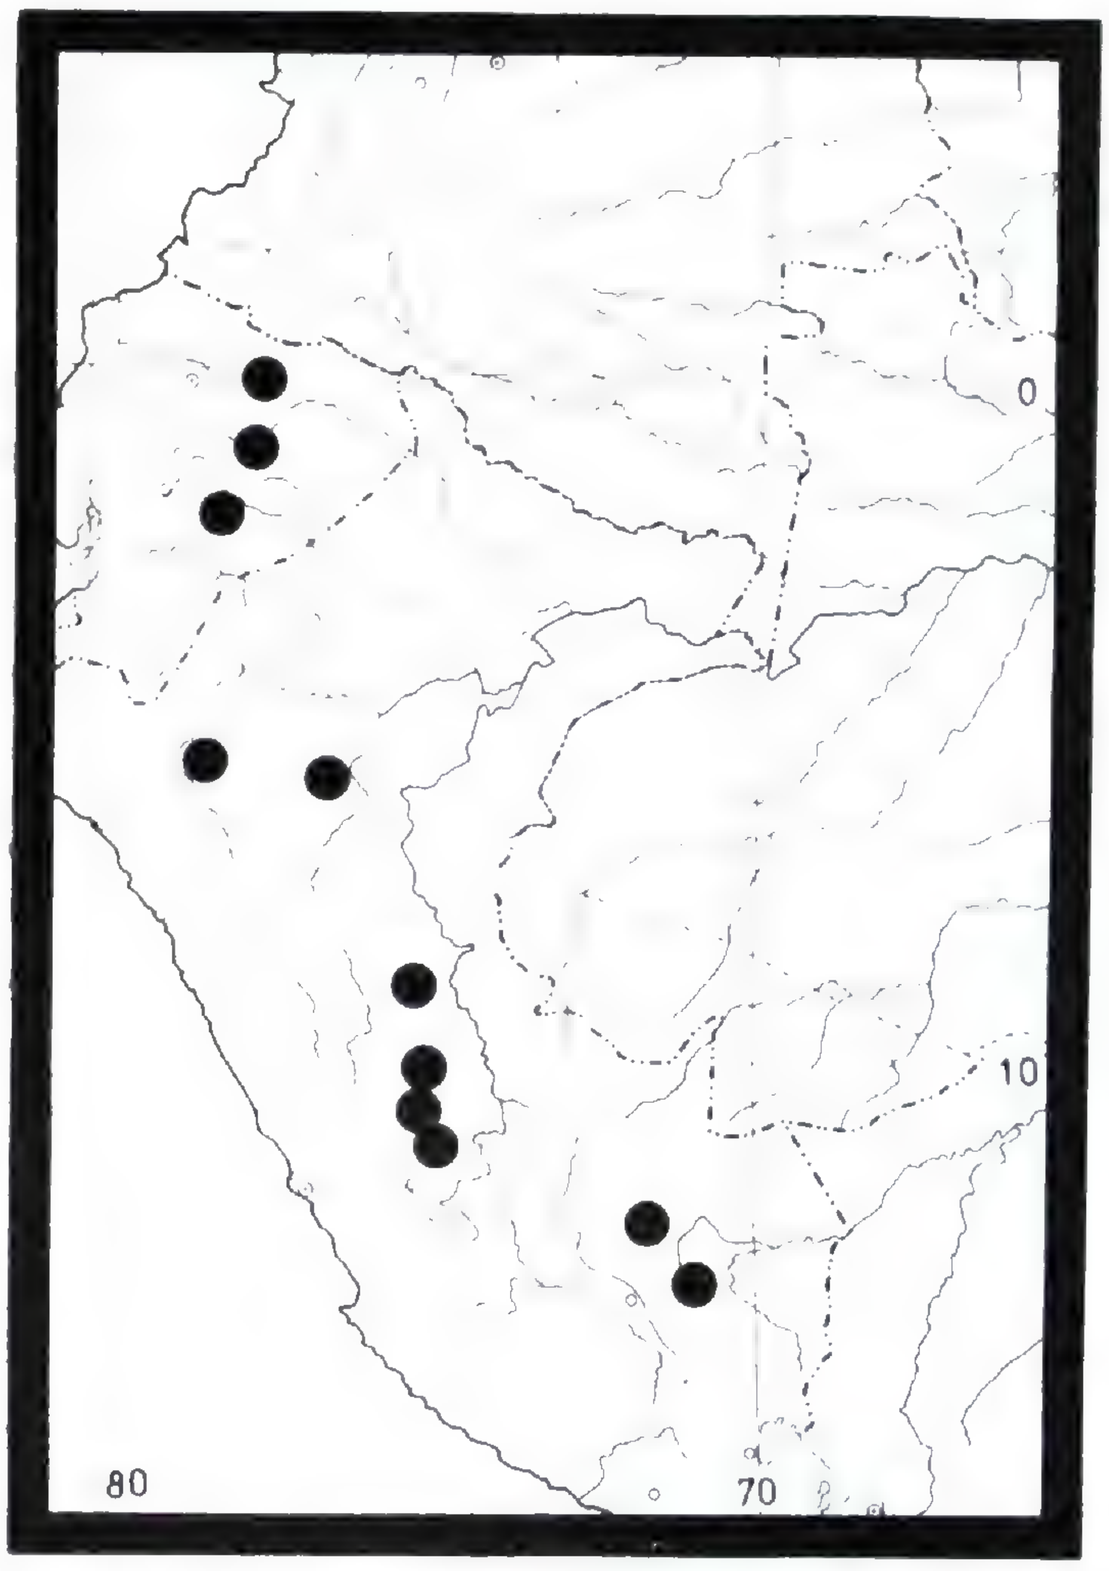
near summit, 2,000 m, *Hutchison 1196* (F, G, M, MICH, MO, NY, S). MADRE DE DIOS: Manú, Parque Nacional de Manú, between Panagua and Tayakome, Cocha Cashu, vicinity of ox-bow lake of Río Manú, *Foster et al. 3449* (F); reise von Moyabomba zum Huallaga, bei Lamas, *Stübel 1099a* (B). PASCO: Oxapampa, vic. of Chequitavo, Gran Pajonal, 1,250 m, 10°45′S, 74°23′W, *D. N. Smith 5168* (MO).

*Asplenium repandulum* is characterized by long-creeping rhizomes, prominently carinate rachises, and orientation of the rachidial wings in the same plane as the lamina (Fig. 12). It occurs east of the Andes in Ecuador and Peru (Map 7). It grows in wet forests from 700 to 2,000 m as an epiphyte on large tree trunks. One specimen from French Guiana, disjunct from the Andean populations, has a carinate rachis and may represent *A. repandulum* but was collected on wet soil (Sommet Tabulaire, ca. 50 km SE of Saul, 750 m, *de Granville 3508* (F)). In the carinate rachis, it also resembles *A. triquetrum*, but the main range of that species is even farther away than that of *A. repandulum*. It is not typical of either species to grow on the soil. The identity of the plant from French Guiana needs more research.

As outlined in the key, the rachis cross section and orientation of the adaxial wings on the rachis are important taxonomic characteristics distinguishing *A. repandulum*, *A. triquetrum*, *A. riparium*, and *A. volubile*. The characteristics, however, can be difficult to interpret because of changes during pressing and drying. Although the carinate rachis of *A. repandulum* and *A. triquetrum* is a prominent and striking feature of living plants, in pressed plants the keeled edge of the rachis is pushed to one side, so that only one side of the 3-angled rachis faces up. This gives the impression when viewed from above that the rachis is smooth or rounded. When this distortion occurs, it can usually be detected because pinna bases on one side of the rachis are hidden beneath the keel, but the attachments of the pinna bases on the other side are visible.

The orientation of the rachidial wings may be difficult to determine because the wings sometimes shrivel upon drying and (in *A. riparium* and *A. volubile*) the wings may be pressed flat into the same plane of the lamina. Usually, the best place to observe the orientation of the wings is at the pinna junctures.

*Asplenium repandulum* is most closely related to *A. triquetrum* based on rachidial wing orientation and the strongly carinate rachis. However, *A. repandulum* resembles *A. volubile* by the long-creeping rhizomes and epiphytic habit (see *A. volubile* for comparison).



MAP 7. The distribution of *Asplenium repandulum*.

Although we have not seen the holotype of *A. repandulum*, we feel confident that we are applying the name correctly because this is the only epiphytic species of section *Hymenasplenium* that occurs in Amazonian Peru.

**8. Asplenium riparium** Liebm., Mexic. bregn. 244 (seors. 92). 1849. [= Kongel. Danske Vidensk. Selsk. Skr., Naturvidensk Afd., ser. 5, 1: 244. 1849]. *Asplenium obtusifolium* L. var. *riparium* (Liebm.) Domin, Pteridophyta Isl. Dominica in Rozpr. Král. Ceské Spolecn. Nauk, Tr. Mat.-Prir., Nov. Rad. 2: 175. 1929. LECTOTYPE (designated by A. R. Smith, 1981): Mexico. Veracruz: Hacienda de Java, *Liebmann* [Fl. Mex. 310] (lectotype, C not seen; isolectotypes, B, K). Figure 13B; Map 8.

Plants epilithic or terrestrial; roots 0.7–1.3 mm wide; rhizome 3–6 mm wide, nearly naked; scales 0.8–1.5 × 0.2–0.4 mm, brown, ovate-lanceolate; petiole base 2.5–4.5 mm wide, swollen, 1–2.5 mm distant from each other on the same row; petiole 10–20 × 0.1–0.25 cm, ⅓–½ the leaf length, dark green-brown, fleshy and dull, broadly and shallowly grooved, glabrous; lamina 15–30 cm long, dark green, 1(–2)-pinnate, lanceolate with conform

*Asplenium riparium* grows on boulders along streams in wet forests from 200 to 1,900(–2,300) m. It ranges from Mexico to western Venezuela, Colombia, and Ecuador (Map 8).

The species is characterized by short-creeping rhizomes, petioles ⅓–½ the length of the lamina, and abaxially rounded (not carinate) rachises (Fig. 13A).

Since Liebmann's publication of *Asplenium riparium*, almost all pteridologists have considered it synonymous with *A. repandulum*. The two species clearly differ, however, by the rachidial characteristics used to separate them in the key. In addition, they differ in habitat: *A. riparium* grows on boulders along streams, while *A. repandulum* grows on tree trunks. The two species overlap in range only in eastern Ecuador (Maps 7, 8).

*Asplenium riparium* is most closely related to *A. volubile* because both have strongly carinate

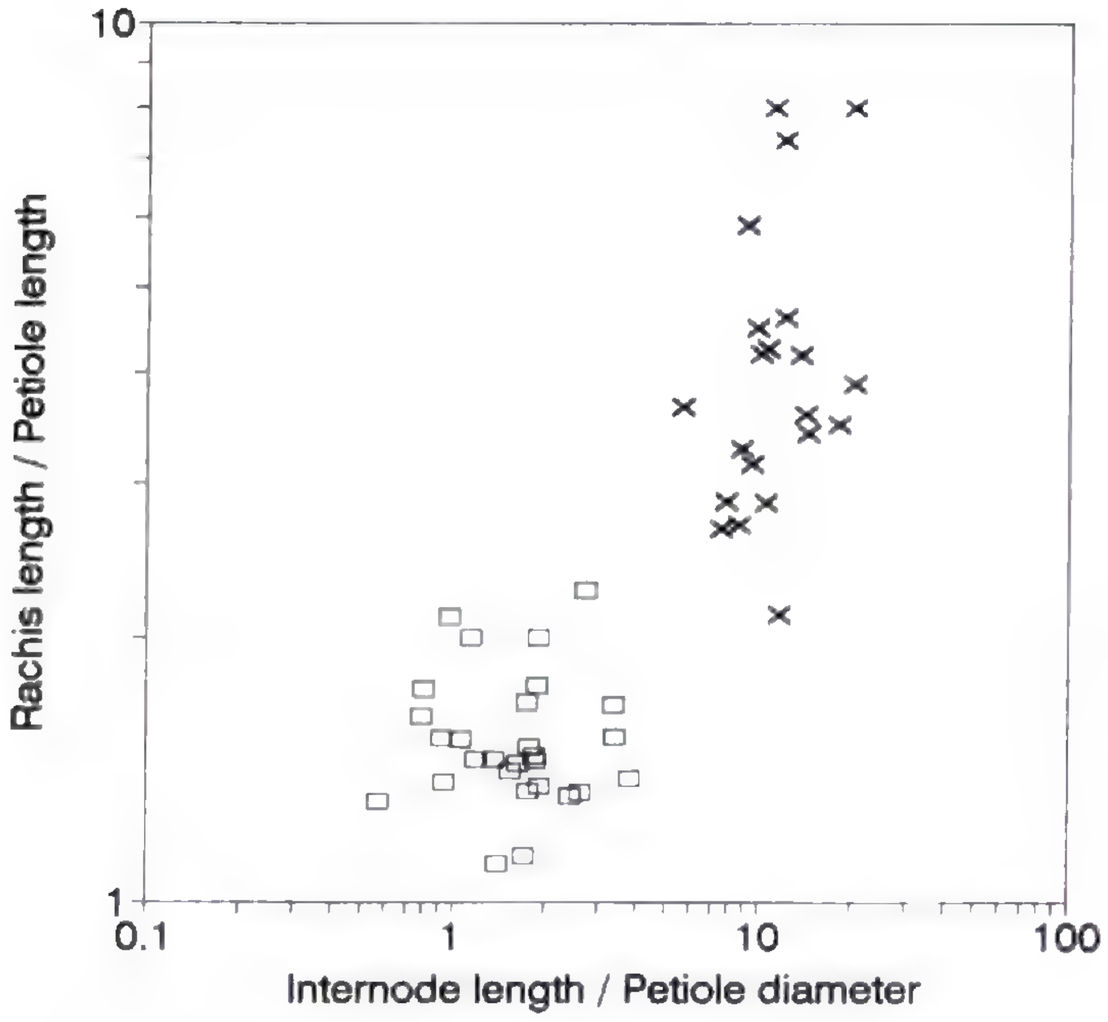

FIGURE 14. Quantitative differences between *A. riparium* (open squares) and *A. volubile* (X). The measurements were taken from herbarium specimens throughout the entire range of both species.

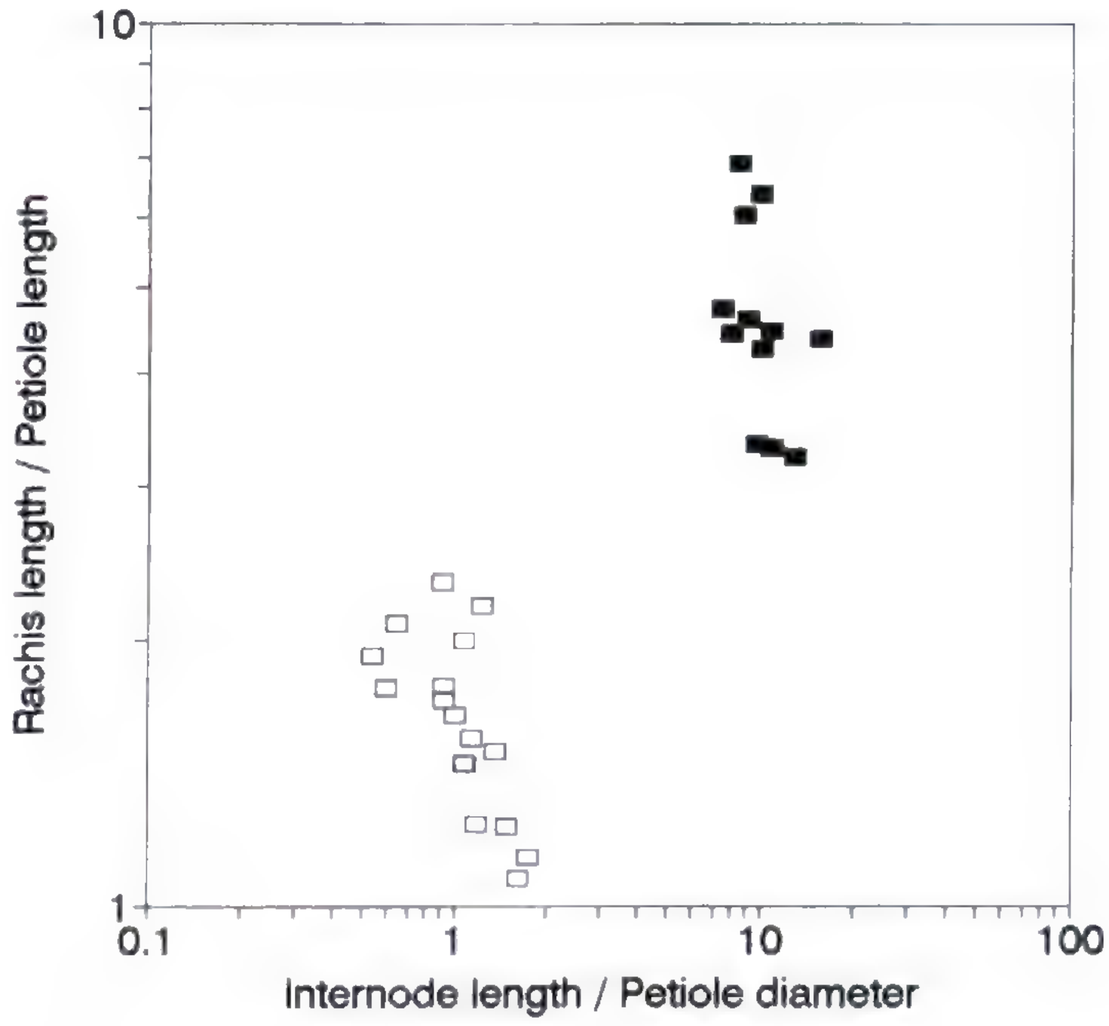

FIGURE 15. Variation in quantitative characteristics of *Asplenium riparium* (open squares) and *A. volubile* (black squares) from the Fortuna Dam area, Panama. The measurements were taken from living plants.

rachises. The two species are easily distinguished by the features given in the key. Petiole length relative to the lamina and internode distance clearly distinguish the two species (Fig. 14). Figure 15 shows that the two species maintain their distinctive characteristics even when growing in the same population.

The most remarkable thing about *A. riparium* is that it produces plantlets from the soral receptacles on senescent leaves that have drooped and touched the soil (Fig. 13C, D). Iwatsuki & Kato (1985) and Kato & Iwatsuki (1985) mentioned that several Old World species of section *Hymenasplenium* produce plantlets on the pinnae, but they did not specify whether the plantlets proliferated from the soral receptacles.

**9. Asplenium triquetrum** Murakami & R. C. Moran, sp. nov. TYPE: Bolivia. La Paz: Prov. Nor Yungas, Polo-Polo bei Coroico, 1,100 m, *Buchtien 625* (holotype, MO; isotypes, BM, K, NY, Z). Figure 8B, C; Map 9.

Plantae terrestres; rhizoma 2–6 mm latum, fere nudum, breviter reptans, internodis 0.4–2 cm longis; squamae 1–2.3 × 0.5–1.2 mm, ovatae, clathratae; laminae 22–40 cm longae, 1-pinnatae, 12–17 jugatae, lanceolatae vel oblongae, apice subconforme; rhachis triquetra, alis viridibus, ad laminam parallelis; pinnae 5 9 × 1.1 1.8 cm; venae 1–3 furcatae; sori 5–9 mm longi; sporae spinosae.

Plants terrestrial; roots 0.4–1.2 mm wide; rhizome 2–6 mm wide, nearly naked; scales 1–2.3 × 0.5–1.2 mm, dark brown, ovate, clathrate; petiole base 2–4 mm wide, swollen, 0.4–2 cm distant from each other on the same row; petiole 10–25 × 0.15–0.25 cm, ⅓–½ the leaf length, dark green-brown, fleshy and dull, glabrous, shallowly grooved; lamina 22–40 cm long, dark green, 1-pinnate, lanceolate to oblong with subconform apex; rachis with abaxial green wings in the same plane as the lamina, strongly carinate abaxially; lateral pinnae 5–9 × 1.1–1.8 cm in the middle of the leaf, 12–17 pairs, obliquely oblong to oblong-lanceolate, the margin occasionally lobed, almost entire to only slightly toothed, the basiscopic margin excavate for ⅐–⅓ the pinna length, acute at apex, broadly cuneate and almost sessile at base, auricle 2–6 mm long; veins 1–3 times forked; sori 5–9 mm long; spores 40–52 μm, 64 per sporangium, spiny.

*Asplenium triquetrum* is the southernmost species of the section (Map 9). It grows from 400 to 1,100 m on wet rocks along deeply shaded streambanks, around cave entrances, and near small waterfalls.

*Asplenium triquetrum* is characterized by its epipetric habitat, strongly carinate rachis, and orientation of the rachidial wings in the same plane as the lamina (Fig. 8B, C). It is most closely related to *A. repandulum* (which see).

**10. Asplenium volubile** Murakami & R. C. Moran, sp. nov. TYPE: Ecuador. Cotopaxi: Quevedo–Latacunga road, km 46 from Quevedo, 600 m, 0°55′S, 79°11′W, *Holm-Nielsen et al. 2905* (holotype, MO; isotypes, AAU, F, UC). Figure 13E; Map 10.

Plantae epiphyticae; rhizoma 2.5–3.5 mm latum, fere nudum, longe reptans, internodiis 2–4 cm longis; squamae ovato-lanceolatae; laminae 22 35 cm longae, 1-pinnatae, oblongo-lanceolatae vel ovatae, apice conforme vel subconforme; rhachis abaxialiter rotundata, alis viridibus ad laminas perpendicularibus; pinnae 4–5.5 × 0.9–1.7 cm, 11 18 pares; venae 2-furcatae; sori 5–10 mm longi; sporae spinosae.

Plants epiphytic; roots 0.5–1.2 mm wide; rhizome 2.5–3.5 mm wide, nearly naked; scales 1–1.3 × 0.2–0.4 mm, brown, ovate-lanceolate; petiole base 2.2–3.8 mm wide, swollen, 2–4 cm distant from each other on the same row; petiole 4.5–11 × 0.1–0.25 cm, ⅐–¼ the leaf length, dark green-brown, fleshy and dull, shallowly grooved; lamina 22–35 cm long, dark green, 1-pinnate, oblong-lanceolate to ovate with a conform to subconform apex, thin-herbaceous; rachis like petiole, with green wings perpendicular to the plane of the lamina; lateral pinnae 4–5.5 × 0.9–1.7 cm in the middle of the leaf, 11–18 pairs, oblong-lanceolate, the margin only slightly toothed, excavate ⅛–⅓ portion of the basal basiscopic side absent, acute-obtuse at apex, broadly cuneate and almost sessile at base, auricle 1.5–5 mm long; veins 2-forked; sori 5–10 mm long; spores 48–50 μm, 64 per sporangium, spiny.

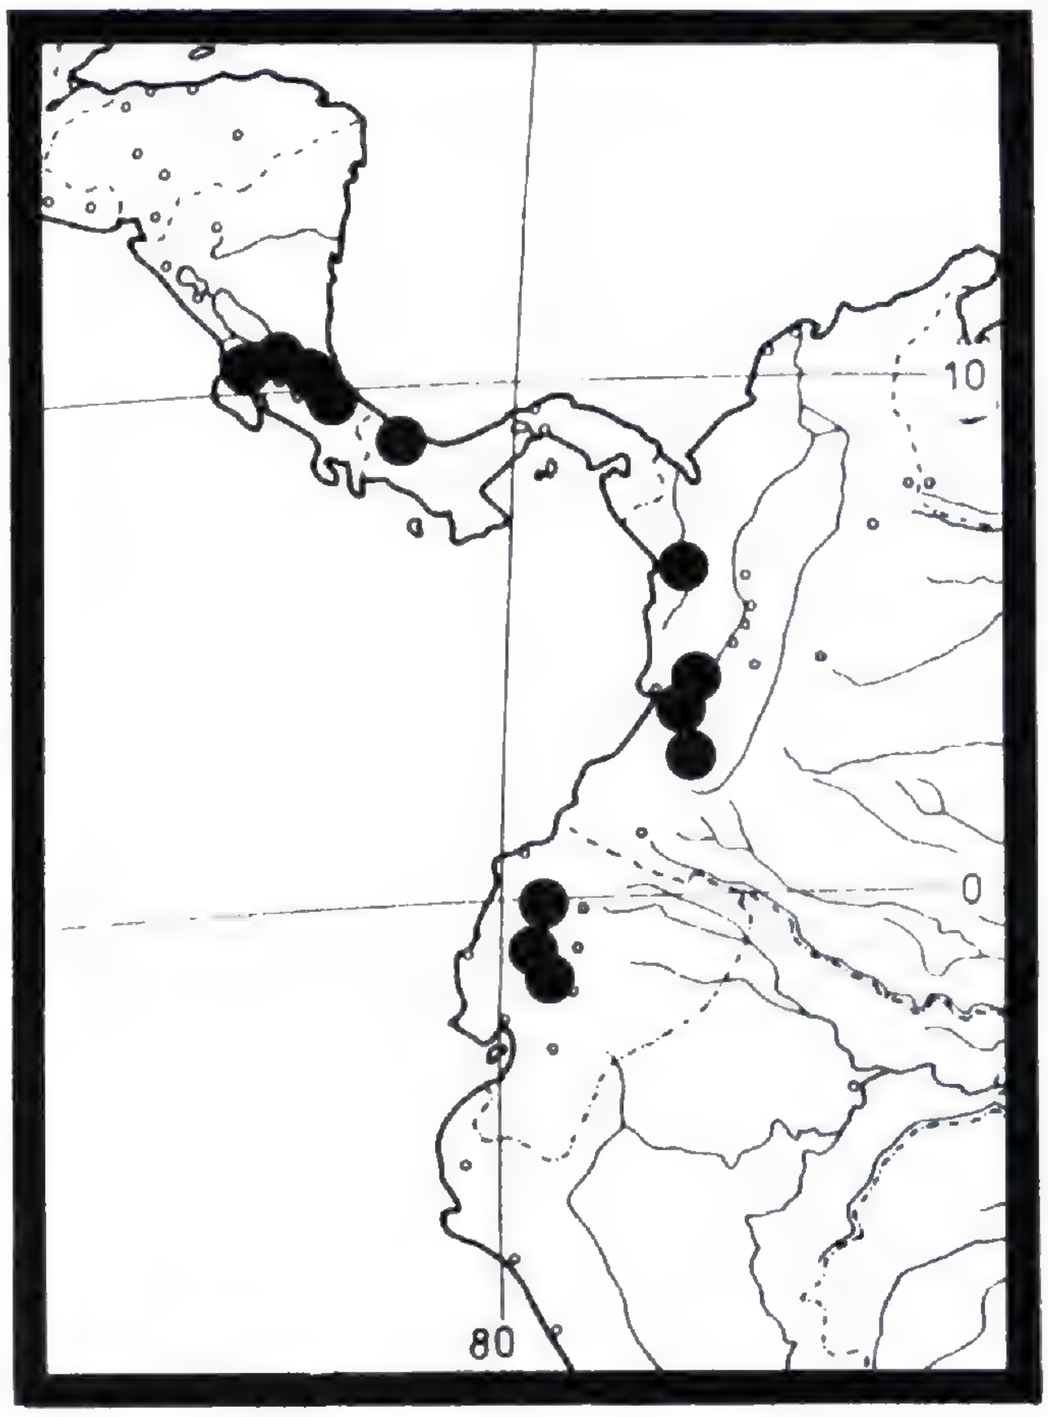
*Paratypes.* COSTA RICA. Cerro Mombe, Hacienda Clementina on Río Pita, 660 m, *Asplund 5550* (S); Hacienda Clementina, Samana, 750 m, *Harling 552* (S). NAPO: slopes of Guagra Urcu, on the loma above Río Bretania, 200–2,200 m, 0°28′S, 77°45′W, *Holm-Nielsen et al. 26835* (AAU). PICHINCHA: Toachi ad San Miguel, *Sodiro 66* (UC).

*Asplenium volubile* occurs in Costa Rica, Panama, and coastal Colombia and Ecuador (Map 10). It grows from 300 to 2,200 m in wet forests as an epiphyte on small trees or saplings.

*Asplenium volubile* has been previously identified as *A. repandulum*. In addition to the rachis characteristics given in the key, it differs from *A. repandulum* by its shorter petiole (4.5–11 cm long), which is only ⅐ to ¼ the leaf length (petiole 10–25 cm long and about ⅓ the leaf length in *A. repandulum*). In both species the rhizome is long-creeping and epiphytic, but field observations by both of us have shown that the rhizomes differ in habit. *Asplenium volubile* has a twining rhizome that grows spirally around the trunks of young trees or saplings that are usually less than 5 cm wide. This characteristic can usually be ascertained in herbarium specimens because the rhizomes appear sinuous or contorted. In contrast, *A. repandulum* grows on large trees and the rhizome is more or less straight, not spiraling upward around the trunk. *Asplenium volubile* has a longer-creeping rhizome than *A. repandulum*. The distance between petiole bases on the same side of the rhizome (orthostichy) is 2.2–3.8 cm in *A. volubile*, and 0.4–2 cm in *A. repandulum*. In addition to the morphological characteristics, the two species differ completely in range: *A. volubile* is restricted to the western side of the Andes (Map 10) and *A. repandulum* is restricted to the eastern side (Map 7).

See *A. riparium* for comparison to that species.



MAP 10. The distribution of *Asplenium volubile*.

HYBRIDS

**11. Asplenium ×papyraceum** (Jermy & T. Walker) Murakami & R. C. Moran, comb. nov. *Diplazium ×papyraceum* Jermy & T. Walker, Bull. Brit. Mus. (Nat. Hist.), Bot. 13: 264, fig. 10. 1985. TYPE: Trinidad. Charuma Ward: Central Range Forest Reserve, Brickfields Teak Plantation, 3 mi. S of Forest Resthouse, 60 m, in wet ground by stream, 9 July 1963, *Walker T6178* (holotype, BM not seen).

Plants terrestrial; rhizome 2–3 mm wide, sparsely scaly; scales 1–1.5 mm long, narrowly lanceolate, blackish, entire; petiole base 2–3 mm wide, ca. 1 mm distant on the same row; petiole 15–22 cm long, brown, slightly shorter than the lamina, gray-green with narrow black wings, glabrous; lamina 25–30 × 12–17 cm, 1-pinnate, ovate-lanceolate, the apex abruptly to gradually reduced, pinnatifid; rachis brown, sparsely scaly with minute (0.5–1 mm long) filiform, unicostate scales and slightly longer, narrowly triangular scales; pinnae 7–8.5 × 1.5–2.2 cm, short-petiolulate, 9–12 pairs, the basal basiscopic margin slightly excavate, the acroscopic margin coarsely serrate, the serrations 1–2 mm deep; veins 2 or 3 times forked; sori 3–11 mm long; spores abortive.

*Specimen examined.* TRINIDAD. CHARUMA WARD: Central Range Forest Reserve, Brickfields Teak Plantation, 3 mi. S of Forest Resthouse, 60 m, in wet ground by stream, 9 July 1963, *Jermy 2178* (BM).

*Asplenium ×papyraceum* is known only from the above-cited locality in Trinidad. Jermy & Walker (1985) have an excellent photograph of the paratype (*Jermy 2178*). The plants resemble *A. delitescens* but differ by their shorter, relatively wider, and more numerous pinnae.

*Asplenium ×papyraceum* is believed to be a hybrid based on its irregular meiosis, two size classes of chromosomes, triploid chromosome number, and abortive spores (Jermy & Walker, 1985). The asplenioid characteristics of *A. ×papyraceum* are clathrate scales and an X-shaped petiolar strand that unites distally in the petiole. It belongs to section *Hymenasplenium* as evidenced by its short-creeping rhizome with a typical broad ventral meristele and by its rachis-costa structure.

Jermy & Walker (1985) discussed the evidence relating the hybrid to *Asplenium*, but concluded that it belonged in *Diplazium* based on the chromosome count of $n = 123$, a multiple of 41, which is the base number for *Diplazium*. The count of $n = 123$, however, does not exclude *Asplenium*. Although a base number of 41 is not known in *Asplenium*, it is not far off from the numbers known in section *Hymenasplenium*, which have $n = 38$ or 39 (Mitui et al., 1989). The most likely explanation of $n = 123$, given the morphological evidence that clearly indicates the plant is an *Asplenium*, is that the parents had the unusually high chromosome number of $n = 41$. The resemblance to *A. delitescens* suggests that that species is one of its parents; however, *A. delitescens* is not known from Trinidad (Map 2).

**12. Asplenium delitescens** (Maxon) L. D. Gómez × **A. laetum** Sw. Figure 6B.

The specimens listed below are presumably hybrids based on their intermediate morphology between *A. delitescens* and *A. laetum*.

*Specimens examined.* BELIZE. STANN CREEK: Stann Creek Railway, 50 m, *Schipp 49* (BM, MICH, MO, UC). COSTA RICA. ALAJUELA: Río Chiquito, ca. 40 km on road to Upala, 800 m, *Gómez 18620* (MO, UC). SAN JOSE: Zona Protectora El Rodeo, along Fila Diamante, S from Alto Gracias a Dios, 4 km (by air) SW of Ciudad Colón, 900 m, *Grayum & Zamora 9661* (MO, UC). VENEZUELA. ARAGUA: near Guamitas, Parque Nacional, 760 m, *Alston 5828* (MO). FALCON: Parque Nacional Quebrada de la Cueva El Toro, steep, wet valley along river, 600 m, *Liesner et al. 7724* (MO, NY, UC). COLOMBIA. BOLIVAR: Mpio. de San Jacinto, ca. 16 km NW of San Jacinto, N slope of Cerro Maco, 600 m, *Zarucchi & Cuadros 4040* (MO). MAGDALENA: 7 km E of Codazzi, 300 m, *Haught 3761* (COL, GH). META: La Macarena, Río Gúejar ca. 10 km below junction with Río Zanza, 470 m, *S. G. Smith & Idrobo 1523* (COL, GH, UC). ECUADOR. MORONA-SANTIAGO: Cordillera de Cutucú, road Méndez–Morona, 800 m, *van der Werff & Palacios 10403* (F, MO, QCNE). NAPO: Parque Nacional Yasiní, Anangu, Río Anangu near junction with Río Napo, 270 m, *Luteyn et al. 8502* (NY, UC). PERU. HUANUCO: ca. pueblo de Puerto Inca, a unos 85 km de la confluencia con el Río Ucayali, 400–500 m, *Schunke V. 2967* (NY). LORETO: above Pongo de Manseriche, 250 m, *Mexia 6223* (BM). MADRE DE DIOS. Manú, Parque Nacional Manú, Pakitsa Station, Tachigali Trail to 8 km N of camp, 350 m, 11°56′S, 71°16′W, *Foster & Baldeón 12806* (F). BOLIVIA. BENI: Prov. Ballivián, Río Colorado, Collegio Técnico Agropecuario de Río Colorado, 235 m, 15°00′S, 67°10′W, *Fay 2078* (MO). LA PAZ. Prov. Larecaja, Isupuri, 500 m, *Williams 1091* (GH, NY); Prov. Nor Yungas, puente sobre el Río Beni, 550 m, *Beck 13367* (F).

The above specimens would key to *A. laetum* because of their number of pinna pairs (10–21) and atropurpureous petioles and rachises. These intermediates differ from *A. laetum* by their larger laminae and often abruptly contracted apices. The above specimens differ from *A. delitescens* in the shape of the lamina apices (especially the shape of the pinnae below the apical segment), greater number of pinna pairs, and dark petioles (Fig. 6B). The shape of the lamina apex is perhaps the best characteristic to detect the intermediates, but it is difficult to characterize the plants because of their inherent variability in features that distinguish the parents.

Most of the specimens have aborted spores, but some appear to have normal spores. The specimens treated here need to be investigated cytologically and enzymatically to confirm their hybridity and determine their parentage. A few may eventually be shown to have *A. ortegae* or *A. purpurascens* as the other parent.

**13. Asplenium ×incisoserratum** (Rosenstock) Murakami & R. C. Moran, stat. nov. *Asplenium laetum* Sw. var. *incisoserratum* Rosenstock, Repert. Spec. Nov. Regni Veg. 22: 8. 1925. TYPE: Costa Rica. San José: Grenadilla, 1,200 m, 26 Dec. 1910, *Brade 425* (holotype, S; isotypes, B, M, UC). Figure 16.

Plants epilithic; roots 0.1–0.5 mm wide; rhizome 2–4 mm wide, scaly at the apex; scales 2–2.5 × 0.25–0.35 mm, blackish, narrowly triangular to linear; petiole base 0.5–2 mm wide, swollen, 1–1.5 mm distant from each other on the same row; petiole 3–8 × 0.03–0.1 cm, ca. ⅛–⅓ the leaf length, mostly stramineous to greenish, sometimes brown basally (especially in large leaves), glabrous; lamina 8–20 cm long, green, 1-pinnate, lanceolate, gradually to abruptly tapered to a pinnatifid apex; rachis greenish; lateral pinnae 1.4 × 0.5–1 cm, 6–14 pairs, lanceolate, acute to obtuse, coarsely dentate, the teeth 1–2 mm deep, the basal basiscopic side excavate for ⅓–½ the length of the pinna; veins 1-forked; sori 3–5 mm long; spores irregular, aborted.

*Additional specimens examined.* MEXICO. OAXACA: Tuxtepec, above Jalapa de Díaz, 330 m, *Hallberg 1467* (NY). COSTA RICA. CARTAGO: Río Reventazón, below Turrialba, 540–600 m, *Skutch 4681* (CR, F, GH, MO). SAN JOSE: Río Surubres, 300 m, *Brade 430* (B, GH, M, S, UC); vic. of El General, 1,100 m, *Skutch 2531* (MICH, MO, S); basin of El General, 675–900 m, *Skutch 4790* (CR, MICH, MO). TRINIDAD. No locality, *Fendler 61 pro parte* (B, GH, MO). COLOMBIA. VALLE: valley of Río Digua, 950 m, *Alston 7837* (MO).

*Asplenium ×incisoserratum* grows on wet cliffs and boulders in streams from 300 to 1,200 m.

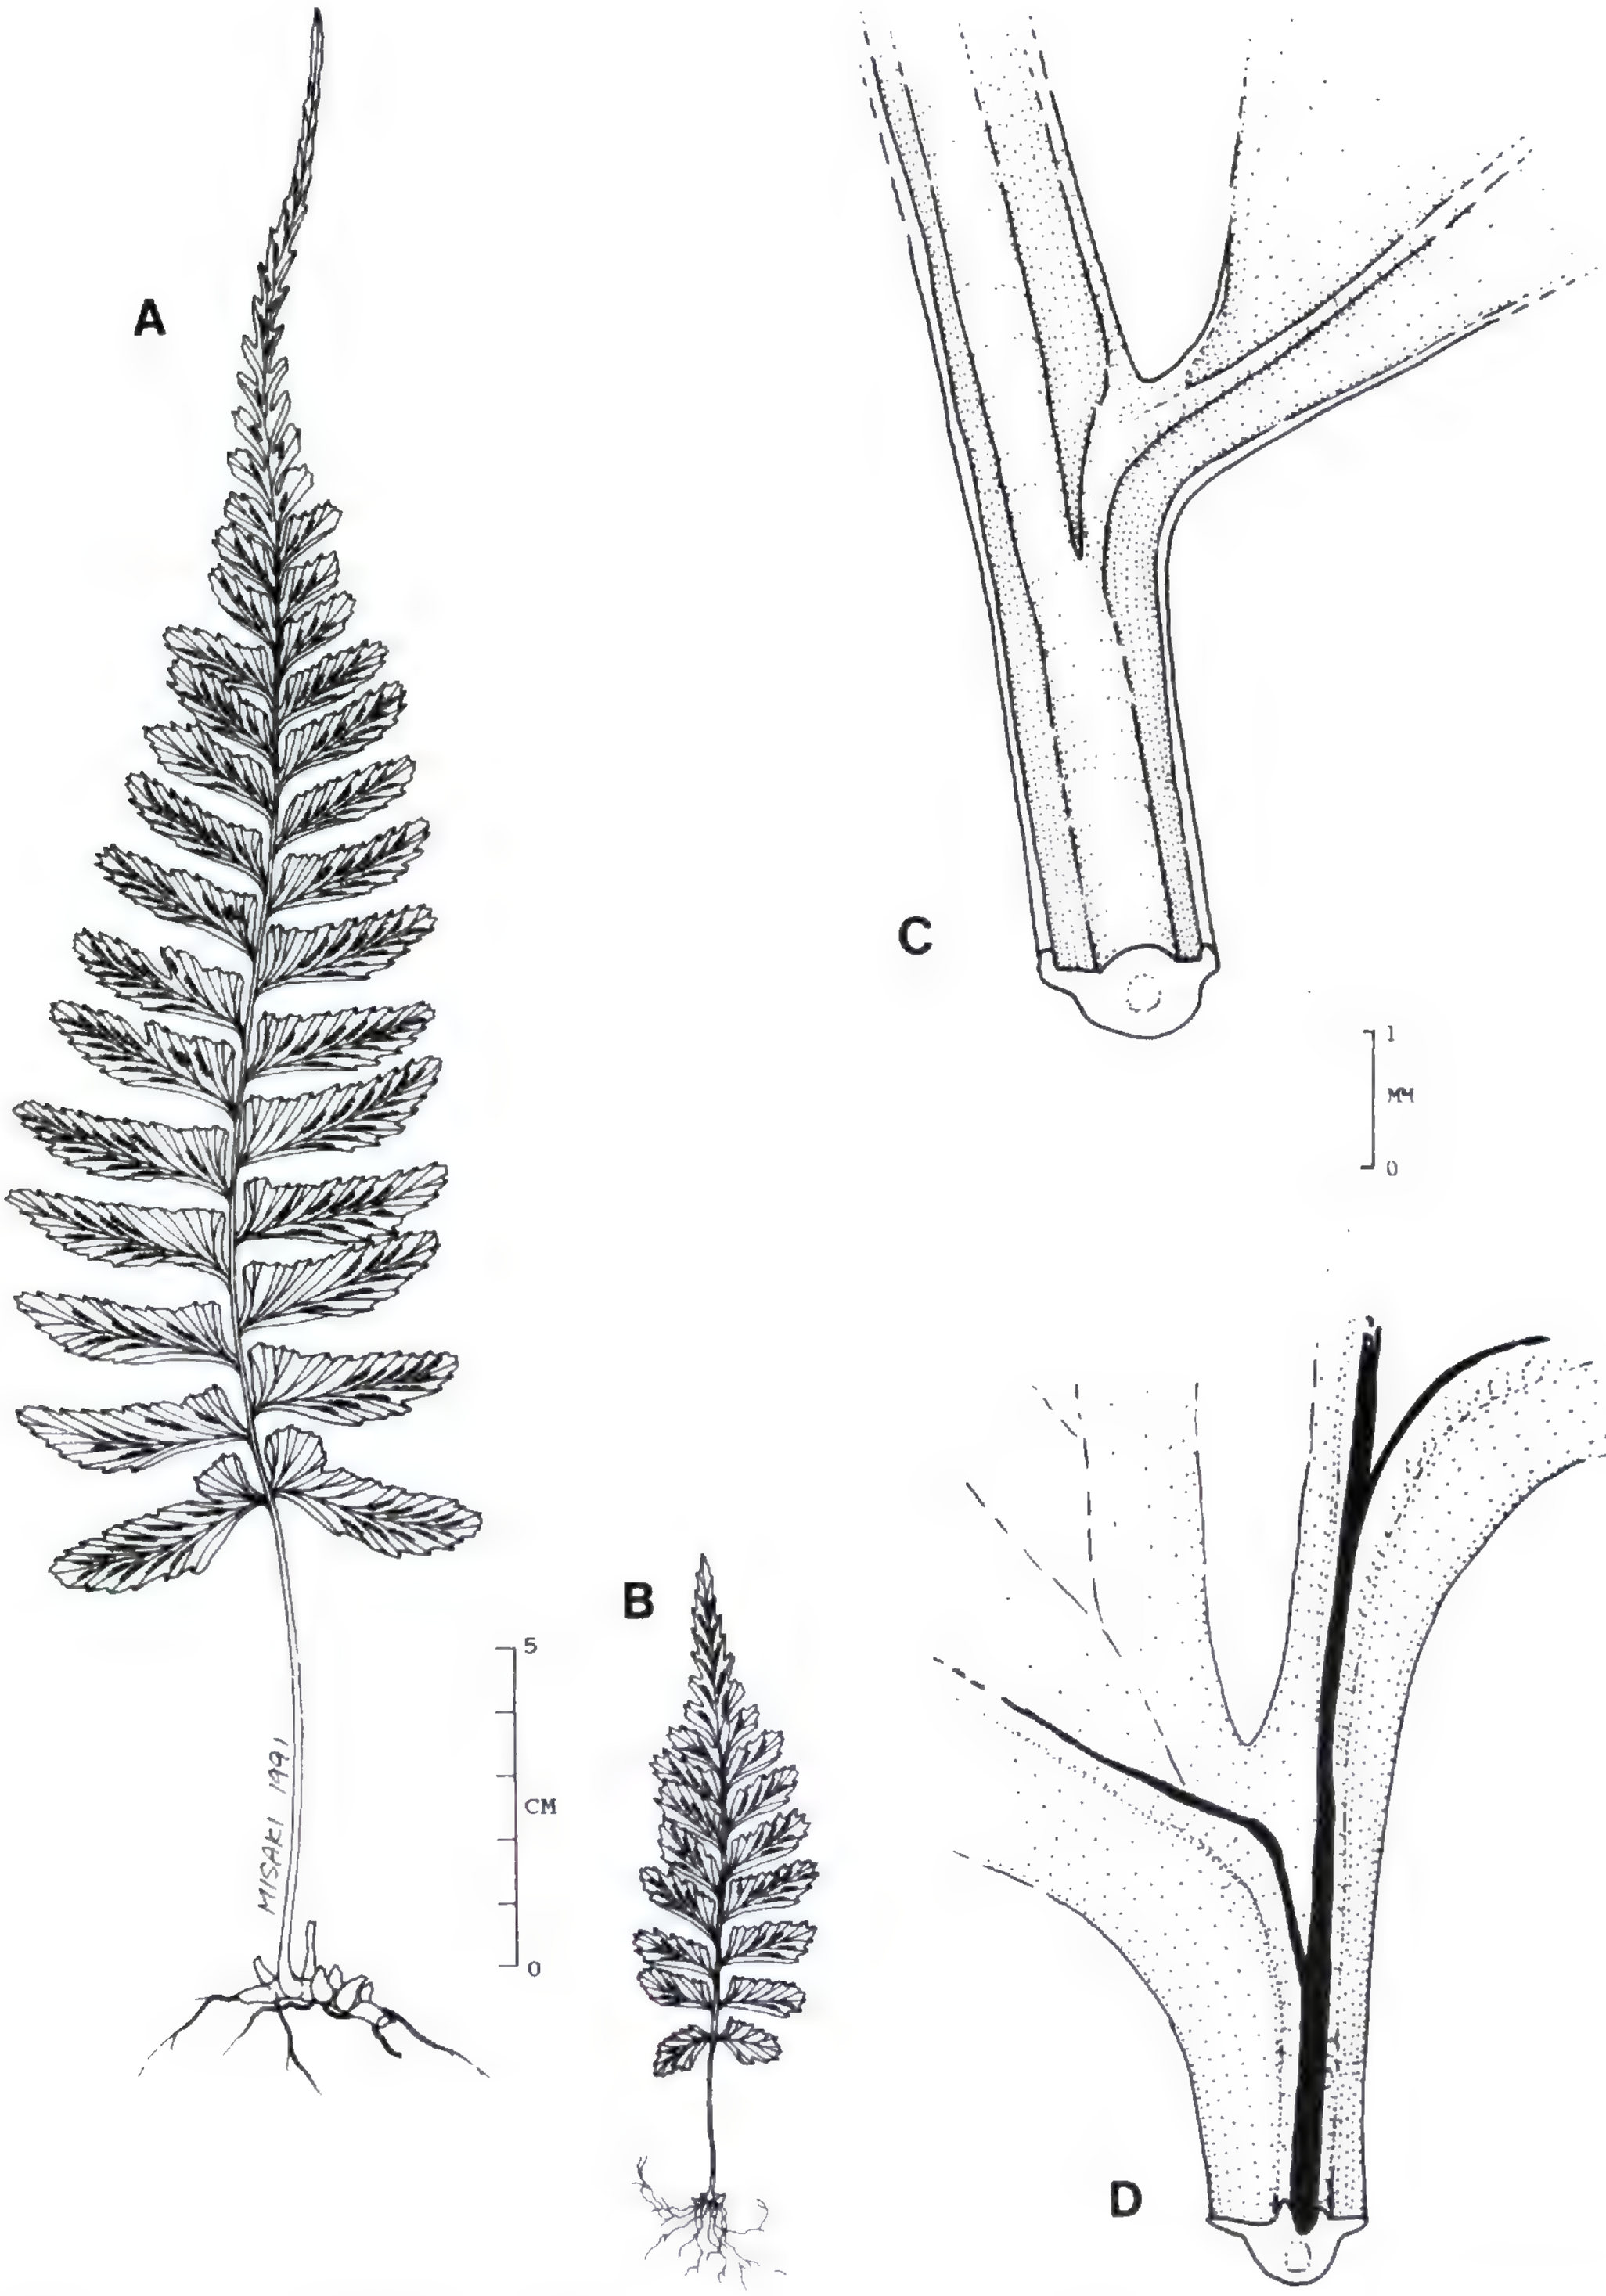


FIGURE 16. A, B. *Asplenium* ×*incisoserratum* (*Brade 430*, GH).—A. Large fertile leaf.—B. Small fertile leaf.—C. *A. abscissum*, juncture of rachis and pinna, note the raised, ungrooved rachis and costa, and thickened decurrent pinna margins (*Skutch 2339*, MO).—D. *A. delitescens*, juncture of rachis and pinnae, note the grooved rachis and the narrow wing that borders the costules and the rachidial groove (*Martínez S. 16399*, MO).

Based on morphology (Fig. 16), it appears to be a hybrid between *A. hoffmannii* and *A. laetum*. From *A. hoffmannii*, it differs by having more pinna pairs, more than two or three leaves per rhizome, and a basally darkened petiole (especially in large leaves). From *A. laetum*, it differs by its usually greenish petiole, greenish rachis, fewer number of pinna pairs, and more deeply and thoroughly incised-serrate pinnae. All of the specimens cited above have aborted spores.

Two miscellaneous notes: The specimen cited from Colombia appears to be this hybrid, but *A. hoffmannii* is not known from western Colombia where the specimen was collected. Apparently, Rosenstock (1925) did not publish a new name when referring to *Brade 430* as representing a "forma minor, die vorliegenden Exemplare fruktifizieren schon bei 6 cm Höhe." This diagnosis is in German, contrary to Rosenstock's varieties in the same paper, which are in Latin. Also, the typography of "forma minor" is in roman, not boldface or italic as he usually used when publishing new names.

## Index to Collectors' Names and Numbers

This monograph is based on the specimens cited below, which consist of about 1,800 herbarium sheets representing approximately 780 gatherings from 22 herbaria (see acknowledgments for list of herbaria). Types are in boldface. The numbers in parentheses refer to the number of the species and hybrids in this monograph, given below for easy reference.

### SPECIES

1. A. delitescens (Maxon) L. D. Gómez
2. A. hoffmannii Hieron.
3. A. laetum Sw.
4. A. obtusifolium L.
5. A. ortegae Murakami & R. C. Moran
6. A. purpurascens Mett. ex Kuhn

7. A. repandulum Kunze
8. A. riparium Liebm.
9. A. triquetrum Murakami & R. C. Moran
10. A. volubile Murakami & R. C. Moran

HYBRIDS

11. A. ×papyraceum (Jermy & T. Walker) Murakami & R. C. Moran
12. A. delitescens × A. laetum
13. A. ×incisoserratum (Rosenstock) Murakami & R. C. Moran

# A REVISION OF THE GENUS *PLEUROTHYRIUM* (LAURACEAE)[1]

*Henk van der Werff*[2]

## Abstract

*Pleurothyrium*, a genus of Lauraceae mostly consisting of trees, ranges from Guatemala to Bolivia and possibly Southern Brazil. The genus is best represented in Peru, Ecuador, and Colombia and mostly occurs at low elevations. In this revision 39 species are included in *Pleurothyrium*, of which 19 are described as new. Taxonomic history, characters, and phylogenetic classification are discussed. Data on phenology, habitat preference, and altitudinal range are presented when available.

In the course of identifying neotropical Lauraceae accumulated in MO or received on loan from other institutions, I found several undescribed species of *Pleurothyrium*. Four of those were published in earlier papers (van der Werff, 1987, 1988), but because the number of novelties kept increasing, I decided that writing a revision of the genus was the best way to deal with the many new species. Notable among those are the collections by J. Cuatrecasas from Chocó and Valle, Colombia, which include three striking, undescribed species. Recent collections by Missouri Botanical Garden staff members have also added significantly to the number of species. In this paper 19 species of *Pleurothyrium* are described, which brings the number of accepted species to 39. Because so many undescribed species were collected recently, I anticipate that the number of *Pleurothyrium* species will continue to grow. Another indication of this future growth is that 12 species are known from the type collection only, and an additional seven are known from two collections. Only three species have been collected more than 20 times. The large number of undescribed species found during this study shows clearly that our knowledge of neotropical Lauraceae is still incomplete. It is not coincidence that the largest percentage of undescribed species comes from Ecuador, a country where an active tree collecting program has been in place during the past seven years. Seven of the 12 *Pleurothyrium* species known from Ecuador are new to science.

There is little information available about economic uses of *Pleurothyrium* species. In central Peru the wood is used as timber and is considered to be of reasonably good quality. The wood of several Colombian species is used for making boards or canoes. It is likely that the wood of other species is also used locally, but because most of these species are rare and several do not grow into tall trees, their use is economically not very important.

## Materials

This revision is based on about 300 collections, some with many duplicates, found in many herbaria. A general difficulty with a generic revision in the Lauraceae is that many specimens are not identified to genus and therefore will not be sent when a loan of material of a particular genus is requested. One can solve this problem by personally selecting loans or by having a knowledgeable friend do so. In this case, Jens Rohwer kindly annotated all *Pleurothyrium* specimens in F, NY, and US to genus for me. In addition to these collections, I received loans from B, BM, BR, C, E, INPA, K, L, LE, P, S, U, UC, and VEN. I also had the opportunity to study the specimens of COL, IAN, MG, RB, and SP and thank the curators of these herbaria for loans and assistance during my visits. Recent collections by Missouri Botanical Garden botanists (notably B. Hammel, Costa Rica and Panama; G. McPherson, Panama and Colombia; A. Gentry, Colombia and Peru; C. Dodson, Ecuador;

[1] This study would not have been possible without the collecting efforts of many collectors, especially J. Cuatrecasas and Missouri Botanical Garden staff members, as well as the often large loans I received from several herbaria. I gratefully acknowledge their contributions. J. Crisci's assistance with the cladistic analysis is gratefully acknowledged. I thank several botanists (C. Berg, G. McPherson, R. Moran) who tried out the key and suggested improvements. The illustrations, both older and new ones, were made by J. Myers. The project was supported by National Science Foundation grant BSR-8918096.

D. Neill, Ecuador; C. Cerón, Ecuador; W. Palacios, Ecuador; R. Vásquez and J. Jaramillo, Peru) have contributed a great deal to this study.

## Taxonomic History and Generic Relationships

The genus *Pleurothyrium* was published by Nees in Lindley's *Natural System of Botany*, ed. 2, which appeared in July 1836 fide *Taxonomic Literature 2*, followed soon (October 1836) by a more detailed treatment in Nees's *Systema Laurinarum*. Initially, Nees included two species, *P. chrysophyllum* and *P. bifidum*, in his genus but added in his *Systema Laurinarum P. poeppigii* and *P. cuneifolium*. He described the genus as having six staminal glands and characterized it by the large glands and the lateral anther cells, which open back-to-back. Nees did not designate a type species. Bentham & Hooker (1880) expressed the opinion that *P. chrysophyllum* Nees fits the generic description best, and this species has been generally accepted as the lectotype species (Pax, 1889; Kostermans, 1952; Rohwer, 1986). In 1848, Nees described a fifth species of *Pleurothyrium*. Meissner (1864) added three species to *Pleurothyrium*, all of which are now placed in other genera. In his generic description, he mentioned the presence of a hypogynous disk forming a narrow ring on which stamens and glands are inserted. Meissner also stated that only six glands were present at the base of stamens of whorl III and that the staminodia do not possess glands at their base, this in contrast to Nees (1836a, b), who reported glands at the base of the staminodia. Baillon (1870) essentially accepted Meissner's circumscription of the genus; he stated that the disk was situated in the receptacle and that its apex was curved inward. The number of staminal glands remained six. Bentham & Hooker (1880) described *Pleurothyrium* as having a fleshy disk with six lobes alternating with six stamens, this in contrast to earlier authors, who described the disk as a narrow ring. Bentham & Hooker (1880) also mentioned the presence of glands at the base of the stamens of whorl III but did not describe how the glands are placed in relation to the disk. Actually, their description of the disk applies to the glands; the later confusion between disk and glands has its beginning here. Pax's description (1889) is brief and essentially the same as Bentham & Hooker's. Mez (1889) did not mention the presence of a disk in his description of *Pleurothyrium* but stated that all nine stamens had two glands at their base, which were almost always fused. In comparison to Nees's description, two other differences are noteworthy: Mez did not mention staminodia in his generic description, but Nees included biglandular staminodia in his description; according to Mez, the outer six anthers have two introrse and two extrorse, rarely lateral dehiscing locelli, whereas Nees described the locelli as lateral. Mez was the last person to revise *Pleurothyrium*; he excluded the three species Meissner (1864) described, but added one species described by Meissner (1864) as a *Nectandra*. Mez recognized five species in the genus. In the 1930s, several species of *Pleurothyrium* were described (Ducke, 1930; Smith, 1935; Schmidt, 1928, 1933) without any change in generic circumscription. MacBride (1938) essentially accepted Mez's description of the genus. Lasser (1942) described two Venezuelan species of *Pleurothyrium*, but did not discuss the generic concept. Kostermans (1952, 1957) looked critically at the validity of *Pleurothyrium* as a genus. He found that *Pleurothyrium* only differed from *Ocotea* in the position of the anther cells and the presence of glands at the base of all stamens. In his opinion, these differences were not sufficient for the recognition of *Pleurothyrium* as a genus, and he proposed to treat it as a section (1952) or subgenus (1957) of *Ocotea*. In 1952, he formally transferred all *Pleurothyrium* species to *Ocotea*. Bernardi (1962) followed Kostermans and treated *Pleurothyrium* as a subgenus of *Ocotea*. His description, however, partly followed Meissner: he mentioned a disk in the form of a narrow ring with the stamens inserted on the ring, but differed from Meissner in crediting all stamens with glands at their bases. Hutchinson (1964) fell back on Bentham & Hooker's concept of *Pleurothyrium*, with fleshy disk, this with six teeth alternating with the stamens as well as glands at the base of the inner three stamens. He accepted five species, half the number Kostermans (1952) included. Allen (1966b) discussed the concept of *Pleurothyrium* in detail and concluded that it deserved generic status, characterized by the presence of glands at the base of all stamens and the position of the anther cells. It is worth noting that Kostermans (1952) did not accept that these characters warranted recognition of *Pleurothyrium* as a genus. Kubitzki (1981) expressed the opinion that *Pleurothyrium* is a heterogenous genus and that its species actually belong to *Ocotea* and *Nectandra*. In contrast to this view, Rohwer & Kubitzki (1985) stated (based on a detailed analysis of *Ocotea* sens. lat.) that *Pleurothyrium* is a valid genus characterized by the lateral position of the locelli and the greatly enlarged glands. They pointed out that in *Pleurothyrium* only the inner three stamens (not all nine

stamens) have glands at their base, thus accepting Nees's description and rejecting that of Mez and subsequent authors. Rohwer (1986) further discussed and illustrated this concept and accepted eight species groups in *Pleurothyrium*, based on a survey of the types of the published species. Van der Werff (1987, 1988) accepted the circumscription of *Pleurothyrium* given by Rohwer & Kubitzki (1985), as did Burger & van der Werff (1990); in these publications an additional five species are described. However, in recent British literature (Willis, 1973; Mabberley, 1987) only one species is attributed to *Pleurothyrium*; in all likelihood, these authors follow Bentham & Hooker (1880), who wrote that only one species matched Nees's description.

In this study I accept *Pleurothyrium* as a distinct genus, most closely related to *Ocotea* and *Nectandra*. It differs from these two genera in two easy to observe androecial characters. In *Pleurothyrium* the outer six stamens have at least two anther cells in a lateral position (and often all four are lateral), and the six staminal glands are strongly enlarged and always grow outward between the six outer stamens and separate these stamens. In many species the glands become confluent and form a large, pillowlike mass with the anthers embedded in the surface. Other characters that are uncommon or lacking in *Ocotea* and *Nectandra*, but frequently present in *Pleurothyrium*, are the position of the inflorescences in the axils of cataphylls (not or rarely in axils of normal leaves) and the presence of a marginal vein in the leaves. Whether *Ocotea* or *Nectandra* is the closest relative of *Pleurothyrium* is still an open question. This study has not pointed to a particular genus or species group as the closest relative.

Van der Werff (1991) published a key to the New World genera of Lauraceae, including *Pleurothyrium*.

Although the greatly enlarged and fused glands are unique among neotropical Lauraceae, they also occur in the Asian-Australian genus *Endiandra*. Several Australian species are illustrated in Hyland (1989). The enlarged, fused glands are about the only character *Pleurothyrium* and *Endiandra* have in common. *Endiandra* has only three two-celled stamens and does not have a cupule subtending the fruit; it is closely related to *Beilschmeidia*. Thus, the character of the glands is considered to be an example of convergence and does not indicate a close relationship.

## DISTRIBUTION AND ECOLOGY

*Pleurothyrium* species have been collected from Guatemala, the northernmost extension, to Bolivia and southern Brazil, the southernmost extension. It has been collected in all countries between these extremes with exception of El Salvador and the three Guianas. The genus is absent from the West Indies. Table 1 shows the species present in each country. The greatest concentration of species occurs in Peru, Brazil, Ecuador, and Colombia, while *Pleurothyrium* is represented by only a few species in the other countries. The Brazilian species are, with exception of *P. amplifolium*, Amazonian, and most occur in the upper part of the Amazon basin; only one or two species have been found downstream from Manaus. Most species are only known from lowland forests or the lower foothills of the Andes (below 1,000 m elevation). In Peru, *P. cuneifolium* and *P. poeppigii* occur at 1,800 m near Oxapampa, but these species are better represented in the lowlands. The Ecuadorian *P. obovatum* is only known from three collections at 1,200–1,800 m. In Venezuela, *P. costanense* has been collected

at 2,200 m, but is more common around 1,000 m; the poorly known *P. steyermarkianum* has been collected at 1,400 and 2,000 m.

Our knowledge about the habitat requirements of *Pleurothyrium* species is very poor. Older collections usually do not have habitat information other than "forest" and besides, many species are known from very few collections. For a reliable estimate of the habitat requirements, I would want at least ten collections with the same habitat information. This is only available for *P. parviflorum*, a species restricted to seasonally flooded forests in Peru, Brazil, and Ecuador. It is to be expected in the Amazonian forests of Colombia as well, but it has not yet been collected there. *Pleurothyrium panurense* is known from fewer collections, but all of these were made in flooded forest.

Most of the new or recently described species are from Colombia and Ecuador. For instance, six of the ten species from Colombia are new; for Ecuador these figures are seven out of twelve, but for Brazil it is two out of eleven species. Because of the Projeto Flora Amazonica, Amazonian Brazil has been reasonably well collected, probably better than Colombia, and it seems unlikely that many additional *Pleurothyrium* species will be collected in Brazil. On the other hand, Colombia has at least three additional, but incompletely known species. Taking this into consideration, I expect that the greatest diversity will be in Peru, Ecuador, and Colombia.

## Morphology and Taxonomic Characters

At the beginning of this survey of the taxonomic characters of *Pleurothyrium* species, it should be emphasized that about half of the species are known from only one or two collections. This is not enough for a good understanding of the morphological variation within the species, and there are difficulties interpreting differences in degree of pubescence, leaf size, and color of pubescence. Therefore, I decided not to recognize taxa based solely on these characters, even though, for instance, the Peruvian collection of *P. insigne* and the Costa Rican collection of *P. hexaglandulosum* look different from the types. Additional collections of many species are needed for a better understanding and, when available, may well lead to changes in the classification here proposed.

*Habit.* *Pleurothyrium* species vary from small to tall trees. There is no information about different types of tree architecture represented in the genus, but it is likely that species with clustered leaves have a different growth type than species with evenly spaced leaves.

*Habitat.* As with habit, label information on habitat is poor. The great majority of the species are restricted to the wet lowlands (below 500 m). *Pleurothyrium cuneifolium* and *P. poeppigii* have been found from the lowlands up to 1,800 m, an unusually wide range of altitude. *Pleurothyrium costanense* is restricted to cloud forest in Venezuela, between 800 and 2,200 m. *Pleurothyrium trianae* occurs occasionally up to 1,200 m, but is most common at elevations between 300 and 600 m. *Pleurothyrium palmanum* is known from four collections in Costa Rica and Panama, between 1,000 and 1,600 m. Finally, there are three montane species known from only three or fewer collections: *P. bracteatum* at 1,000 m in Colombia, *P. obovatum* at 1,200–1,800 m in southern Ecuador, and *P. racemosum* at 900 m in Panama. More detailed habitat preferences are only known for *P. panurense* and *P. parviflorum*: both are restricted to flooded forests in the upper Amazon basin. In the vicinity of Iquitos, Peru, I collected *P. parviflorum* in flooded forests on sandy and clay soils, but never found it outside flooded forests.

*Fistulose twigs.* Four species, *Pleurothyrium cuneifolium*, *P. obovatum*, *P. parviflorum*, and *P. poeppigii*, have consistently fistulose twigs, while *P. trianae* has rarely fistulose twigs. This is a reliable and readily visible character mentioned by Nees (1836b) in his descriptions. Mez (1889), citing Poeppig (In ramulis revera fistulosis degunt formicarum agmina pessime pungentia), referred to the ants living in the hollow twigs. On several, but certainly not all, labels of these species, the presence of aggressive ants is mentioned; I found *P. parviflorum* sometimes inhabited by aggressive ants and sometimes by timid ones, although each tree was inhabited by one kind only. In Lauraceae fistulose twigs inhabited by ants are not restricted to *Pleurothyrium*, but also occur in *Ocotea javitensis* (HBK) Pitt., *O. dendrodaphne* Mez, the species related to *O. atirrensis* Mez & J. D. Smith, including *Aiouea vextrix* van der Werff, a *Licaria* species from Costa Rica, and an *Aniba* species from Iquitos, Peru. Most Lauraceae with hollow twigs occur in the lowlands, but *P. obovatum*, known only from 1,800 m, has clearly hollow stems with exit holes. An undescribed *Ocotea* species from northern Ecuador, collected at 2,400 m elevation, also had hollow twigs inhabited by ants, as did an undescribed *Cinnamomum* species from central Ecuador, collected at 2,200 m elevation. Both high-elevation species were inhabited by non-aggressive ants, which did not defend the twigs and scarcely left the hollow core when the twigs were broken.

In *Pleurothyrium cuneifolium* and *P. poeppi-*

*gii*, the main axis of the inflorescences is not rarely fistulose. A good example is the type collection of *P. poeppigii*. These fistulose inflorescences tend to have very short lateral branchlets with the flowers rather densely fasciculate. In the past, all collections with this striking inflorescence shape were annotated as *P. poeppigii*, but floral characters show that this inflorescence shape also occurs in *P. cuneifolium*. In *Ocotea javitensis* the entire inflorescence can be reduced and carry a dense cluster of flowers; such specimens have also been identified as *Pleurothyrium* (for instance, *Klug 2908* as *P. densiflorum* Smith). Exactly how the activity of ants induces this peculiar inflorescence shape is not known to me.

*Leaf position.* Most species have alternate leaves, the predominant arrangement in Lauraceae. About ten species have the leaves clustered at the tips of the branches, potentially a useful character to separate species. However, I found this character not as useful as I hoped, because in some species the leaves are more or less clustered, and in some others the leaves are so large that an herbarium specimen consists of one leaf and an inflorescence and does not show the arrangement of additional leaves. Thus, I used leaf position in the key only when separating relatively small-leaved species.

*Leaf shape.* Leaf shape ranges from elliptic to strongly obovate. In most species it is rather stable, but I found it difficult to express leaf shape accurately in words and have not used it very much in the key. A few striking leaf shapes should be mentioned: in *Pleurothyrium maximum*, *P. insigne*, and *P. williamsii* the leaves are gradually narrowed toward the base and at the base are abruptly rounded to cordate; in *P. racemosum* and *P. pilosum* the leaves are obtuse or rounded both at the base and apex. *Pleurothyrium tomiwahlii* has a similar leaf shape, but the base is sometimes acute, not obtuse.

*Leaf venation.* Leaf venation includes both camptodrome and brochidodrome types as well as their intermediates. All species with small flowers and free staminal glands (the first eleven species in the key) have predominantly camptodrome venation, while the species with larger, rotate flowers have camptodrome or brochidodrome venation. Leaf size or shape does not seem to affect venation type strongly; some species with large, obovate leaves have a strongly developed marginal vein (*Pleurothyrium insigne*, *P. maximum*), but others (*P. tomiwahlii*, *P. giganthum*) do not. Among the species with small leaves, *P. marginale* has a strong marginal vein, but *P. golfodulcense*, *P. glabritepalum*, and *P. westphalii* do not have a marginal vein. Although venation type seems characteristic for each species, the various types are hard to describe accurately and have not been used much in the key. A detailed study of the venation types of *Pleurothyrium* is in preparation and will be published separately.

*Indument.* The type of indument is a very useful character for identification. Because indument on leaves and twigs can be different, I have mostly used the indument on the lower leaf surface, in which I recognize three types. A little more than half the species have glabrous leaves or carry a sparse, appressed indument, which never covers the entire lower surface. A group of ten species has erect straight or tortuous (in *Pleurothyrium racemosum*) hairs, which never cover the entire surface and which, in some species, can be sparse. The third group has a dense (mostly tomentose) pubescence, which completely covers the lower leaf surface. With the exception of three species (*P. crassitepalum*, *P. panurense*, and *P. tomiwahlii*), these pubescence types can easily be recognized. In the three exceptions, it is sometimes difficult to choose between group one (glabrous or sparse, appressed pubescence, the surface visible) or group three (dense pubescence, covering the entire surface). These species are therefore included twice in the key. The three groups based on pubescence types are not natural; sometimes closely related species (for instance, *P. insigne-P. maximum*) are placed in different groups. These groups are formed solely to allow easy identification.

*Inflorescences.* Inflorescences of *Pleurothyrium* are as a rule thyrso-paniculate in the sense of Weberling (1985). They consist of a central axis with a number of alternately positioned lateral axes. The lateral axes are once to several times cymosely branched; the central flower of each cyme flowers before the lateral ones and is usually absent in all but the terminal cymes. Of each cyme, the lateral elements may again be cymosely divided, but the central element always develops into a single flower. Sometimes the lateral elements of the lateral branches fail to develop and then the inflorescence is racemose (as in *P. racemosum*).

In most species inflorescence bracts are early deciduous and absent at anthesis. Exceptions are *Pleurothyrium bracteatum* and *P. golfodulcense*, both of which have rather large bracts at anthesis.

The thyrso-paniculate inflorescence type is very common among neotropical Lauraceae and occurs in all larger genera, such as *Ocotea*, *Nectandra*, *Persea*, *Aniba*, *Licaria*, *Aiouea*, *Endlicheria*, and *Cinnamomum*.

In general, the inflorescences are found in the axils of cataphylls just below the terminal bud.

Although they appear terminal, I have always found them to be lateral. In the species group characterized by erect tepals, inflorescences occur occasionally in the axils of regular leaves, but this is uncommon. In *Pleurothyrium giganthum*, the inflorescences are inserted in the axils of cataphylls below the leaves. However, many species are represented by very few collections and I am not certain that the position of the inflorescences, below or above the leaves, is of any significance.

The nearly consistent presence of inflorescences in the axils of cataphylls is a helpful character for the identification of *Pleurothyrium*. The great majority of species of *Ocotea* and *Nectandra* have inflorescences in the axils of normal leaves, but such species as *O. fasciculata* (Nees) Mez and *N. megapotamica* (Spreng.) Mez are exceptions.

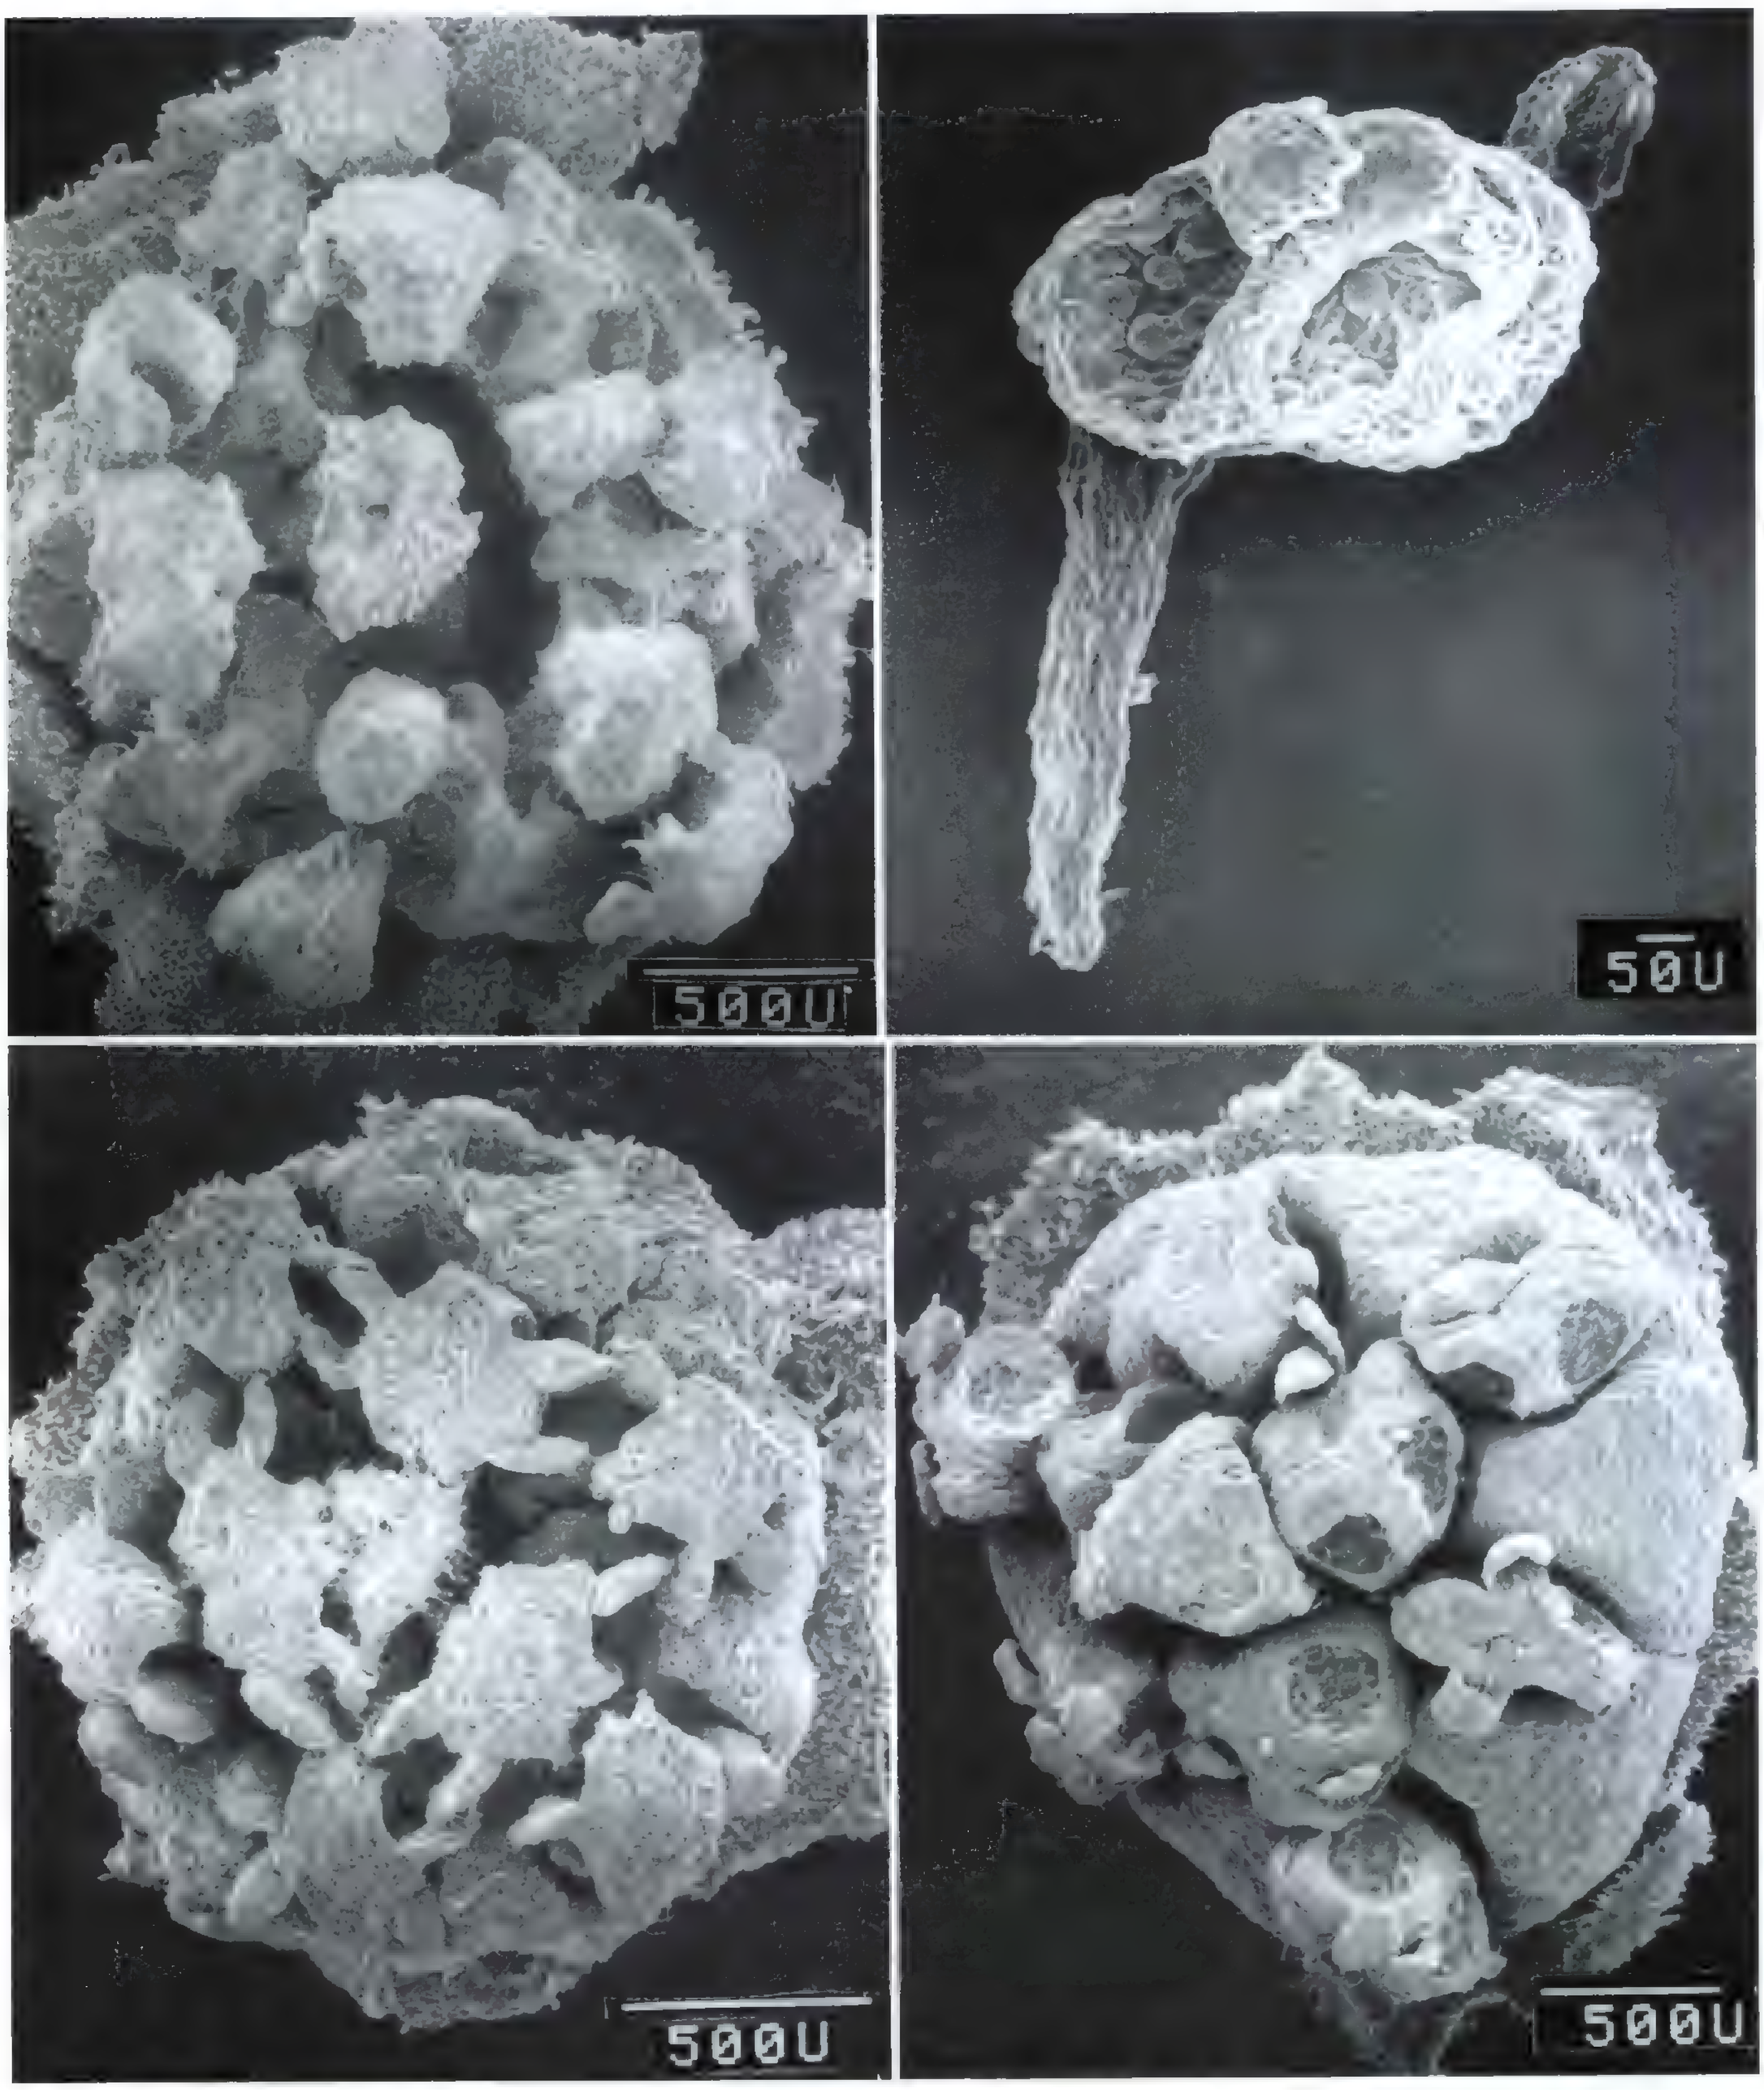
*Flowers.* The flowers offer a number of discriminating and/or interesting characters. Eight species have more or less erect tepals at anthesis, this in contrast to the remaining species, which have a rotate flower shape. Six of these eight (the exceptions are *Pleurothyrium acuminatum* and *P. amapaense*) also have reflexed margins of the tepals. These reflexed margins are not a result of aging of the flowers; I have seen *P. parviflorum* and *P. trianae* in the field and even young flowers have reflexed margins of the tepals. On herbarium sheets one can see that sometimes buds have already reflexed margins of the tepals. I consider the species with erect tepals, together with *P. cuneifolium* and *P. obovatum*, a closely related group, characterized by flower shape, absence of a marginal vein, similar indument on the pistil, occurrence of fistulose stems, and the rather slender tepals.

Most other species have rotate flowers and broadly ovate to roundish tepals. Species with flowers more than 10 mm in diameter show a tendency toward unequal tepals, with the inner tepals slightly shorter and narrower than the outer ones. The group of species with erect tepals always has equal tepals. In one species, *Pleurothyrium tomiwahlii*, the tepals are strongly reflexed at anthesis and become parallel to the pedicel in older flowers.

The pubescence on the outside of the tepals is frequently much denser or longer on the areas exposed to the outside in bud than on areas protected from the outside. Thus, the outer three tepals and a basal, triangular patch on the inner tepals have a similar pubescence. This is an unusual character in Lauraceae, but is fairly common in the group of species with rotate flowers. It does not occur in the group of species with erect tepals.

The pubescence on the inside of the tepals is variable and is a useful character in separating the taxa. A few species (*Pleurothyrium cuneifolium*, *P. glabrifolium*, *P. glabritepalum*, *P. panurense*, and *P. prancei*) have a glabrous inner surface of the tepals (in *P. prancei* the outer three are glabrous inside, the inner three papillose). Occasionally, some scattered papillae or hairs may be present, especially near the base of the tepals, but a homogeneous cover of papillae or hairs is lacking. The group of species with pubescent inner surfaces of the tepals is also small; it includes *P. bracteatum*, *P. giganthum*, *P. crassitepalum*, *P. tomiwahlii*, *P. grandiflorum*, *P. marginale*, *P. pilosum*, and *P. westphalii*. In *P. racemosum* the inner tepals are pubescent and the outer three have a large, triangular, pubescent patch at the base and are otherwise papillose. The remaining species all have a papillose inner surface.

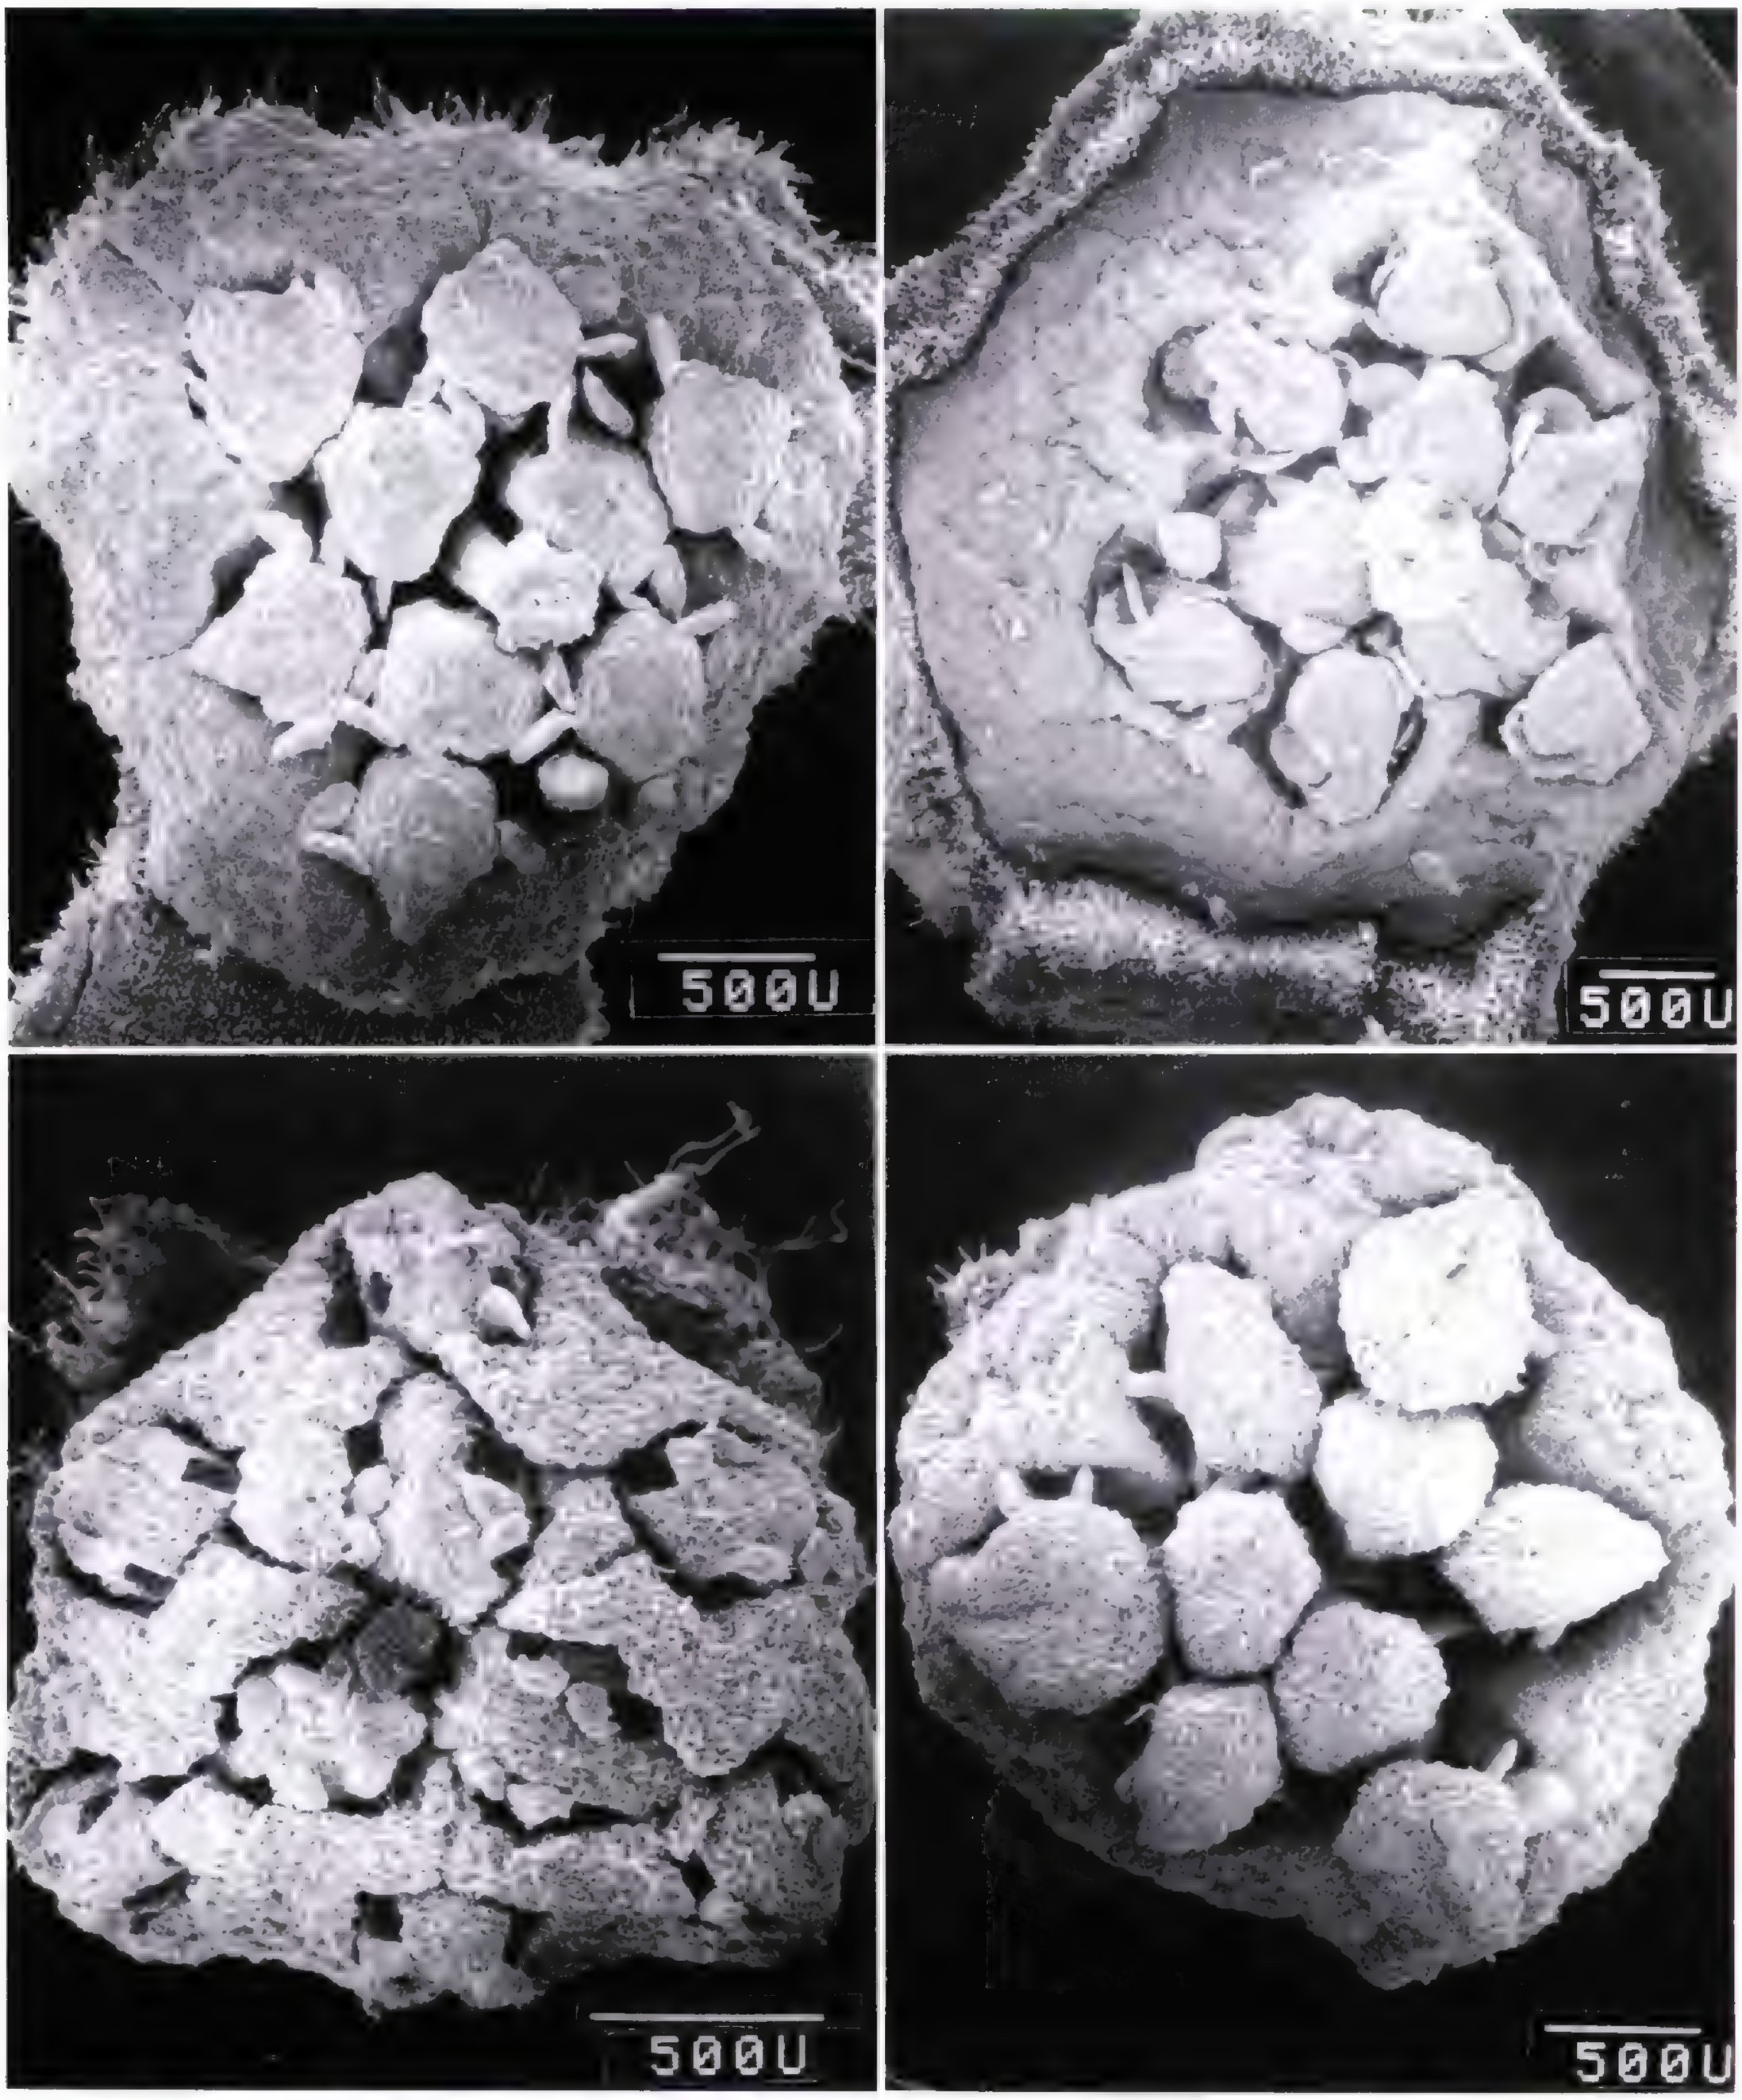
The different androecial configurations are the most interesting feature of *Pleurothyrium*. In the group of species with erect tepals the enlarged glands grow outward, and the six outer stamens are separated from each other by the glands (Fig. 1). In this flower type the glands do not grow around the outer anthers, and the glands do not touch each other at the periphery of the flower. The stamens have relatively long filaments and the anther cells occupy nearly the entire anther (Fig. 2). The anther is somewhat curved inward, but not horizontal; thus, the anther cells are arranged in an upper and lower pair. The lower pair is always toward the outside in relation to the upper pair. Because of the long filaments, the anthers are clearly raised above the glands. In the next stage, the glands begin to enclose the outer stamens, while the anthers become horizontal, have lateral anther cells, and are not raised above the glands. An example is *P. vasquezii* (Fig. 3). In other species the glands completely surround the outer stamens and appear to form a wall around the stamens. The contact lines between the glands are sometimes clearly visible (Fig. 4) or almost disappear (Fig. 5). In the final stage all stamens are crowded in the center of the flower, surrounded by a broad wall of completely fused glands (Fig. 6). The enlarged glands do not confine the stamens to the center of the flower in all species. In some species the glands grow between the stamens and separate them, especially the stamens of the second whorl (Fig. 7). This configuration is not common; it occurs in *P. golfodulcense*, *P. cinereum*, *P. tomiwahlii*, *P. crassitepalum*, and *P. racemosum*. The species with this flower type also tend to have stamens and



FIGURES 1–4.—1. (Top left.) Flower of *Pleurothyrium poeppigii*, tepals removed (*Palacios 2775*).—2. (Top right.) Stamen (Whorls I–II) of *P. acuminatum* (*van der Werff 9967*).—3. (Bottom left.) Flower of *P. vasquezii*, tepals removed (*Vasquez 7889*).—4. (Bottom right.) Flower of *P. tomentellum*, tepals removed (*Gudiño 12*).

glands forming a taller "dome"; this dome can be as high as its width. In *P. tomiwahlii* the dome is also seated on a short column, thus further raising the androecium. All species with horizontally bent anthers and glands that are (nearly) enclosing the outer stamens have rotate flowers. These species have, on the average, distinctly larger flowers than the species with erect tepals. Unfortunately, no data on pollination are available, but it seems likely that the species with large, rotate flowers are pollinated by different organisms than those with small flowers with erect tepals.

The indument of the pistil shows considerable variation. Sixteen species were found to have the pistil more or less covered with papillae. Often the lower part of the ovary was glabrous and the density



FIGURES 5–8.—5. (Top left.) Flower of *P. insigne*, tepals removed (*Palacios 4388*).—6. (Top right.) Flower of *P. grandiflorum*, tepals removed (*Juncosa 1675*). —7. (Bottom left.) of the papillae decreased also on the style, but papillae were easily seen on the upper part of the ovary. This condition is present in all species with erect tepals, as well as in *Pleurothyrium bifidum*, *P. brochidodromum*, *P. nobile*, *P. palmanum*, *P. panurense*, *P. vasquezii*, and *P. williamsii*. Ten species have a glabrous pistil: *P. tomiwahlii*, *P. crassitepalum*, *P. glabrifolium*, *P. glabritepalum*, *P. grandiflorum*, *P. marginale*, *P. pilosum*, *P. racemosum*, *P. giganthum*, and *P. westphalii*. The remaining species have a (partly) pubescent pistil. In a few species one finds six bald spots on the upper part of the pubescent ovary corresponding to the contact points between the six glands and the ovary. I have not used the indument of the pistil frequently in the key, because the pu-

bescence is only readily visible on the style in a few species.

Fruits and cupules are unknown for many species. When known, the cupules are relatively deeply cup-shaped and have nearly always conspicuous lenticels or warts. Because of the deep cupules, fruiting collections have sometimes been misidentified as *Aniba* sp., but venation (*Pleurothyrium* has in general more lateral veins and sometimes a distinct marginal vein) and indument (ferruginous tomentum is a good indication for *Pleurothyrium*) help separate the two genera. Frequently, the tepals are persistent on the young cupules. The tepals eventually become damaged and break off or the growing cupule causes the tepals to fall off. In this character, *Pleurothyrium* species differ from *Nectandra*, where the tepals tend to be basally united and fall off as a unit, together with the stamens. Unusual characters are the presence of six large lobes on the cupules of highland populations of *P. poeppigii* in the Selva Central in Peru; the common name "roble zapallo" alludes to this (zapallo = squash). Young cupules of *P. giganthum* are sharply hexangular, a feature not found in other species. In *P. cinereum* the tepals are persistent on the mature cupule, which may be double-rimmed.

*Pollen.* In a survey of pollen types of neotropical Lauraceae, Raj & van der Werff (1988) found that, with the exceptions of *Cryptocarya* and *Cassytha*, all investigated species had inaperturate, spinulose pollen grains. Pollen of *Pleurothyrium* was found to be very similar to that of *Ocotea*, the main differences being size and ultrastructural details of the sporoderm. Pollen of *Nectandra* is more distinct. Three species of *Pleurothyrium* (*P. parviflorum*, *P. trianae*, and *P. cuneifolium*) were included in this study. Because these three species belong to the group with erect tepals and erect or curved anthers, I checked pollen of two species with rotate flowers and bent anthers (*P. insigne* and *P. racemosum*). These two species have the same inaperturate, spinulose pollen that is present in nearly all neotropical Lauraceae. Because all five investigated *Pleurothyrium* species have the same pollen type, it seems unlikely the pollen will be useful in the classification of *Pleurothyrium* species, and pollen of the other species has not been studied.

## Cladistic Analysis

A cladistic analysis, based on the principles of phylogenetic systematics as developed by Hennig (1966), was made of *Pleurothyrium*, using the 39 species recognized in this revision as terminal taxa. Because several species of *Pleurothyrium* are still poorly known, the choice of characters to be used in the analysis was limited to those characters visible on a herbarium sheet. Ideally, one wishes for characters from other fields (such as embryology, anatomy, chemistry) as well as more characters. The characters and the character states used are listed in Table 2; the data matrix is presented in Table 3. The choice of outgroup, and therefore also the polarity of the character states, initially posed considerable problems. Of all genera of Lauraceae, *Nectandra* and *Ocotea* are the closest to *Pleurothyrium*, based on overall morphology. However, neither of the two seems closer to *Pleurothyrium* than the other. Because *Ocotea* and *Nectandra* are very similar in the character states used in this analysis, which of them was chosen as the outgroup seemed relatively unimportant, thus a preliminary analysis was made with the generic concept of *Nectandra* as outgroup. This analysis resulted in 1,988 trees; after successive weighting 293 trees were generated. A strict consensus tree showed as the most derived group of species those species with erect tepals and free, weakly enlarged glands. This topology ran completely counter to my ideas of trends within *Pleurothyrium*. Based on knowledge gained from my nine years of studying Lauraceae, I consider the following character states in *Pleurothyrium* as primitive: free, weakly enlarged glands, stamens with only two of the four anther cells lateral and the anthers raised well above the glands, the occasional presence of inflorescences in the axils of normal leaves, the absence of a marginal vein, and erect tepals. As derived character states, I regard fused, strongly enlarged glands, stamens with four lateral anther cells, anthers that are not or scarcely raised above the glands, inflorescences strictly in the axils of cataphylls, presence of a marginal vein and spreading, rotate (or even reflexed) tepals. These ideas on primitive and derived characters in *Pleurothyrium* are based on my extensive experience with neotropical Lauraceae. Because *Nectandra* and several hermaphroditic species of *Ocotea* (including most South American *Ocotea* species with perfect flowers) have flowers with spreading tepals, the *Pleurothyrium* species with erect tepals ended up as derived in the phylogenetic tree. There are some *Ocotea* species with perfect flowers and erect tepals (for instance, the *O. insularis* group), but various reasons (entirely different indument of anthers, presence of flattened branchlets of inflorescence) make it highly unlikely that *O. insularis* can be considered as outgroup for *Pleurothyrium*.

TABLE 2. Characters and character states used in cladistic analysis of *Pleurothyrium*.

| | |
|---|---|
| 1. Position of tepals | 0 = spreading<br>1 = erect |
| 2. Margin of tepals | 0 = plane<br>1 = inrolled |
| 3. Marginal vein | 0 = lacking<br>1 = present |
| 4. Indument on inner surface of tepals | 0 = glabrous<br>1 = papillose<br>2 = pubescent |
| 5. Indument of pistil | 0 = glabrous<br>1 = papillose<br>2 = pubescent |
| 6. Indument of floral tube | 0 = glabrous<br>1 = papillose<br>2 = pubescent |
| 7. Glands | 0 = free, not surrounding stamens<br>1 = surrounding stamens, ± fused |
| 8. Stamens | 0 = adjacent<br>1 = separated from each other by glands |
| 9. Twigs | 0 = solid<br>1 = fistulose |
| 10. Number of lateral veins | 0 = 5–9<br>1 = 10–15<br>2 = 16 or more |
| 11. Tepals | 0 = equal<br>1 = subequal |
| 12. Position of leaves | 0 = alternate<br>1 = clustered |
| 13. Pubescence on lower leaf surface | 0 = glabrous or appressed<br>1 = erect |
| 14. Position of inflorescence | 0 = in axils of leaves<br>1 = in axils of bracts |
| 15. Position of anther cells | 0 = 2 lateral<br>1 = 4 lateral |
| 16. Pubescence of bracts | 0 = only on outer surface<br>1 = on inner and outer surface |

Character states of 4, 5, 6, and 10 are unordered.

A second analysis was made with a primitive species of *Pleurothyrium*, *P. acuminatum*, as outgroup. This species was chosen because it lacks the derived characters listed earlier, and it also lacks fistulose twigs and has plane, not inrolled, tepal margins. Analysis of the data matrix using the MHennig* and bb* Wagner parsimony options of Hennig86 (Farris, 1988) produced 540 most parsimonious trees (length 79 steps, consistency index 0.25). A strict consensus tree based on these 540 trees showed an alphabetical listing of 32 species, with only seven species slightly better resolved. The successive weighting procedure on the 540 trees resulted in at least 1,149 trees (overflow) with a length of 110 steps and a consistency index of 0.50. Note that the high value for the length is a function of the weight being scaled up to a value of 10. Although most characters were weighted after the successive weighting procedures, four of the sixteen characters (10, 11, 13, and 14) weighted zero. The analysis was repeated without those characters and resulted in 230 most parsimonious trees with a length of 44 steps and a consistency index of 0.34. After successive weighting, the analysis produced 118 trees with a length of 98 steps and a consistency index of 0.58. As a consequence of deleting the four "weightless" characters, the analysis resulted in a smaller number of trees with fewer steps and a higher consistency index: these four characters must have contributed a great deal of homoplasy to the first analysis.

A strict consensus tree based on the 118 trees of the second analysis is presented in Figure 9a, while one of the 118 equally parsimonious trees, selected at random, is presented in Figure 9b. The following comments apply to both cladograms. The changes in character states throughout the cladogram are added to the tree. In both cladograms, the species group I consider primitive forms the basal group. The second, largest group is not well

resolved; the large number of trees before constructing the consensus tree reflects variation in topology in this group. The cladograms include only four synapomorphies (for characters 1, 2, 7, and 10), indictaing that all other changes are changes in unordered states or homoplasies. Although nearly all cladograms include some amount of homoplasy, to have a cladogram for 39 terminal taxa with only four synapomorphies suggests that the data needed for a cladistic analysis were not available.

Reviewing this attempt at making a phylogenetic classification as a byproduct of a taxonomic revision of *Pleurothyrium*, one may note several problems. First, the number of characters is much lower than the number of terminal taxa. Second, the poor understanding of relationships within Lauraceae makes the choice of an outgroup somewhat arbitrary, and therefore the choice of polarity of the character states cannot be defended very well. Because the choice of outgroup influences the classification strongly, the cladogram cannot be any more reliable than the choice of outgroup. Third, the phylogenetic classification is entirely based on gross morphological characters of herbarium specimens. These characters were not selected because

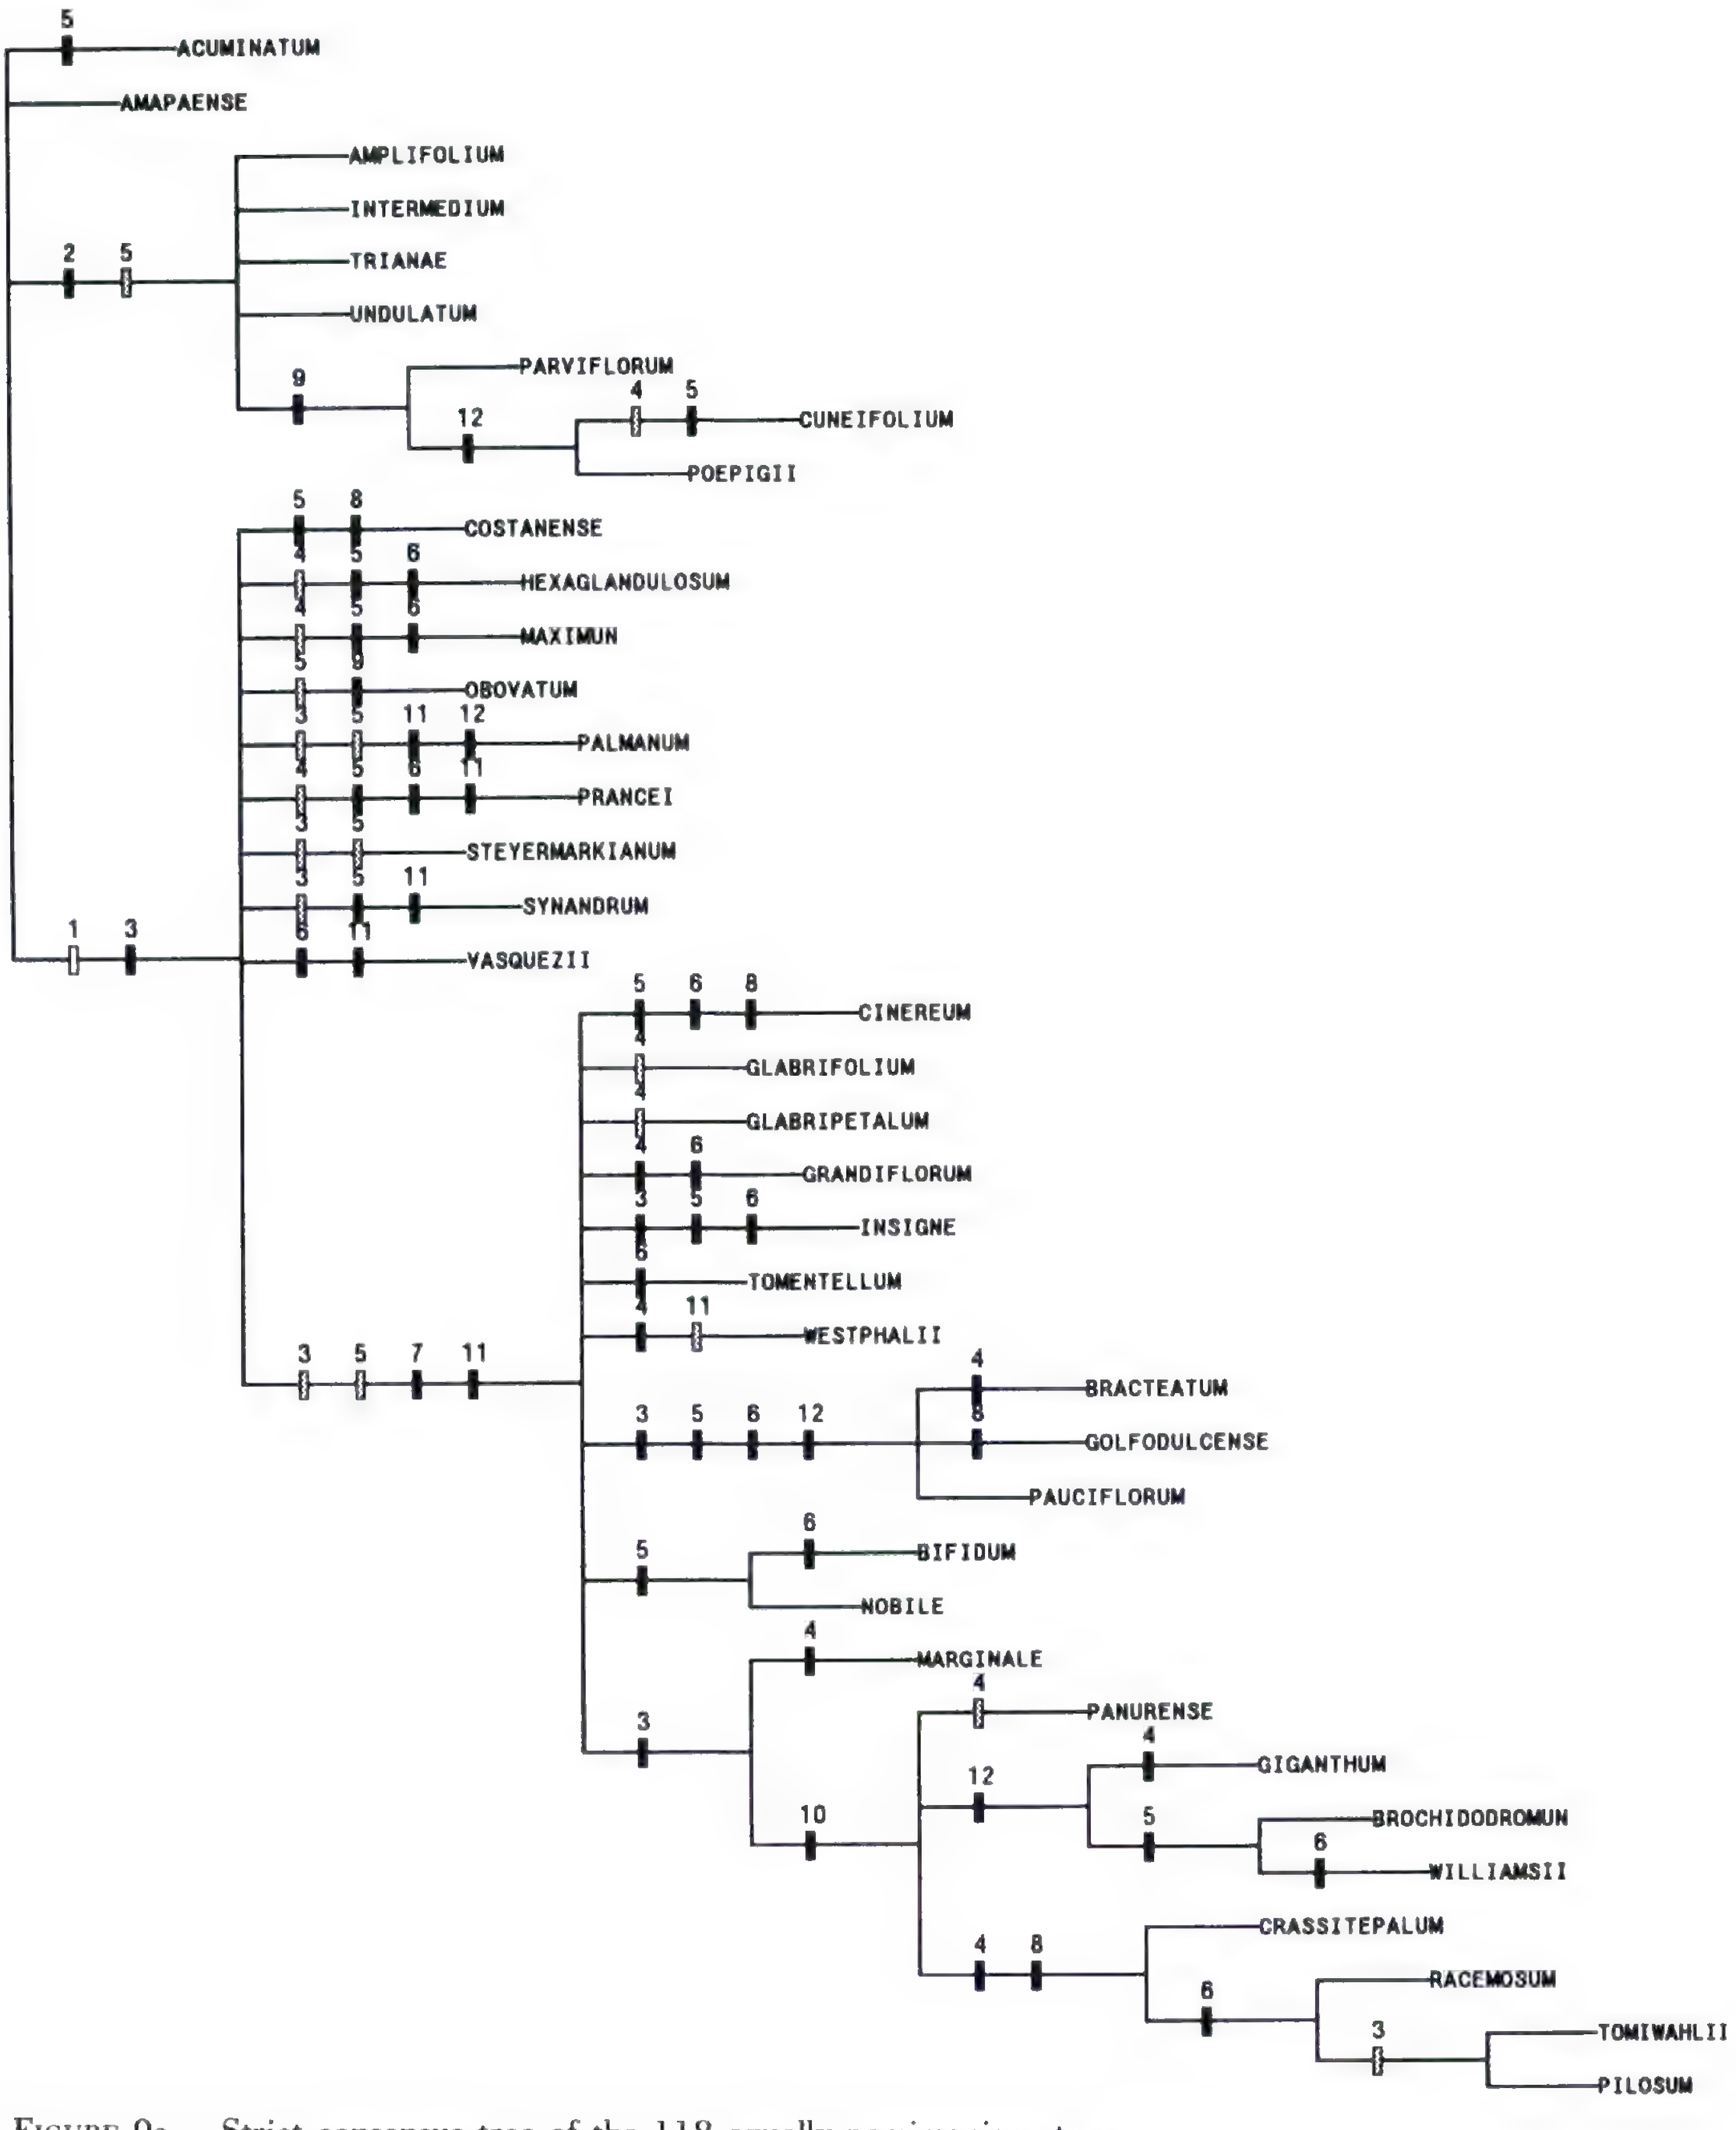

FIGURE 9a. Strict consensus tree of the 118 equally parsimonious trees.

they were regarded as good indicators of phylogenetic relationships, but because they were all that was available. Ideally, one wishes for characters that are regarded as good indicators of phylogenetic relationships. In reality, one does not have much choice about quantity and quality of characters when 19 of the 39 terminal taxa are known from only one or two collections.

In general, a taxonomic classification of a group requires the data needed for the circumscription and identification of the taxa involved. For a phylogenetic classification one needs, in addition to the data for a taxonomic classification, also data showing the evolution within the group over time. Or, to phrase it differently, a phylogenetic classification contains more information than a taxonomic clas-

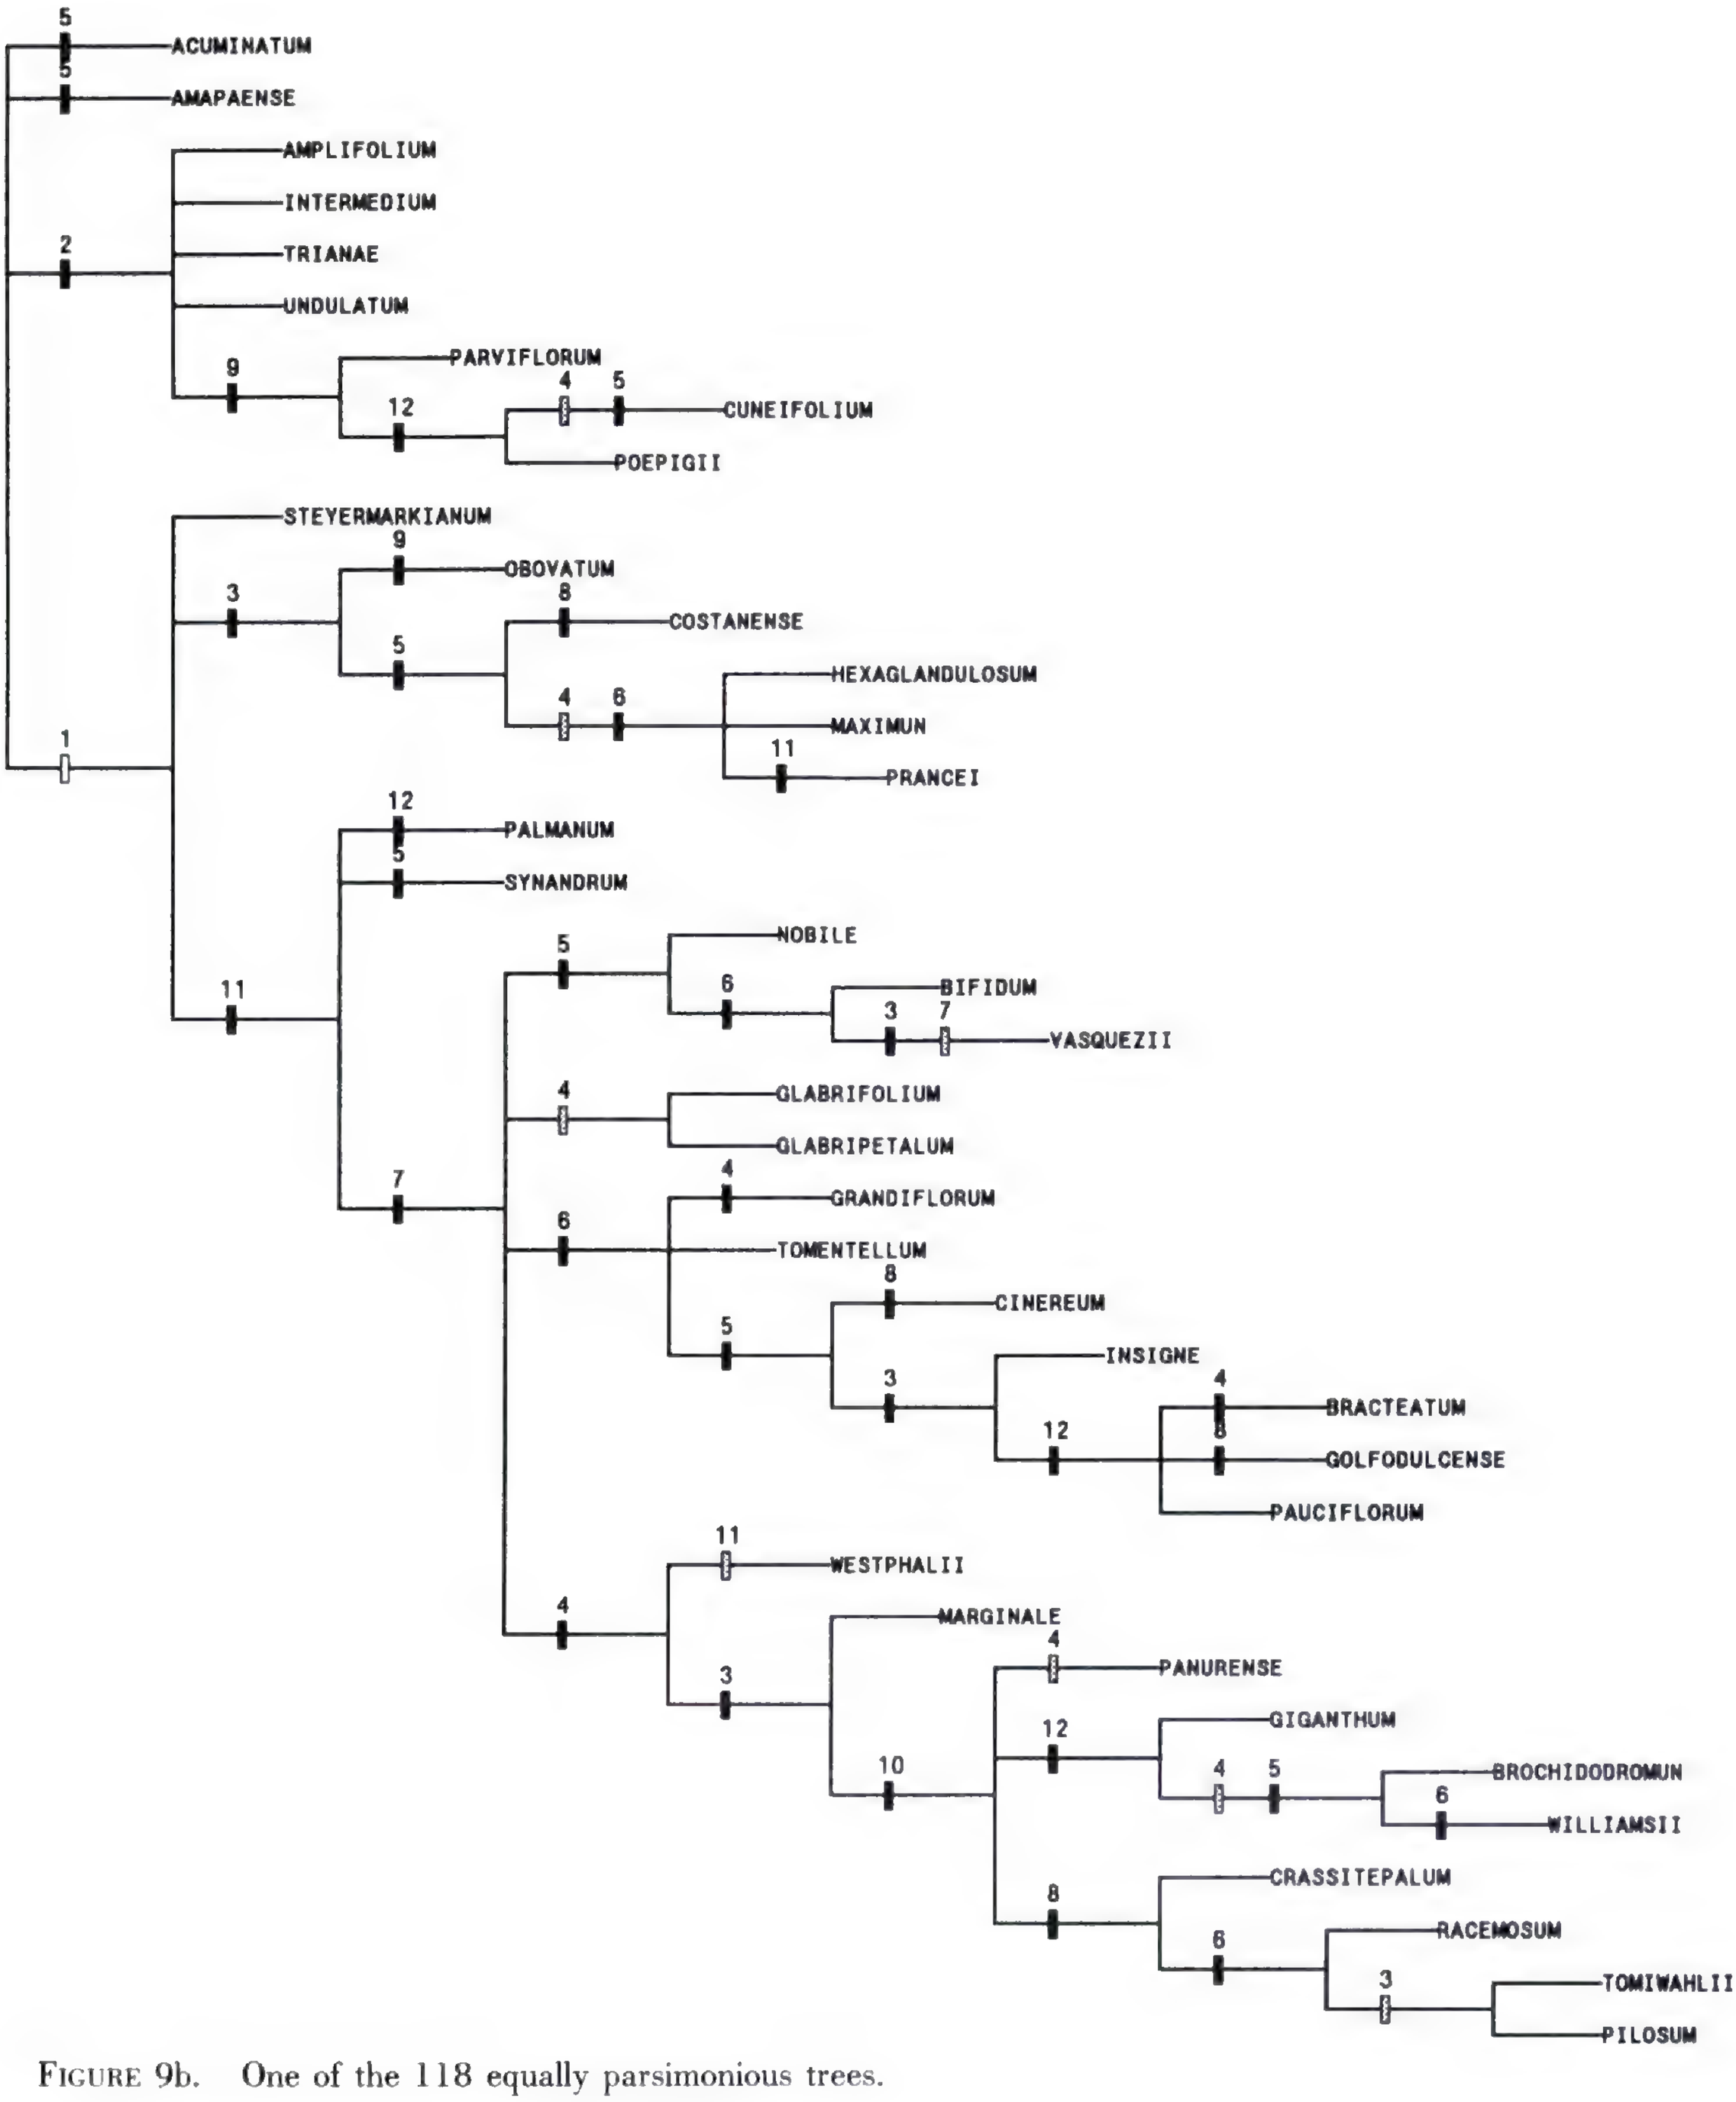

FIGURE 9b. One of the 118 equally parsimonious trees.

sification, and consequently requires a larger input of information. In the case of *Pleurothyrium*, sufficient information is available for taxonomic revision, but not enough for a phylogenetic classification. Obtaining sufficient information for a proper phylogenetic analysis is a project unto itself and making a phylogenetic analysis cannot be merely tacked on to making a taxonomic revision.

Relationships between *Pleurothyrium* species as expressed in the cladogram and as based on morphological similarities show some congruence. For instance, I consider *P. racemosum*, *P. tomiwahlii*, and *P. pilosum* as closely related, a relationship expressed in all cladograms inspected. Likewise, the species with erect tepals, usually with inrolled margin of the tepals, are closely related, as shown

in the cladograms; I would also include *P. obovatum* in this group, a species placed in the more advanced group in the cladograms. Other pairs of closely related species (at least in my opinion) placed well apart in the consensus tree are *P. insigne* and *P. maximum* and, to a lesser degree, *P. costanense* and *P. synandrum*, as well as *P. westphalii* and *P. grandiflorum*.

## Species Concept

In preparing this treatment, it was necessary to deal with the number of published species whose distinctiveness was less than convincing. In some cases ample recent collections made it clear that certain taxa (for instance, *P. reflexum* and *P. zulianense*) had to be synonymized. In other cases such collections were not available. In these instances I let myself be guided by the principle to only change the status quo if there was a strong reason for doing so. This means that some species whose distinctiveness I doubt are being maintained (examples are *P. amplifolium*, *P. undulatum*, *P. amapaense*, and *P. intermedium*) and that other taxa, represented by, in my opinion, inadequate collections, are not being described. My reasons for not describing these taxa are twofold: (a) incomplete descriptions make identification of future, complete collections very difficult; (b) the absolute certainty that specimen X (sterile or in fruit) represents an undescribed species of genus A can turn a few weeks later into nagging doubt.

## Typification

Botanists who described species of *Pleurothyrium* in the nineteenth century never designated holotypes. Usually they cited only a type collection, often indicating in which herbaria they had seen duplicates of the type collection. When only one specimen was cited, I have regarded this as the holotype, even though it was not explicitly annotated as such. If several duplicates exist of the type collection, I have listed them as syntypes. In all cases the syntypes I have seen belonged to the same species, and there cannot be any confusion about the application of the names in question. For this reason it seemed unnecessary to designate lectotypes, and I have therefore not selected lectotypes. Another reason not to select lectotypes is that I very likely have not seen all the existing syntypes, as required by the Code. For instance, I have not seen the specimens at P, and I have no doubt that syntypes of some species are present in other herbaria I did not consult. Lectotypification would be advisable if two or more collections are cited as types of a given species, but this is not the case for any *Pleurothyrium* species.

## Taxonomic Section

**Pleurothyrium** Nees, in Lindley, Nat. Syst. Bot.: 422. 1836. *Ocotea* sect. *Pleurothyrium* (Nees in Lindley) Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. *Ocotea* subg. *Pleurothyrium* (Nees in Lindley) Kostermans, Comm. Forest Res. Inst. 57: 40. 1957. TYPE: *Pleurothyrium chrysophyllum* Nees (lectotype, selected by Kostermans, 1952).

Trees. Twigs solid or in a few specimens fistulose and inhabited by ants. Leaves alternate or clustered near the tips of branches, mostly elliptic or obovate; venation camptodrome or brochidodrome. Inflorescences in axils of cataphylls, rarely in axils of normal leaves, thyrso-paniculate, rarely by reduction racemose, the ultimate divisions cymose. Flowers rotate at anthesis or in some species with erect tepals. Tepals 6, equal or subequal, then with the inner three a little narrower and shorter. Fertile stamens 9, all 4-celled, the outer 6 with the anthers curved inward or sharply bent inward, the cells mostly lateral, sometimes 2 cells extrorse or introrse; inner three anthers mostly curved outward, with lateral cells. Staminodia frequently present, but small and inconspicuous. Filaments of the inner three stamens each with two glands near the base, these strongly enlarged and growing outward, sometimes fused and enclosing the outer stamens and the anthers embedded in the glandular tissue. Pistil glabrous, papillose or pubescent, largely immersed in the receptacle. Cupule usually deeply cup-shaped, conspicuously warty. Fruit a one-seeded drupe.

## Key to the Species of *Pleurothyrium*

| | | |
|---|---|---|
| 1 | Twigs fistulose | 2 |
| 1. | Twigs solid | 6 |
| 2(1). | Flowers rotate, 7–14 mm diam.; tepals glabrous or papillose on inner surface | 3 |
| 2. | Tepals ± erect at anthesis, flowers ca. 5 mm diam., tepals papillose on inner surface | 4 |
| 3(2). | Terminal buds, inflorescences, and flowers ferruginous-tomentellous; leaves glabrous below | *P. obovatum* |
| 3. | Indument, when present, brown; leaves mostly papillose or tomentellous below, rarely glabrous | *P. cuneifolium* |
| 4(2). | Twigs, inflorescences, and flowers glabrous or minutely puberulent | *P. parviflorum* |
| 4. | Twigs, inflorescences, or flowers papillose or tomentellous | 5 |

5(4). Lateral veins 14–18 on each side; leaves firmly chartaceous to subcoriaceous; always with fistulose twigs ..... *P. poeppigii*
5. Lateral veins 8–12; leaves chartaceous; rarely with fistulose twigs ..... *P. trianae*
6(1). Tepals at anthesis erect and sometimes twisted, the margins usually reflexed; staminal glands free, never coalesced; diameter of flowers 5 mm or less; marginal vein lacking, lower leaf surface never with erect hairs ..... 7
6. Tepals at anthesis rotate, plane, the margins not reflexed; staminal glands free or coalesced; diameter of flowers equal to or greater than 8 mm (in *P. glabrifolium*, *P. vasquezii*, and *P. tomentellum* flowers 5–8 mm diam.); marginal vein present or absent, in some species lower leaf surface with erect hairs ..... 12
7(6). Leaves ± clustered at tips of branches; pubescence on inflorescences and young twigs ferruginous-tomentellous ... *P. amapaense*
7. Leaves alternate, not clustered; pubescence on inflorescence and young twigs gray or (light) brown, never ferruginous ..... 8
8(7). Margin of tepals not reflexed; tepals ± twisted at anthesis; leaf apices acuminate ..... *P. acuminatum*
8. Margin of tepals reflexed; tepals not twisted; leaf apices acute ..... 9
9(8). Twigs and inflorescence axes sparsely pubescent; flowers and terminal bud much more densely pubescent ..... *P. intermedium*
9. Degree of pubescence on flowers and terminal bud similar as on inflorescence axes and twigs ..... 10
10(9). Flowers subsessile, the pedicels shorter than the flowers ..... *P. undulatum*
10. Flowers with pedicels as long as or longer than the flowers ..... 11
11(10). Petioles 8–14 mm long; filaments of stamens longer than anthers, clearly visible in old flowers; leaves 7–10 cm wide; known only from Rio de Janeiro ..... *P. amplifolium*
11. Petioles 10–20 mm long; filaments as long as or shorter than anthers, scarcely exceeding glands and not readily visible in old flowers; leaves usually narrower than 8 cm; northern South America ..... *P. trianae*
12(6). Lower leaf surface tomentose or tomentellous, the leaf surface completely hidden by the indument ..... 13
12. Lower leaf surface glabrous or sparsely pubescent, the leaf surface never completely hidden ..... 20
13(12). Indument of lower leaf surface whitish, very short, the individual hairs scarcely visible 14
13. Indument of lower leaf surface brown or ferruginous, very short or longer and then individual hairs visible ..... 15
14(13). Inner surface of tepals glabrous; inflorescences 5–10 cm long; leaves 15–30 cm long ..... *P. panurense*
14. Inner surface of tepals papillose; inflorescence 15–25 cm long; leaves 30–40 cm long ..... *P. bifidum*
15(13). Bracts to 1 cm long present on inflorescence during anthesis; marginal vein present; pubescence on young twigs and inflorescence reddish brown ..... *P. bracteatum*
15. Bracts generally lacking on inflorescences at anthesis (if present, small); marginal veins lacking or present; pubescence on inflorescence brown or yellow-brown ..... 16
16(15). Lateral veins 18–24; leaves generally widest below the middle ..... *P. synandrum*
16. Lateral veins to 15–16; leaves widest at or above the middle ..... 17
17(16). Tepals subequal, the inner three shorter and narrower than the outer three, both inner and outer surface pubescent; marginal vein present ..... *P. crassitepalum*
17. Tepals equal, the inner surface papillose or puberulous; marginal vein weakly developed or lacking ..... 18
18(17). Flowers 10–12 mm diam. ..... 19
18. Flowers to 8 mm diam. ..... *P. tomentellum*
19(18). Style gray-pubescent; receptacle pubescent inside; indument of lower leaf surface ± appressed, the hairs very short ..... *P. cinereum*
19. Style papillose; receptacle glabrous inside; indument of lower leaf surface tomentellous, the hairs ± erect, curled ... *P. palmanum*
20(12). Lower leaf surface with erect hairs, this indument sometimes sparse ..... 21
20. Lower leaf surface glabrous or with appressed hairs ..... 30
21(20). Leaves obovate or oblong-obovate, 20–60 cm long, the marginal vein strongly developed from near the base to the apex ..... *P. insigne*
21. Leaves obovate or elliptic (in *P. racemosum* oblong, but less than 15 cm long), a marginal vein lacking or only present in the distal half of the leaf ..... 22
22(21). Leaves 30–60 × 15–24 cm, obovate, clustered, marginal vein lacking or weakly developed; flowers large, ca. 2 cm diam. ..... *P. giganthum*
22. Leaves smaller and narrower, alternate or clustered, marginal vein sometimes present; flowers less than 15 mm diam. ..... 23
23(22). Tepals reflexed at anthesis; androecium situated on top of a short, pubescent column; pubescence on lower leaf surface sparse; leaves obovate, clustered ..... *P. tomiwahlii*
23. Tepals spreading at anthesis; androecium never raised on a short column; pubescence on lower leaf surface visible; leaves elliptic, oblong, or obovate, alternate or clustered 24
24(23). Leaf base and apex obtuse or rounded ..... 25
24. Leaf base and apex not both obtuse or rounded, usually at least apex acute or acuminate ..... 26
25(24). Leaves 15–25 cm long, densely pilose below ..... *P. pilosum*
25. Leaves 6–14 cm long, glabrescent with age, indument persisting longest near the base along margin and veins ..... *P. racemoseum*
26(24). Inflorescences few-flowered (± 7 flowers per inflorescence), 2–5 cm long ..... 27

26. Inflorescences with (many) more than 7 flowers, (8–)10–25 cm long ..... 28
27(26). Flowers ca. 8 mm diam., tepals half-erect; leaves 16–35 cm long; ovary and receptacle pubescent ..... *P. pauciflorum*
27. Flowers ca. 13 mm diam.; tepals spreading; leaves 10–18 cm long; ovary and receptacle glabrous ..... *P. glabritepalum*
28(26). Pistil pubescent; pubescent style easily visible above the androecium ..... *P. costanense*
28. Pistil papillose; style not pubescent ..... 29
29(28). Flowers 5–6 mm diam.; leaves alternate ..... *P. vasquezii*
29. Flowers 9–10 mm diam.; leaves ± clustered ..... *P. brochidodromum*
30(20). Inner surface of tepals glabrous (in *P. prancei* only larger, outer three tepals; inner, smaller ones are papillose) or with a few small lines of papillate hairs ..... 31
30. Inner surface of tepals uniformly pubescent or papillose-pubescent ..... 34
31(30). Leaves 30–50 cm long, the base abruptly rounded or cordate; inflorescences 40–65 cm long ..... *P. maximum*
31. Leaves 10–30 cm long, the base acute or obtuse; inflorescences to 20 cm long ..... 32
32(31). Leaves clustered at tips of branches; lower leaf surface with minute, appressed, whitish indument, thus lower and upper leaf surface markedly discolorous; inundated forests ..... *P. panurense*
32. Leaves not clustered; upper and lower leaf surface not or scarcely discolorous ..... 33
33(32). Inner tepals papillose inside, shorter and narrower than the outer ones, these glabrous inside; inflorescence tomentose ..... *P. prancei*
33. All tepals equal in shape and glabrous inside; inflorescence tomentellous ..... *P. glabrifolium*
34(30). Leaves clustered at tips of branches ..... 35
34. Leaves not clustered ..... 37
35(34). Leaves at base abruptly cordate, the tip acuminate; petioles to 8 mm long; inner surface of tepals papillose ..... *P. williamsii*
35. Leaves at base attenuate to cuneate, tip obtuse; petioles to 17 mm long; inner surface of tepals tomentellous ..... 36
36(35). Tepals spreading at anthesis, subequal; androecium not at top of a short, pubescent column; leaf base cuneate; lower leaf surface covered with very short, ± hairlike papillae ..... *P. crassitepalum*
36. Tepals reflexed at anthesis, equal; androecium situated on top of a short, pubescent column; leaf base obtuse or (on shade-leaves) acute; lower leaf surface glabrous or with few scattered, erect hairs, never with a cover of papillae ..... *P. tomiwahlii*
37(34). Inner surface of tepals pubescent; pistil glabrous ..... 38
37. Inner surface of tepals papillose; pistil papillose or pubescent (in *P. steyermarkianum* pistil glabrous) ..... 40
38(37). Marginal vein prominent on lower leaf surface ..... *P. marginale*
38. Marginal vein lacking on lower leaf surface 39
39(38). Lateral veins 15–20 on each side; flowers 15–17 mm diam., inner tepals narrower than outer ones ..... *P. grandiflorum*
39. Lateral veins 5–8 on each side; flowers 8 mm diam., tepals equal ..... *P. westphalii*
40(37). Leaf base abruptly rounded or abruptly cordate; petioles thick, to 8 mm long ..... 41
40. Leaf bases acute, obtuse or rounded, but never abruptly rounded; petioles 6–30 mm long (*P. nobile*, with rounded leaf bases, has petioles 20–30 mm long) ..... 42
41(40). Pedicels ca. 3 mm long; leaves narrowly obovate or oblanceolate; Amazonian Peru and Ecuador ..... *P. williamsii*
41. Pedicels 1.5–2 cm long; leaves obovate; Panama and Costa Rica . *P. hexaglandulosum*
42(40). Bracts of inflorescences present at anthesis; leaf tips sharply acute to acuminate; upper leaf surface dull ..... *P. golfodulcense*
42. Bracts of inflorescences lacking at anthesis; leaf tips obtuse to acute; upper leaf surface somewhat shiny ..... 43
43(42). Style densely gray-pubescent; receptacle pubescent inside ..... *P. cinereum*
43. Style glabrous or brown-papillose; receptacle glabrous inside ..... 44
44(43). Lateral veins 7–10 on each side; glands forming a flat, pillowlike mass ..... *P. nobile*
44. Lateral veins 11–16 on each side; glands forming ridges surrounding stamens ..... *P. steyermarkianum*

**Pleurothyrium acuminatum** van der Werff, sp. nov. TYPE: Peru. Loreto: Prov. Requena, Arboretum Jenaro Herrera, *van der Werff, Vasquez & Jaramillo 9967* (holotype, MO; isotypes, AAU, AMAZ, BR, C, F, G, HBG, K, MEXU, NY, QRS, S, U, US, USM). Figures 10, 11.

Arbor. Ramuli teretes, solidi, dense, minute adpresse pubescentes. Gemma terminalis dense, adpresse pubescens. Folia alterna, tenuiter chartacea, 10–20 × 3–6 cm, elliptica, basi sensim in petiolum attenuata, apice acuminata, acumine 1–1.5 cm longo, supra glabra, punctata, subtus glabra vel pilis minutis adpressis praedita praecipue secus costam nervosque et ad basim; nervis lateralibus 6–10 utroque costae latere, sursum arcuatis et in dimidio distali parum brochidodromis; venatione supra immersa, subtus costa elevata, nervis et venatione paullo elevata. Petioli 1  2 cm longi, supra applanati, basi paullo incrassati. Inflorescentiae ex axillis cataphyllorum ortae, 8–12 cm longae, graciles, ramulis semel vel bis de modo cymae furcatis, tomentellae, bracteis deciduis. Pedicelli (4–)5(–8) mm longi, tomentelli. Flores albi. Tepala 6, aequalia, per anthesin plerumque erecta, oblonga, 3 × 1 mm, saepe torta, sed marginibus non reflexis, tres exteriora extus minute puberula vel papillosa, tres interiora extus basi papillosa, demum glabra, omnia intus parum papillosa vel glabra. Receptaculum ad apicem constrictum. Stamina 9, 4-locellata, locellis lateralibus et sursum aperientibus. Filamentis antheris aequantibus; glandulis incrassatis, liberis. Pistillum ca. 1.5 mm longum, ovario ellipsoideo, 1 mm longo, dimidio basale glabro, dimidio distale parum pubescente, stylo pubescente. Fructus ignoti.

FIGURE 10. *P. acuminatum.*—A. Habit.—B. Flower showing abscission line of tepals.—C. Floral detail.—D. Young fruit.—E. Stamens—Whorl I on right, Whorl II in center, Whorl III on left.—F. Branching pattern of inflorescence.

Tree, 15 m. Twigs terete, solid, densely, but minutely appressed gray pubescent, 3 mm diam. ca. 5 cm below the tip. Terminal bud somewhat shiny, densely appressed-pubescent. Leaves alternate, thinly chartaceous, 10–20 × 3–6 cm, elliptic, the base gradually narrowed in the petiole, the tip acuminate, the acumen 1–1.5 cm long, the upper surface glabrous and gland-dotted, this best visible on young leaves, the lower surface glabrous or with some minute appressed hairs, especially along the veins and near the base; lateral veins 6–10 on each side, arching upward near the margin and weakly loop-connected in the upper half of the lamina; venation immersed on upper surface, midrib raised on lower surface, the lateral veins and tertiary venation less so. Petioles 1–2 cm long, adaxially flattened, somewhat swollen near the base, with a similar indument as the twigs. Inflorescences

FIGURE 11. Distribution of *P. acuminatum* (★), *P. amapaense* (●), *P. amplifolium* (○), and *P. bifidum* (■).

in axils of cataphylls, 8–12 cm long, slender, laxly branched, the branchlets once or twice cymosely branched, minutely tomentose, bracts deciduous at anthesis. Pedicels (4–)5(–8) mm long, minutely tomentellous. Flowers white. Tepals 6, equal, mostly erect at anthesis, oblong, 3 × 1 mm, often wrinkled, twisted, but the margins not consistently inrolled, the outer 3 minutely puberulous to papillose outside, the inner 3 with a papillose, triangular base, otherwise glabrous, the inside slightly papillose to glabrous. Tepals united at the very base and falling from old flowers as a unit. Receptacle constricted at the tip, the constriction line turning into a dehiscence line in older flowers. Stamens 9, 4-celled, the cells lateral and opening upward, filaments about as long as anthers, glabrous; glands enlarged, protruding between the outer stamens, free. Pistil ca. 1.5 mm long, ovary 1 mm long, the lower half glabrous, the upper half slightly pubescent, style pubescent. Receptacle glabrous inside. Fruit unknown. Flowers: August–September. Elevation range: 100–200 m.

*Collections studied.* BRAZIL. AMAZONAS: São Paulo de Olivenca, *Ducke RB25676* (RB). PERU. LORETO: Requena, Arboretum of Jenaro Herrera, *?* (MO), *? s.n.* (MO), *Castillo 50* (F, MO), *van der Werff 9967* (AAU, AMAZ, BR, C, F, G, HBG, K, MEXU, MO, NY, QRS, S, U, US, USM).

*Pleurothyrium acuminatum* is only known from a few collections from the Arboretum Jenaro Herrera in Amazonian Peru and one collection from Amazonian Brazil. It is included and illustrated in Spichiger et al. (1989) as *Ocotea undulata* (Meissner) Mez, a species that I place in *Pleurothyrium* and which is closely related to *P. acuminatum*. The erect tepals at anthesis, the relatively small (for *Pleurothyrium*) glands, the shape of the pistil and tepals, and the weakly loop-connected lateral veins all point to the group of species with reflexed margins of tepals as the closest relatives of *P. acuminatum*, even though the margins of the tepals are plane in this species. The other main group of *Pleurothyrium*, characterized among others by rotate flowers, has much broader tepals and usually

larger, fused glands. Within the group of *Pleurothyrium* species with erect tepals, *P. acuminatum* stands apart by its rather long tepals with a plane margin, long, slender pedicels, and the very short, almost papillose indument of the flowers. The acuminate leaves are also a useful character.

**Pleurothyrium amapaense** Allen, Mem. New York Bot. Gard. 15: 92. 1966. TYPE: Brazil. Amapá: Rio Araguari, *Pires et al. 51430* (holotype, NY not seen; isotypes, K, S, US). Figure 11.

Tree, 15 m tall. Twigs terete, solid, the young parts ferruginous-tomentellous, older parts glabrous and with pale bark. Terminal bud ferruginous-tomentellous. Leaves clustered at the tips of branches, chartaceous, elliptic-obovate to elliptic, 10–20 × 4–6 cm, the base cuneate, the tip shortly acuminate, glabrous, lateral veins 8–10 on each side, curving upward near the margin and loop-connected in the upper half of the lamina; venation immersed on upper surface, costa and lateral veins raised on lower surface. Petioles ca. 1 cm long, narrowly canaliculate, with similar indument as twigs. Inflorescences in axils of deciduous bracts, ferruginous-tomentellous, to 12 cm long, paniculate, the branches once or twice cymosely branched, bracts lacking at anthesis. Pedicels slender, 4–5 mm long, ferruginous-tomentellous. Flowers greenish brown fide collectors, ca. 5 mm diam. Tepals 6, equal, minutely tomentellous outside, papillose inside, ovate, 2–2.5 mm long, often twisted, spreading or reflexed in old flowers, finally breaking off along a dehiscence line at the base, the margin plane. Stamens 9, 4-celled, the cells lateral, opening upward, anthers glabrous, filaments about as long as anthers; glands enlarged, free, falling off in old flowers. Pistil ca. 2 mm long, ovary ellipsoid, glabrous near base, becoming progressively more papillose toward the tip, style densely papillose, 0.5 mm long, stigma small. Floral tube deeper than wide, glabrous inside. Fruits unknown. Flowers: October. Elevation range: ca. 100 m.

*Collections studied.* BRAZIL. AMAPA: Rio Araguari, *Pires 51430* (K, NY, S, US). VENEZUELA. AMAZONAS: Río Negro, upper Río Baria, *Davidse 27524* (MO, VEN).

*Pleurothyrium amapaense* is the only *Pleurothyrium* species reported east of Manaus, Brazil. It is only known from the type collections, but as Allen (1966a) already stated, there can be no doubt about its generic position. *Pleurothyrium amapaense* has, for the genus, rather small flowers; it differs from the other small-flowered species in having tepals with plane, not reflexed, margins, in having clustered leaves, and in its ferruginous indument.

Provisionally included here is *Davidse 27524* (MO), collected from Depto. Río Negro, Territorio Federal Amazonas, Venezuela. This collection differs in its thinner leaves, shorter pubescence, more elliptic leaves with a less well-developed marginal vein, and its habit (label states it is a liana). The floral characteristics agree reasonably well with those of *Pleurothyrium amapaense*, but it is possible that, once more collections are at hand, it is better recognized as a distinct species.

**Pleurothyrium amplifolium** (Mez) Rohwer, Mitt. Inst. Allg. Bot. Hamburg 20: 43. 1986. *Nectandra amplifolia* Mez, Arbeiten Königl. Bot. Gart. Breslau 1: 131. 1892. TYPE: Brazil. Rio de Janeiro: Alto Macahé, *Glaziou 17731* (holotype, B; isotypes, B, G, K, NY, P). Figure 11.

Tree, size unknown. Twigs terete, solid, brown-tomentellous, glabrescent, ca. 4 mm diam. 5 cm below apex. Terminal bud brown-tomentellous. Leaves alternate, chartaceous, elliptic to broadly elliptic, 15–20 × 7–10 cm, the base obtuse or slightly acute, the apex rounded or shortly acute, upper surface glabrous and with venation immersed, the lower surface minutely puberulous when young, soon glabrescent, costa and lateral veins raised, tertiary venation immersed; lateral veins 8–11, arching upward near the margin, not loop-connected. Petioles 8–14 mm long, the upper side flat, with similar pubescence as twigs. Inflorescences in axils of cataphylls, brown-tomentellous, 8–12 cm long, paniculate, the branchlets 1–2 times cymosely branched, flowers more than 30, bracts absent at anthesis. Flowers ca. 4 mm diam. Tepals 6, equal, ± erect at anthesis, the margin reflexed, brown-tomentellous outside, but inner three tepals with papillose margin and tip, all tepals papillose inside. Stamens 9, 4-celled, glabrous, the outer six with one pair of cells lateral and one pair introrse, the inner three with one pair extrose and one pair lateral; filaments clearly visible between glands, ca. 0.5 mm long, longer than anthers; glands enlarged, visible as triangular lobes between the outer stamens, but very low in front of the stamens and not fused. Pistil ellipsoid, ca. 1.5 mm long, ovary glabrous, style papillose. Receptacle glabrous except for a few hairs at the very base. Fruit and cupule unknown. Flowers: October. Elevation range unknown.

*Collection studied.* BRAZIL. RIO DE JANEIRO: Alto Macahe, *Glaziou 17731* (B, G, K, NY, P).

*Pleurothyrium amplifolium* is only known from the type and is also, if the label data are correct, the only *Pleurothyrium* species from southern Brazil. It belongs in the group of species with reflexed margins of tepals, small flowers, often with erect tepals and a poorly developed (or without a) marginal vein. It stands apart from the other species in this group by its distribution, broad leaves, and indumentum.

Three isotypes were annotated as *Persea cordata* Mez var. *glabra* Mez, but the holotype does not bear this annotation. *Persea cordata* var. *glabra* is a numen nudum included in Glaziou's list of determinations, while *Persea cordata* (Vell.) Mez, the correct citation, is a later homonym of *Persea cordata* Meissner.

**Pleurothyrium bifidum** Nees, Syst. Laur.: 351. 1836. TYPE: Peru. Loreto: Yurimaguas, *Poeppig 2398* (GZU, LE, W destroyed?, holotype not designated). Figure 11.

Tree, to 10 m. Twigs terete, glabrous or nearly so, solid. Terminal bud brown-tomentulose. Leaves alternate, said to be clustered near tips of branches, subcoriaceous, elliptic to obovate-elliptic, 30–40 × 8–13 cm, the base obtuse or acute, the tip acuminate, acumen to 3 cm long, the upper surface glabrous, lower surface covered with a dense, minute, gray-whitish tomentellous indument; venation immersed on upper surface, midrib and lateral veins raised on lower surface, tertiary venation not visible; lateral veins 12–16 on each side, weakly loop-connected in the distal half of leaf. Petioles 3–5 cm long, glabrous. Inflorescences in axils of cataphylls, ferruginous-tomentellous, 15–25 cm long, paniculate, the upper branchlets once or twice cymosely branched, the lower ones racemosely branched, but ultimate divisions cymose; bracts subpersistent at anthesis; brown-tomentellous outside, glabrous inside. Flowers white or creamy-white, 10–12 mm diam. Tepals 6, the inner three with a slightly narrower base than the outer ones, broadly elliptic, 4–5 mm long, the outer three ferruginous-tomentellous outside, the inner three with a tomentellous, triangular basal patch, otherwise papillose; inside papillose. Stamens 9, 4-celled, the cells lateral or one pair lateral-extrorse, the valves back-to-back, glands large, completely surrounding stamens, but not fully fused. Ovary ellipsoid, ca. 1 mm long, densely papillose, with 6 glabrous patches near the tip, style short, ca. 0.5 mm long, glabrous, stigma platelike. Floral tube papillose inside. Cupule a rather shallow cup, ca. 2 cm wide and 1 cm high, verrucose, the pedicel swollen; fruit ellipsoid, 2.5 × 1.5 cm. Fruits: September. Flowers: June–September. Elevation range: 200–500 m.

*Collections studied.* PERU. AMAZONAS: Río Cenepa, Quebrada Chigka Entsa, *Ancuash 602* (G, MO); Bagua, Cascadas de Mayasi, along Quebrada Tambillo, *Wurdack 2047* (F, GH, K, NY, S, US). LORETO: Yurimaguas, *Poeppig 2398* (GZU, LE).

*Pleurothyrium bifidum* is an uncommon species, only known from three collections in Amazonian Peru. The type specimens (GZU, LE) are in bud, thus I have not been able to study flowers of the type. A type photograph (A) of the type in W shows that this specimen, probably destroyed in World War II, was also largely in bud. My floral description is based on the two recent collections and agrees with earlier floral descriptions based on the type collection. Nees stated in the original description that the leaves were clustered, but the type specimens at hand have a very short piece of the twig, which does not show if the leaves were clustered or not; the W type had clustered leaves, as can be seen on the type photo. The recent collections have the leaves more or less clustered. However, the recent material differs from the types in having thicker twigs and narrower leaves; in other characters it agrees with the type.

*Pleurothyrium bifidum* is closely related to *P. panurense* (Meissner) Mez, as is shown by the, for *Pleurothyrium*, very unusual, whitish indument on the lower leaf surface. *Pleurothyrium bifidum* has larger leaves and longer inflorescences and petioles than *P. panurense*; it also has a papillose ovary and floral tube (glabrous in *P. panurense*), and the flowers are slightly larger and have the inner surface of the tepals brown-papillose (glabrous in *P. panurense*). The size differences do not allow easy identification. For instance, *Krukoff 4800* is identified as *P. panurense* based on floral characters; its leaves can be interpreted equally well as large *P. panurense* or small *P. bifidum*.

Kostermans (1952) made combinations for a number of *Pleurothyrium* species in *Ocotea*; he accepted for *Pleurothyrium bifidum* the name *Ocotea bifidum* Poeppig ex Nees. However, *Ocotea bifidum* is a herbarium name cited by Nees as a synonym in the description of *P. bifidum* and is, therefore, not validly published.

**Pleurothyrium bracteatum** van der Werff, sp. nov. TYPE: Colombia. Boyaca: El Humbo, ca. 130 mi. N of Bogotá, elev. 3,000 ft., *Lawrance 619* (holotype, MO; isotypes, E, F, UC, US). Figures 12, 13.

FIGURE 12. *P. bracteatum.*—A. Habit.—B. Detail of inflorescence showing bracts and flower.—C. Cross section through flower, showing pistil and stamens embedded in glands.—D. Pistil.—E, F. Stamens.—G. Detail of upper leaf surface.—H. Detail of lower leaf surface.

Arbor, 20–25 m alta. Ramuli solidi, teretes vel paullo angulati, rufo-tomentosi. Gemma terminalis ad 7 mm crassa, rufo-tomentosa. Folia alterna, subcoriacea, 15–30 × 8–12 cm, oblonga vel oblongo-elliptica, basi rotundata, apice paullo acuta, supra glabra, subtus rufo-tomentosa, nervis lateralibus 14–20 utroque costae latere, prope marginem sursum curvantibus, vena marginale in dimidio distale praesente, venatione supra immersa, subtus costa nervisque lateralibus elevatis, venatione tertia paullo elevata. Petioli rufo-tomentosi, valde canaliculati, 10–15 mm longi. Inflorescentiae ex axillis bractearum ortae, rufo-tomentosae, 10–15 cm longae, paniculatae, ramulis vulgo duplo cymae more ramosis; bracteis sub anthesi praesentibus, rufo-tomentosis, eis ad ramulorum inferiorum basim ovatis, 12–15 mm longis, eis ad cymarum terminalium basim ca. 5 mm longis. Pedicelli florum apertorum ca. 8 mm longi. Flores cremei, saltem 13 mm diametro. Tepala 6, subaequalia, late ovata, ca. 5 mm longa, intus tomentella. Stamina 9, glabra, 4-locellata, locellis lateralibus, glandulis permagnis, coalitis, stamina cingentibus. Ovarium ellipsoideum, ca. 1.3 mm longum, basi glabrum, parte media tomentellum, parte superiore tomentellum 6 maculis nudis praeditum; stylum glabrum, ca. 1 mm longum. Tubus floralis intus tomentellus. Fructus ignotus.

Tree, 20–25 m tall. Twigs solid, terete or slightly ridged, reddish-brown-tomentose, 5–6 mm diam. 5 cm below the tip. Terminal buds to 7 mm thick, rufous-tomentose. Leaves alternate, subcoriaceous, 15–30 × 8–12 cm, oblong to oblong-elliptic, the base rounded, the tip slightly acute, glabrous above, rufous-tomentose below, venation immersed on upper surface, midrib and lateral veins raised on lower surface, the tertiary venation slightly raised; lateral veins 14–20 on each side, curving upward near the margin and united with the superior vein, forming a marginal vein in the upper half of the lamina.

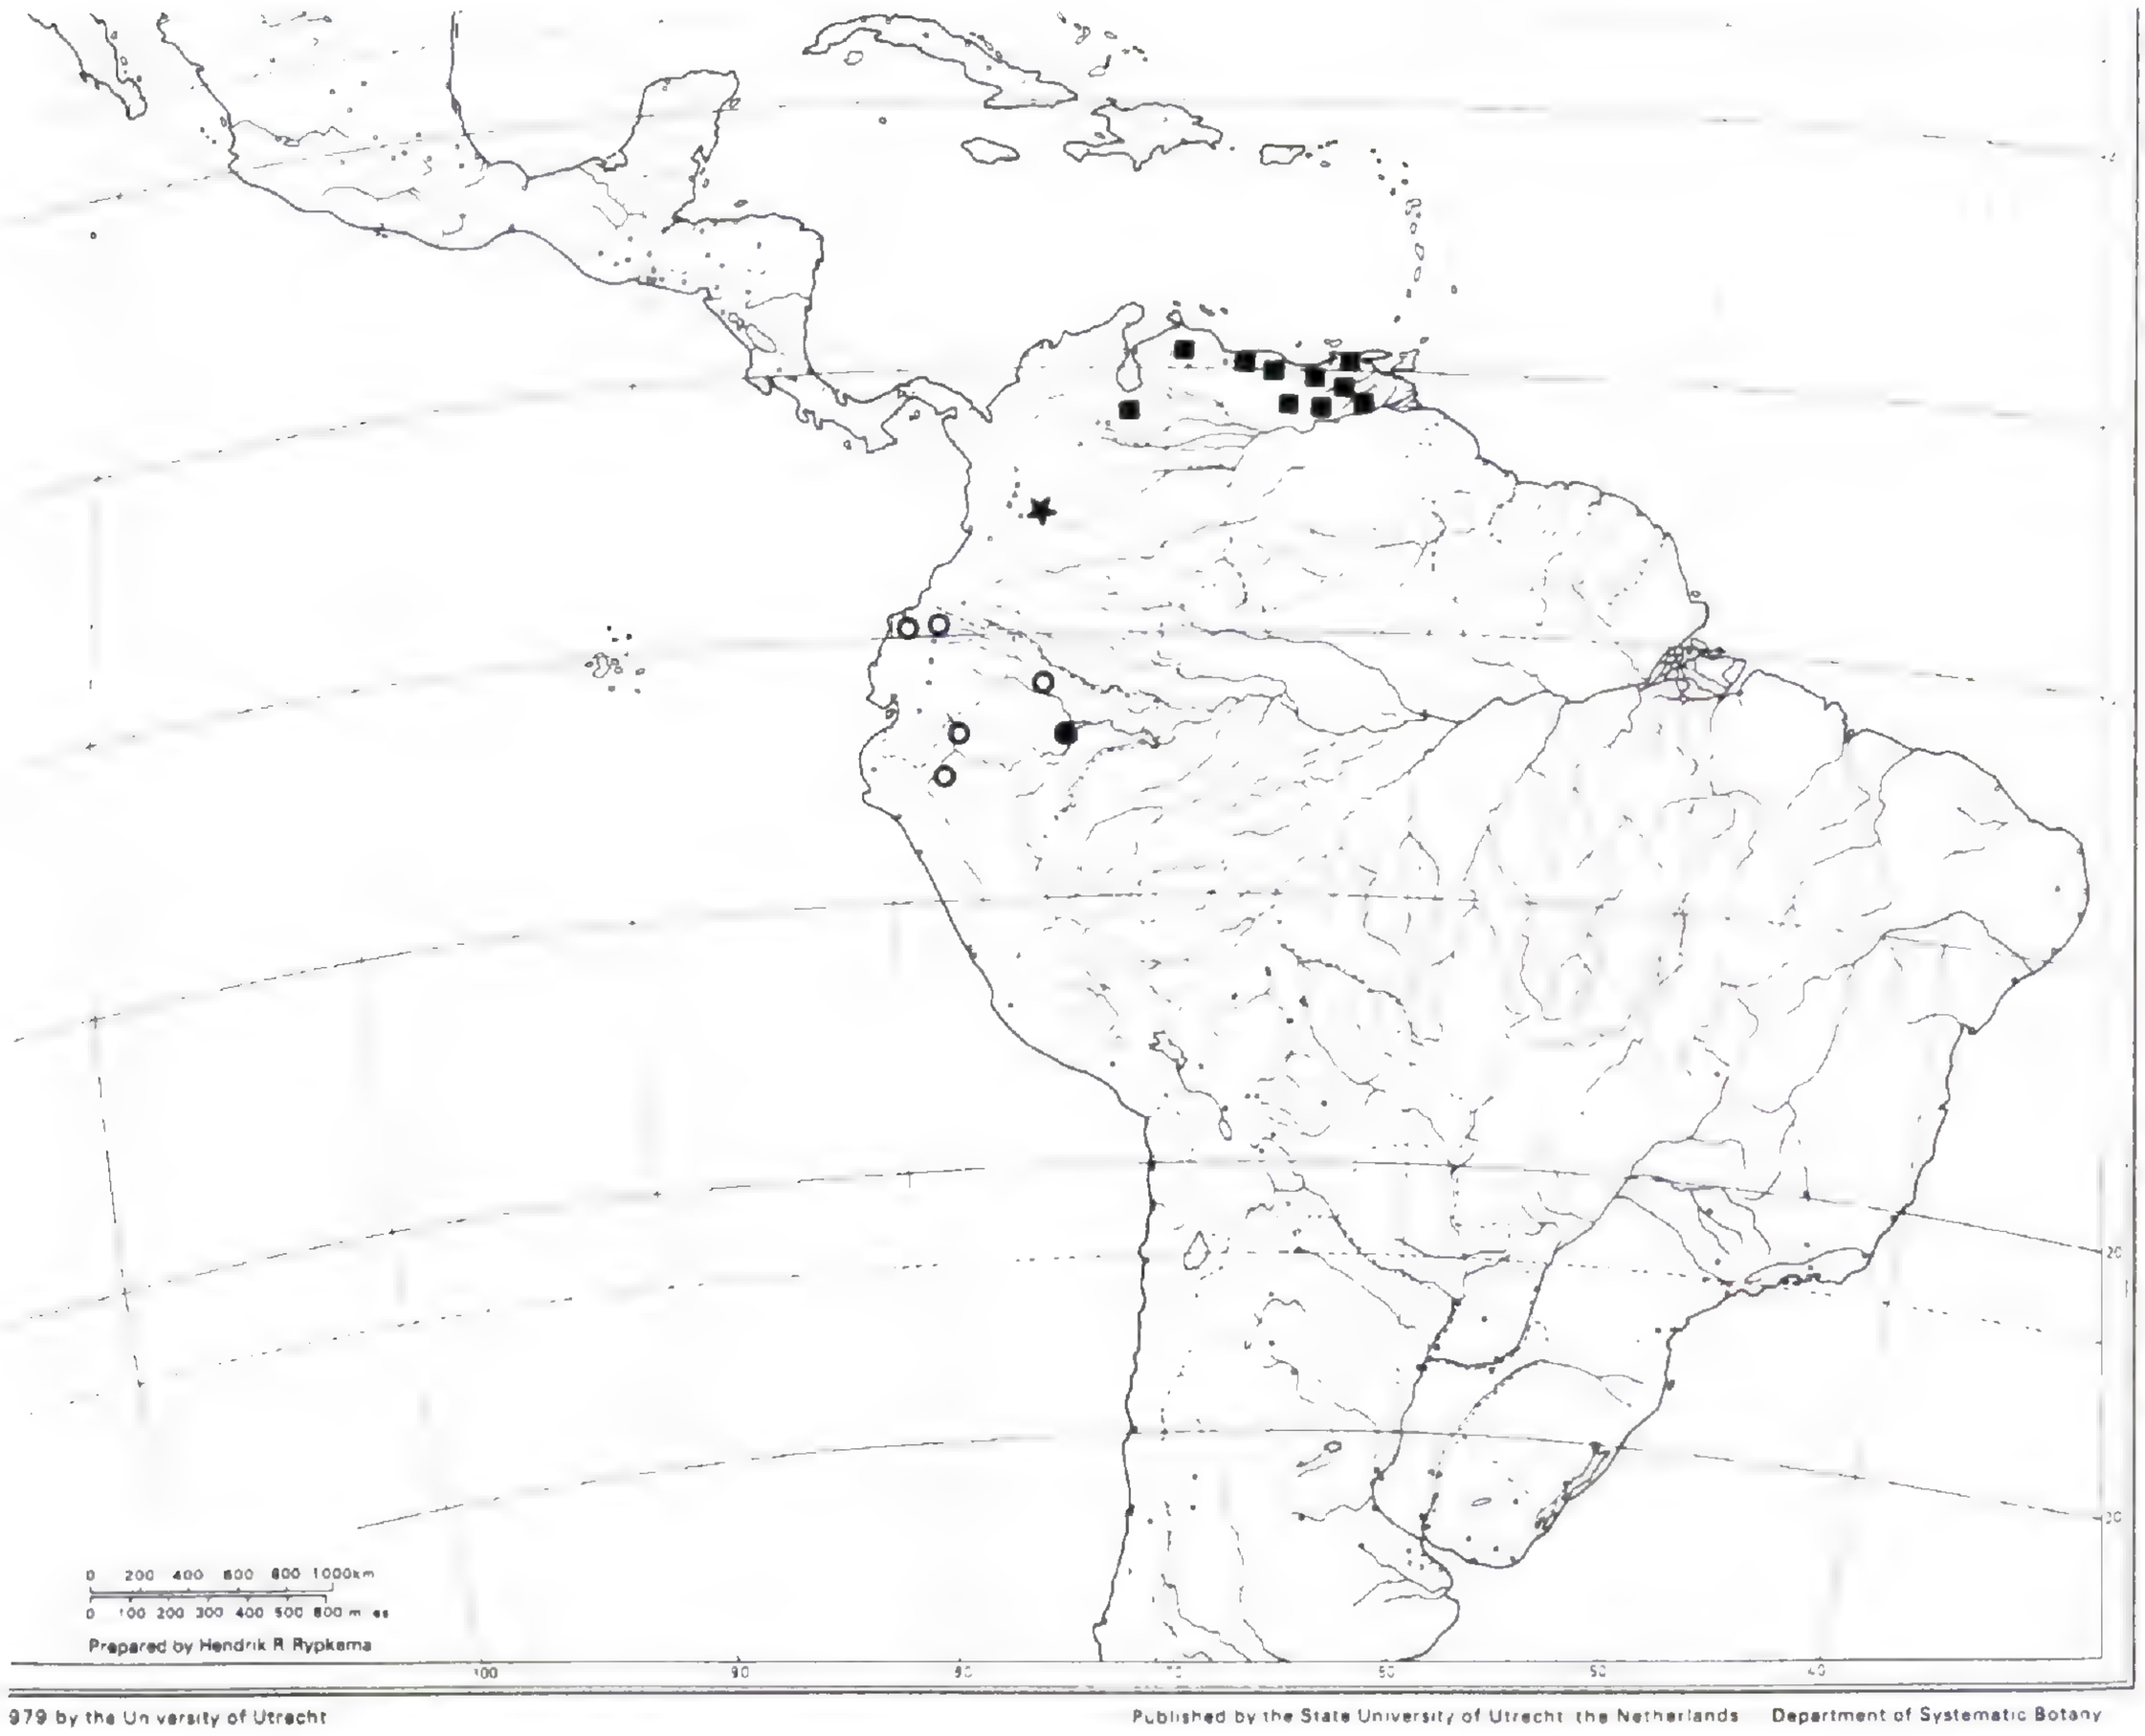

FIGURE 13. Distribution of *P. bracteatum* (★), *P. brochidodromum* (●), *P. cinereum* (○), and *P. costanense* (■).

Petioles rufous-tomentose, strongly canaliculate, 10–15 mm long. Inflorescences in axils of cataphylls, rufous-tomentose, 10–15 cm long, paniculate, the branchlets usually twice cymosely branched; bracts present at anthesis, those at the base of the lower branchlets 12–15 mm long, ovate, rufous-tomentose, gradually reduced in size toward the ultimate divisions, the bracts at the base of the ultimate cymes ca. 5 mm long. Pedicels of open flowers ca. 8 mm long, rufous-tomentose. Flowers creamy white inside, at least 13 mm diam. (none of the flowers had all tepals spreading). Tepals 6, ± equal, broadly ovate, ca. 5 mm long, the outer three tomentose on the outside, the inner three with a tomentose, basal triangular patch, otherwise tomentellous; all tepals tomentellous inside. Stamens 9, glabrous, 4-celled, the cells lateral and opening back-to-back, the glands strongly enlarged and forming a thick wall surrounding the stamens, fused. Ovary ellipsoid, ca. 1.3 mm long, the very base glabrous, the middle part brown-tomentellous, the upper part tomentellous with 6 bare spots where glands touched the ovary; style ca. 1 mm long, glabrous. Floral tube rather deep, brown-tomentellous inside. Fruit unknown. Flowers: February. Elevation range: ca. 1,000 m.

*Collection studied.* COLOMBIA. BOYACA: El Humbo, *Lawrance 619* (E, F, MO, UC, US).

*Pleurothyrium bracteatum* is only known from the type collection from the El Humbo region in Boyaca, Colombia; this area also yielded *Aiouea angulata* Kostermans, another Lauraceae only known from the type collected by Lawrance.

This new species can be readily identified by the large bracts of the inflorescence, which persist during anthesis. Other useful characters are the rufous pubescence (described by the collector as burnt sienna), the rounded leaf bases, and large flowers. It can be confused with *Pleurothyrium costanense* from similar elevation in Venezuela, but the latter species lacks bracts at anthesis, has smaller flowers, a distinctly pubescent style, and an almost glabrous ovary.

The collector noted that the stamens were in the form of a button. The wood is said to be soft and has no economic uses.

**Pleurothyrium brochidodromum** van der Werff, sp. nov. TYPE: Peru. Loreto: Maynas, km 32 of Carretera Iquitos–Nauta, *Vasquez & Jaramillo 7865* (holotype, MO; isotypes, AMAZ, F, G, HBG, NY, USM). Figures 13, 14.

Arbor, 16 m alta. Ramuli teretes, solidi, ferrugineo-tomentosi, glabrescentes. Gemma terminalis fusco-tomentosa, magna, ad 5 mm diametro. Folia ad ramulorum apices conferta, chartacea, 12–22 × 4–7 cm, elliptica vel obovato-elliptica, basi acuta, apice acuminata, supra glabra sed costa pilis parvis praedita, subtus pilis dispersis, erectis praedita (secus costam nervosque indumento densiore); supra venatione immersa, subtus costa nervisque elevata, venatione tertia paullo elevata; nervis utroque costae latere 12–15 in vena maginale terminantibus. Petioli 1.5–2 cm longi; teretes, indumento illo ramuli simile. Inflorescentiae ex axillis bractearum ortae, 8–14 cm longae, ferrugineo-tomentosae, paniculatae, ramulis 1–2-plo cymae more divisis. Flores 9–10 mm diametro. Tepala 6, aequalia, 3–4 mm longa, oblonga, intus ferrugineo-papillosa, extus ferrugineo-tomentella (tepala interiora margine et apice papillosa). Stamina 9, 4-locellata, locellis lateralibus, minute papillosa; glandulae magnae, stamina cingentes, coalitae. Ovarium parvum, ovoideum, in stylum attenuatum, stigmate antheris obtecto. Fructus ignotus.

Tree, 16 m tall. Twigs terete, solid, ferruginous-tomentose, but soon glabrescent, 3–4 mm diam. 5 cm below tip. Terminal bud large, 5 mm thick, fuscous tomentose. Leaves clustered near tips of branches, chartaceous, 12–22 × 4–7 cm, elliptic to obovate-elliptic, the base acute, the tip acuminate, the upper surface glabrous except for some short hairs on midrib, the lower surface with scattered, brown, erect hairs, these denser along main veins and midrib; venation immersed on upper surface, midrib, lateral veins, and to a lesser degree tertiary venation raised on lower surface; lateral veins 12–15 on each side, the lower 2–3 arching upward, the other ones ± straight and ending in a well-developed marginal vein. Petioles 1.5–2 cm long, terete, with similar indument as twig, ca. 2 mm diam. Inflorescences in axils of cataphylls, 8–14 cm long, ferruginous-tomentose, paniculate, the branchlets 1–2 times cymosely branched, ca. 40-flowered, bracts often persisting at anthesis, ferruginous-tomentose on both surfaces, to 4 mm long (but bracts subtending flowers smaller), elliptic. Flowers green fide collectors, 9–10 mm diam. Tepals 6, equal, 3–4 mm long, oblong, spreading to slightly reflexed at anthesis, the inner surface ferruginous papillose, the outer tepals ferruginous-tomentellous on the outside, the inner three with papillose margin and tip, otherwise tomentellous. Stamens 9, all 4-celled, finely papillose, the cells lateral; stamens ca. 1 mm long, the filaments short and nearly as wide as the anthers; glands conspicuously enlarged, completely surrounding the stamens, fused. Ovary small, ovoid, the very base glabrous, situated in the glabrous, shallow receptacle, with a band of coarse papillae near the middle, the upper part gradually narrowed into the style, finely papillose, pistil ca. 1.4 mm long; stigma in all flowers seen not exposed, but covered by the anthers. Floral tube glabrous. Fruits unknown. Flowers: August. Elevation range: ca. 150 m.

*Collection studied.* PERU. LORETO: Maynas, Carretera Iquitos–Nauta, km 32, *Vásquez 7865* (AMAZ, F, G, HBG, MO, NY, USM).

*Pleurothyrium brochidodromum*, only known from the type collection made near Iquitos, Peru, is easily identified by its sparse, erect pubescence on the lower leaf surface, clustered leaves, and floral size. Other *Pleurothyrium* species from Amazonian Peru with an erect pubescence on lower leaf surface include *P. insigne* and *P. vasquezii*. *Pleurothyrium insigne* differs in its much larger, obovate leaves, while *P. vasquezii* differs in its alternate (not clustered) leaves and smaller flowers (5–6 mm vs. 9–10 mm in *P. brochidodromum*).

A brochidodromous venation type is relatively common in *Pleurothyrium*, but is particularly clearly visible in *P. brochidodromum*. However, in such species as *P. maximum* and *P. williamsii* the brochidodromous venation is equally well developed.

Although the type collection has good young and old flowers, the stigma is hidden in all flowers seen. This is unusual in *Pleurothyrium*; normally in the species with large flowers and greatly enlarged glands the stigma is large, almost platelike, and easily visible.

**Pleurothyrium cinereum** van der Werff, sp. nov. TYPE: Ecuador. Esmeraldas: Panadero, 5 km from the river, *Játiva & Epling 2039* (holotype, MO; isotypes, NY, US). Figures 13, 15.

Arbor ad 32 m. Ramuli angulares, fusco-tomentelli, glabrescentes, solidi. Folia alterna, firme chartacea, 13–20 × 6–10 cm, elliptica, basi obtusa, apica acuta, raro obtusa, supra venatione impressa, subtus costa nervisque (10–14 utroque costae latere) elevatis, reticulatione paullo elevata, venatione in dimidio distale brochidodroma, supra glabra, subtus pilis parvis adpressis praedita. Petioli canaliculati, 1.5–2.5 cm longi. Inflorescentiae e axillis cataphyllorum ortae, fusco-tomentellae, 10–15 cm longi, ramulis semel vel bis cymae more divisis. Pedicelli ca. 5

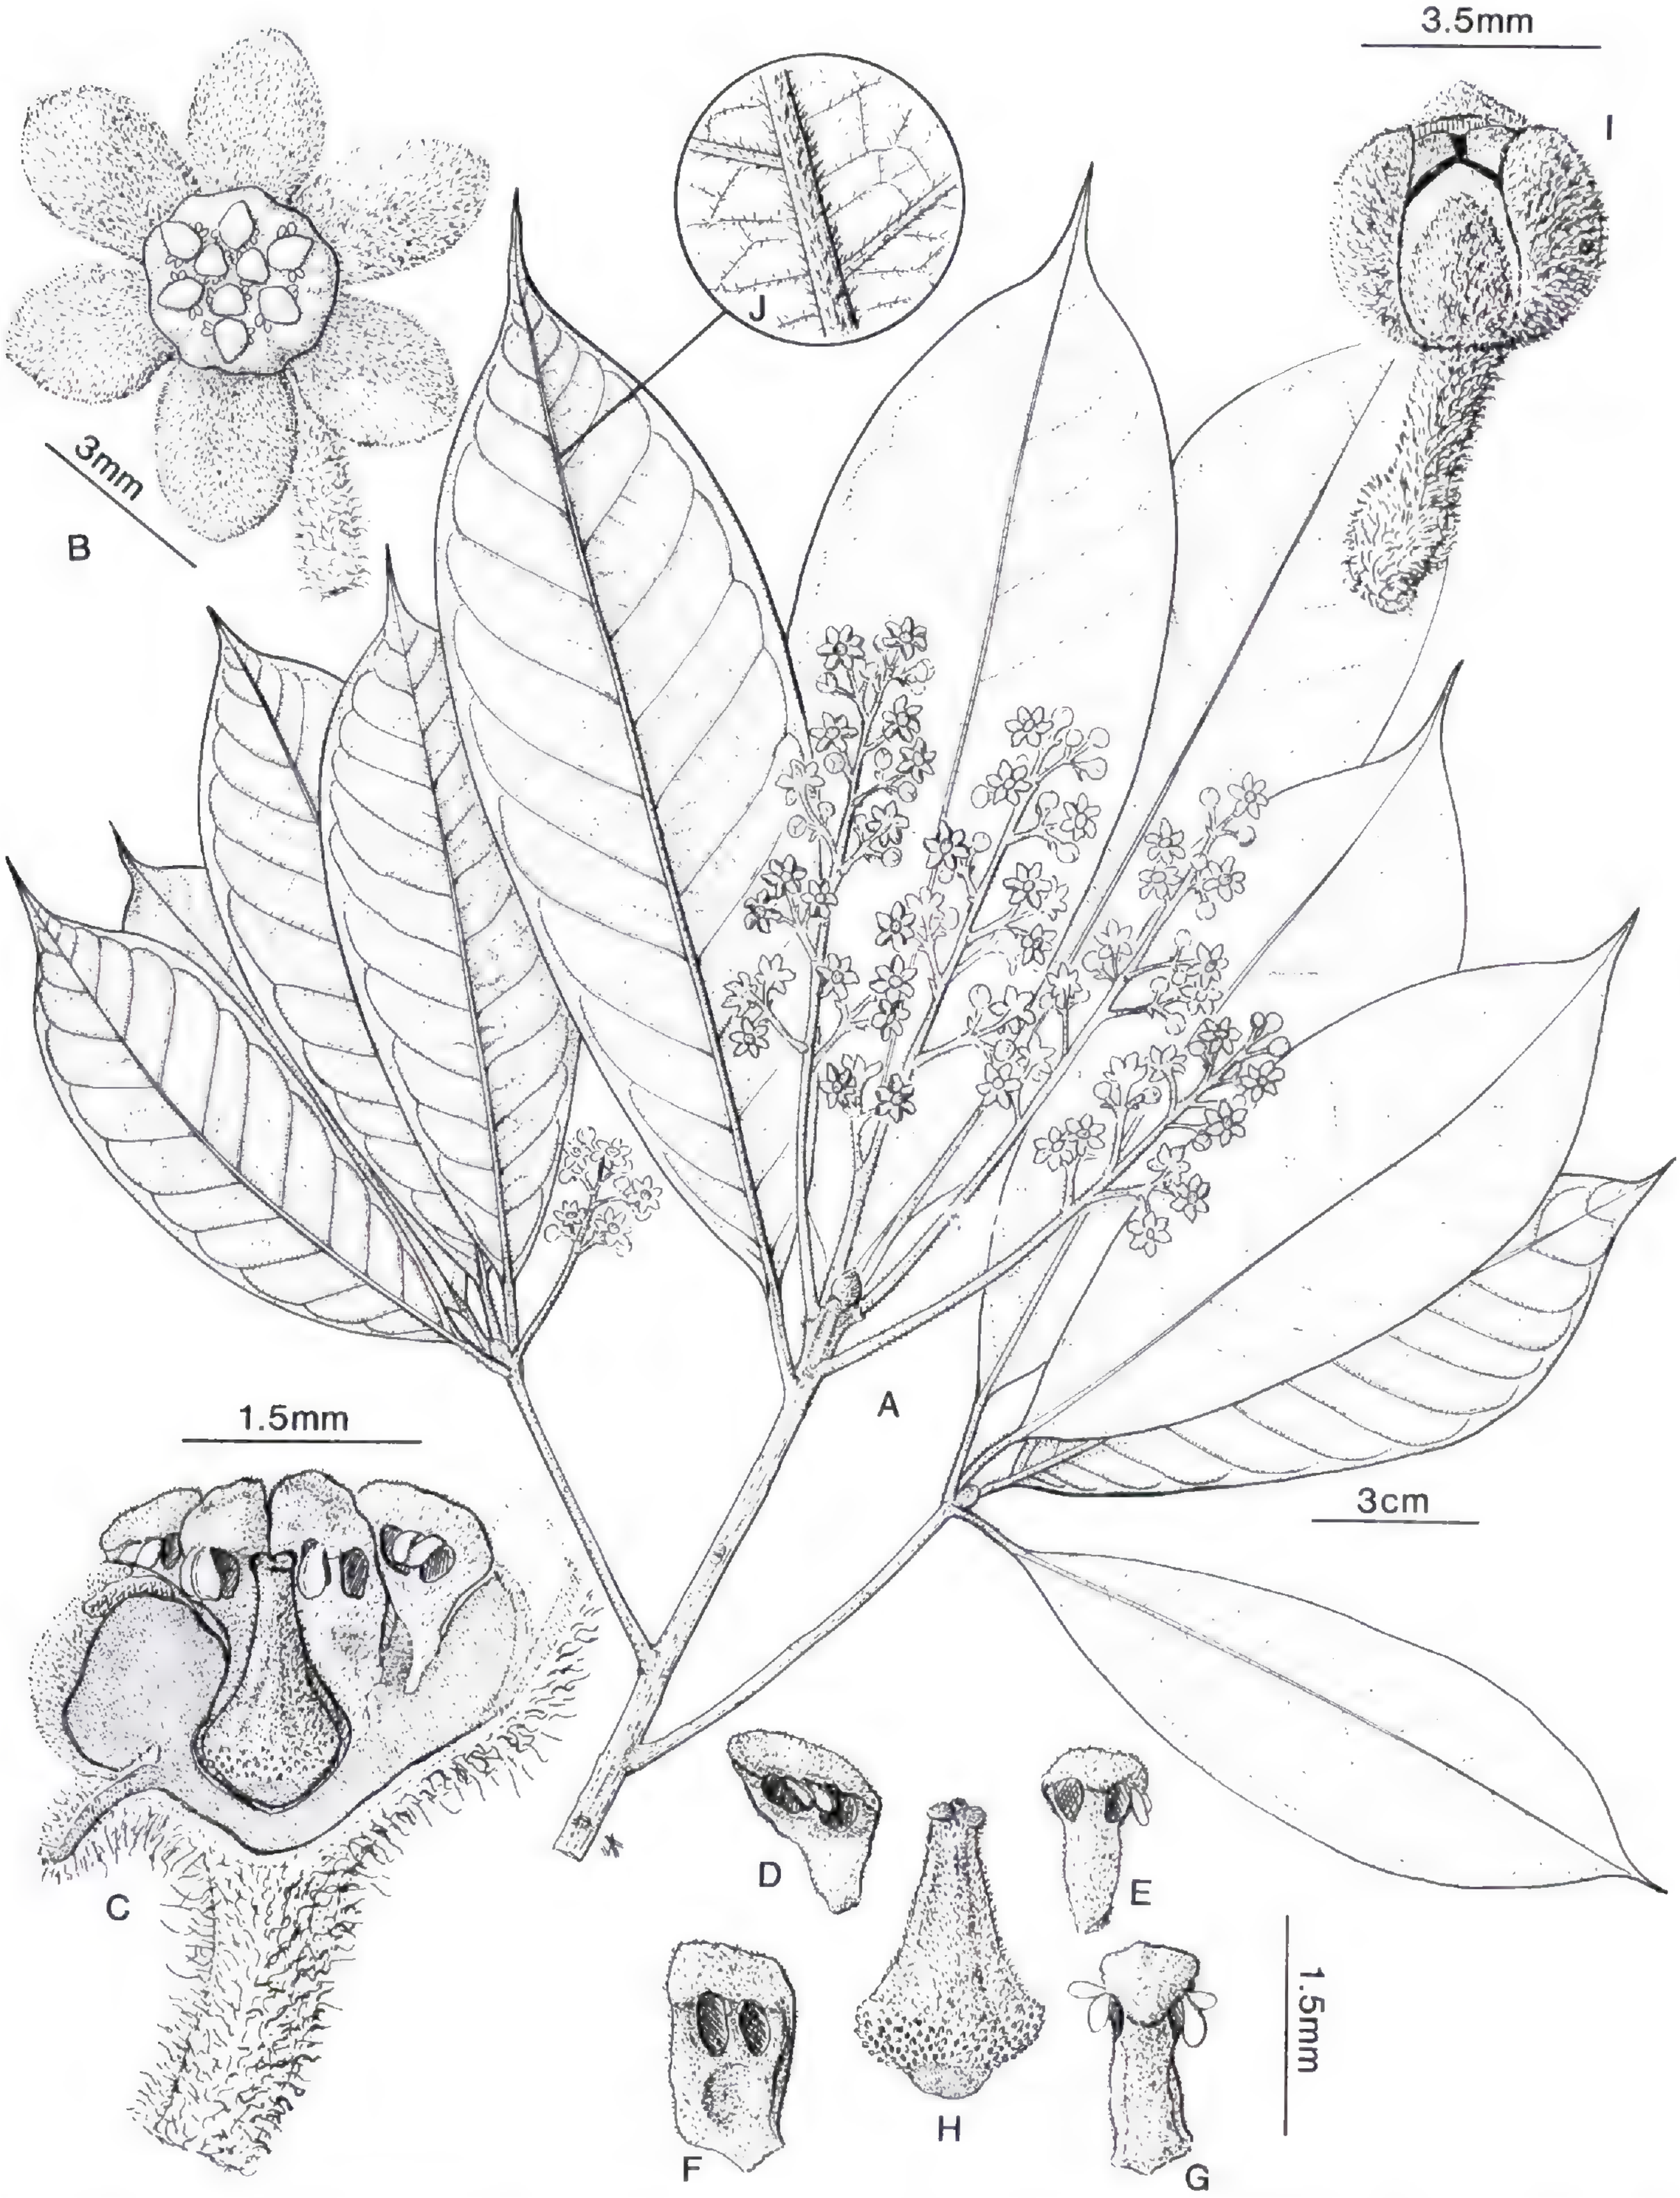

FIGURE 14. *P. brochidodromum.* —A. Habit.—B. Flower.—C. Cross section through flower.—D, E. Lateral and frontal views of outer stamen.—F, G. Lateral and frontal views of inner stamen.—H. Pistil.—I. Bud, showing indument on inner and outer tepals.—J. Detail of lower leaf surface.

mm longi. Flores rotati, 11 mm in diametro. Tepala 6, subaequalia, 3 exteriora late elliptica vel rotundata, 4 × 4 mm, extus cinereo-pubescentia, 3 interiora elliptica, 4 × 3 mm, secus basim angustata, extus cinereo-puberuli sed basi cinereo-pubescenti, omnia intus papillosa basi cinero-pubescenti. Stamina 9, 4-locellata, locellis dorsali-lateralibus; glandulis perdilatatis, fere stamina cingentibus, connatis. Pistillum ad 2 mm longum, cinereo-pubescens,

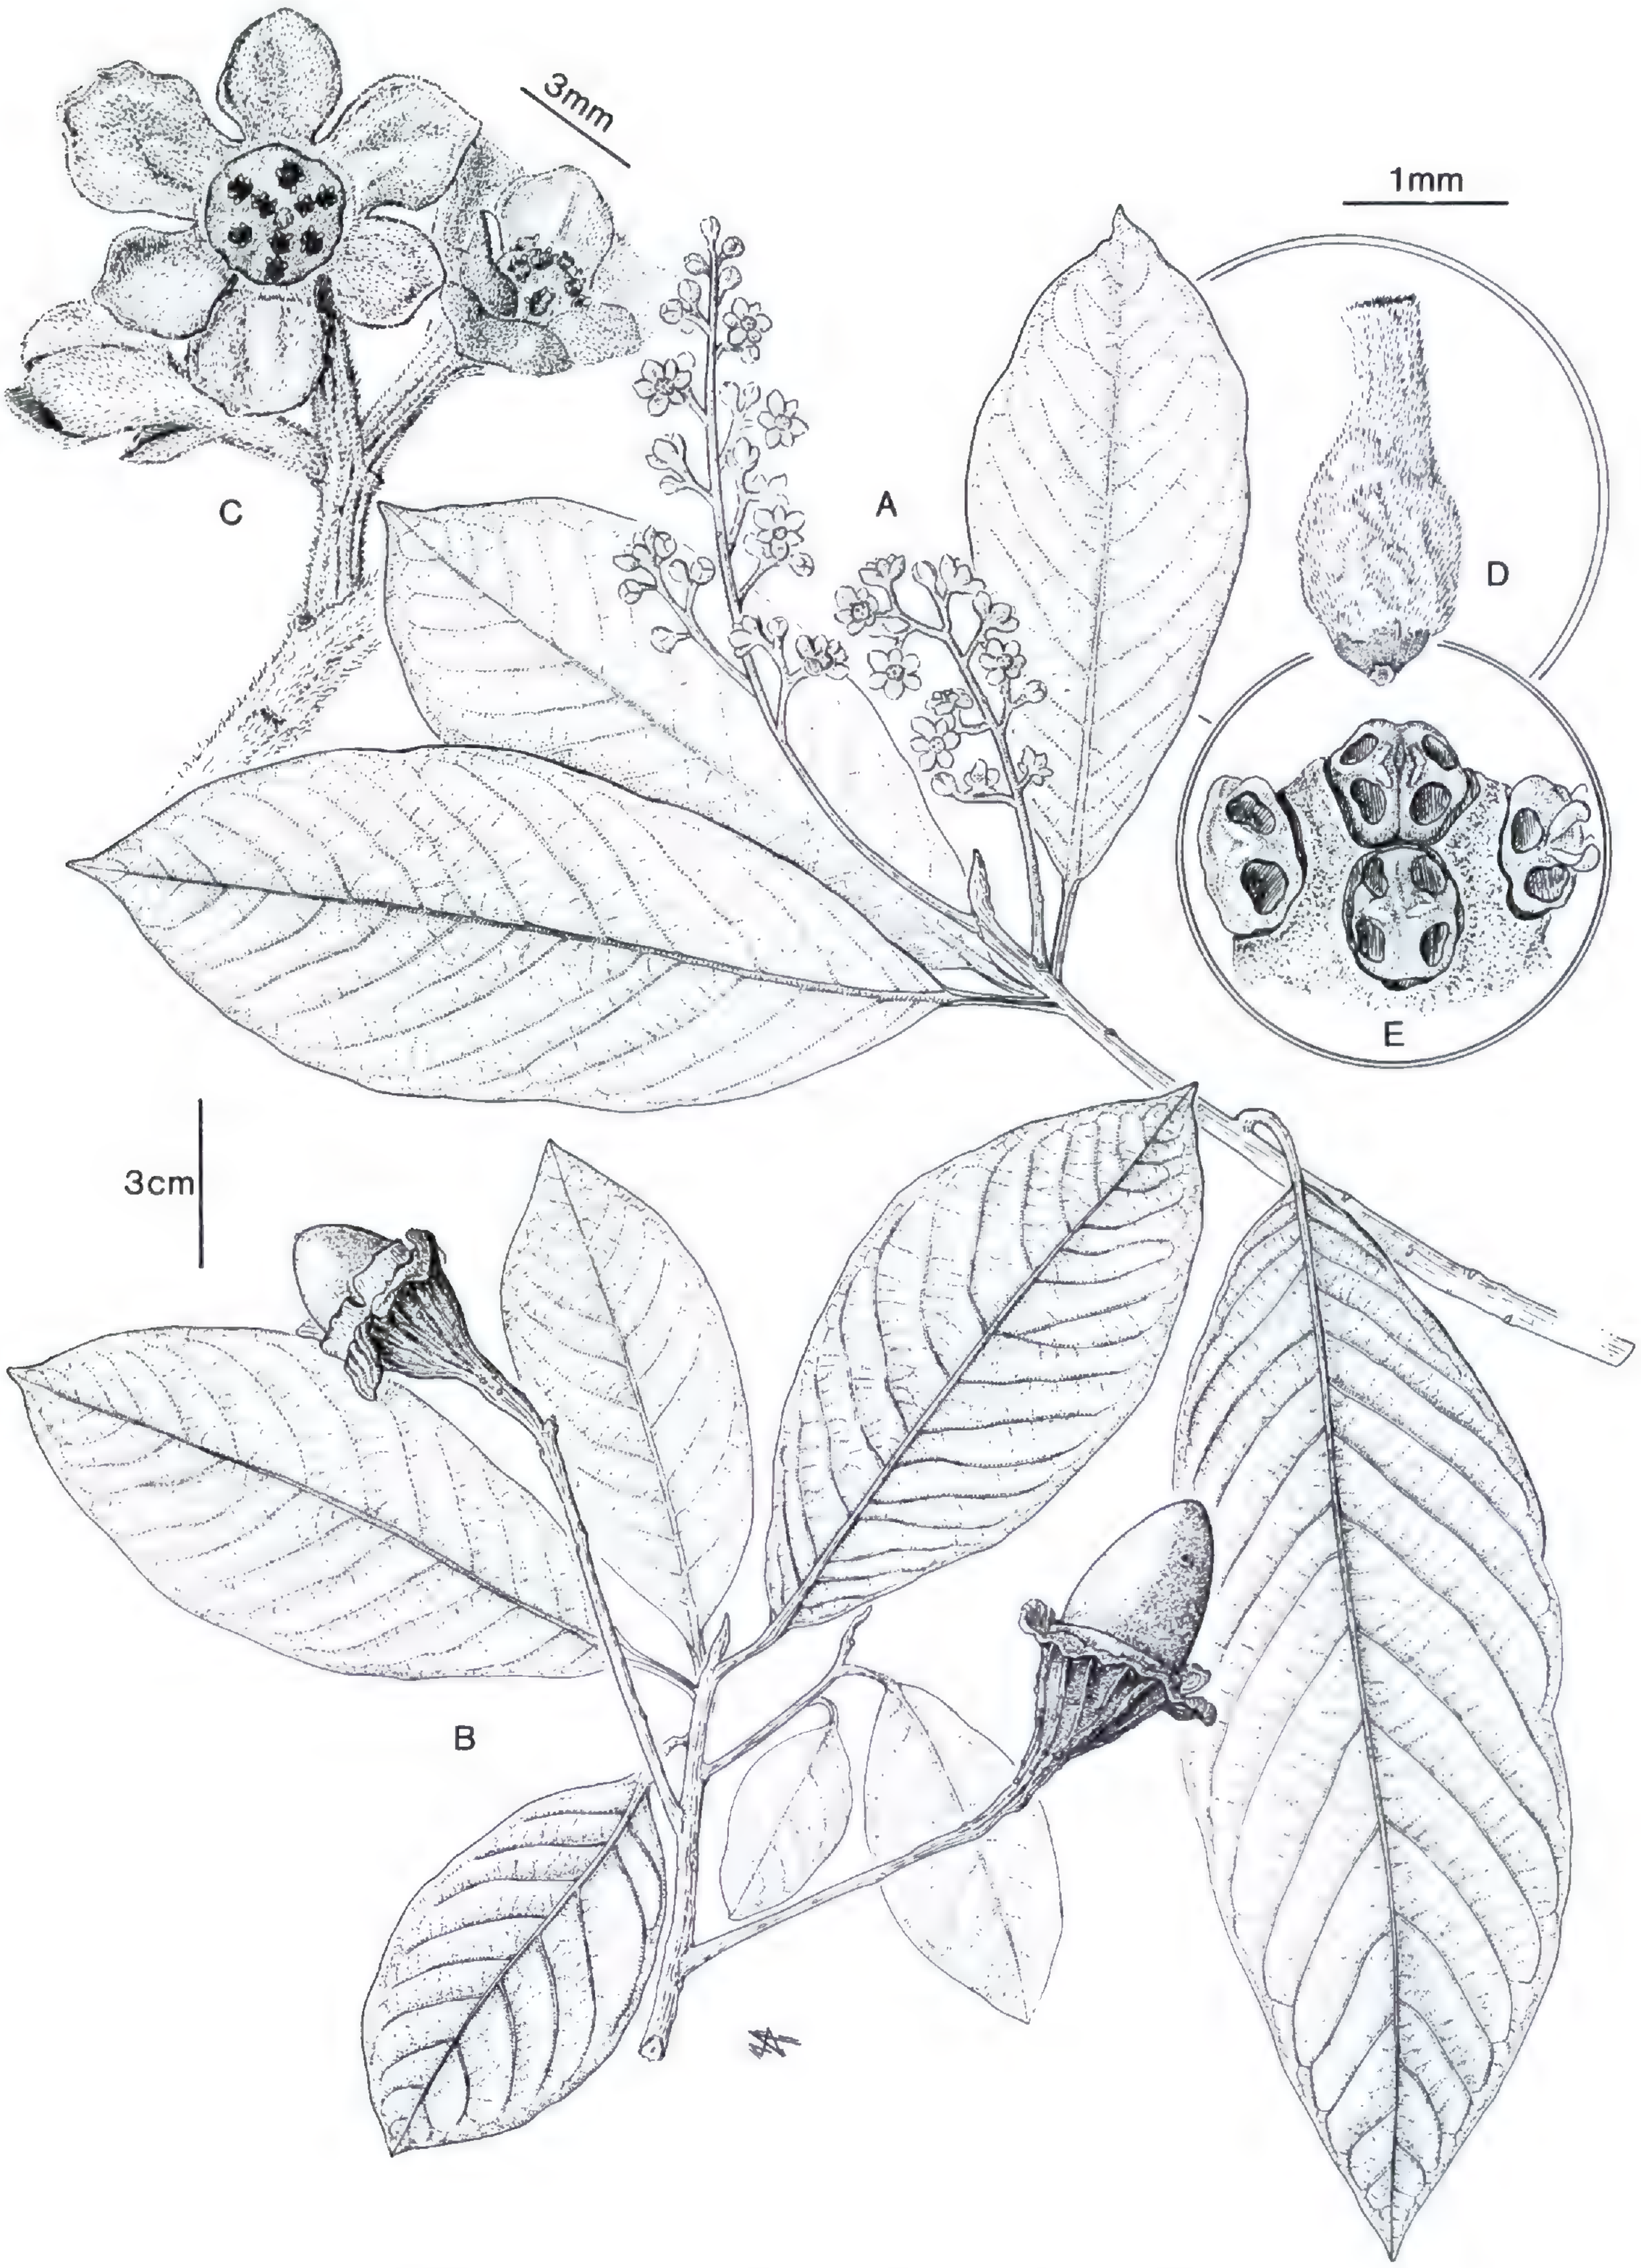

FIGURE 15. *P. cinereum*.—A. Habit, flowering.—B. Habit, fruiting.—C. Flower.—D. Pistil.—E. Detail of flower, showing embedded anthers. B from *Gentry & Smith 45117*, others from *Neill 8954*.

ovario ellipsoideo, sensim in stylum attenuato. Receptaculum intus cinereo-pubescens. Cupula profunda, lenticellata, tepalis persistentibus. Fructus ellipsoideus, ad 6 cm longus.

Tree, to 32 m tall, with buttresses. Twigs angular, brown-tomentellous, becoming glabrous with age, solid, 4 mm diam. ca. 5 cm below apex. Terminal bud brown-tomentellous, about as wide as the twig. Leaves alternate, firmly chartaceous, 13–20 × 6–10 cm, elliptic, the base obtuse, the tip acute, rarely obtuse, venation impressed on upper surface, midrib and lateral veins (10–14 on each side) raised on lower surface, tertiary venation slightly raised, lateral veins weakly loop-connected in the distal half of lamina, upper surface glabrous, the lower surface with varying amounts of minute, appressed hairs. Petioles canaliculate, 1.5–2.5 cm long, with similar indument as twigs. Inflorescences in axils of cataphylls, brown-tomentellous, 10–15 cm long, the branchlets once or twice cymosely branched, bracts deciduous at anthesis. Pedicels ca. 5 mm long. Flowers rotate, 11 mm diam. described as creamy-white, yellowish-ferruginous or brick-red. Tepals 6, subequal, the outer three broadly ovate to rounded, 4 × 4 mm, gray-pubescent outside, the inner three elliptic, 4 × 3 mm, narrowed toward the base, gray-puberulent outside except for a basal, triangular, gray-pubescent patch; all tepals papillose inside except for the gray-pubescent base. Stamens 9, all 4-celled, the cells dorsal-lateral and opening back-to-back; glands strongly enlarged, almost completely surrounding the outer stamens, fused. Pistil ca. 2 mm long, gray-pubescent, ovary ellipsoid and gradually narrowed into the style, the gray-pubescent style in dried flowers visible above the androecium. Floral tube gray-pubescent inside. Cupule deeply cup-shaped, lenticellate, 2 × 2.5 cm, tepals persisting on the margin of the cupule. Fruit an ellipsoid berry, to 6 cm long. Fruits: February–May. Flowers: May, July. Elevation range: sea level to 1,600 m.

*Collections studied.* ECUADOR. ESMERALDAS: Río Onzole, *Jativa 1104* (NY); Panadero, N of San Lorenzo, *Janse 280* (MO, NY, US); Panadero, 5 km from river, *Jativa 2039* (MO, NY, US); Panadero, *Little 21359* (MO, QAME). NAPO: Archidona, S slopes of Volcán Sumaco, *Neill 8954* (MO). PERU: LORETO: Florida, mouth of Río Zubineta in Río Putumayo, *Klug 2122* (A, F, G, GH, K, MO, S, US); Pongo de Manseriche, mouth of Río Santiago in Marañon, *Tessmann 4634* (G). SAN MARTIN: *A. Gentry & D. N. Smith 45117* (MO).

*Pleurothyrium cinereum* is known from several rather widely separated localities. The type collection is from the coast near Esmeraldas, Ecuador. *Little et al. 21359* was collected the same day at the same locality and likely came from the same tree. *Janse 280*, a fruiting collection, is also from Esmeraldas. *Neill et al. 8954* was collected on the slopes of volcano Sumaco 1,150 m elevation, Napo province, Ecuador. This collection, with flowers and a fruit, has slightly smaller and more pubescent leaves than the Esmeraldas specimens and has the pleasant odor commonly encountered in *Aniba*. The third locality is along the Río Putumayo, Dept. Loreto, Peru, at 180 m elevation. The specimens from Esmeraldas have creamy-white flowers, from volcano Sumaco yellowish-ferruginous, and from Peru brick-red flowers. The collections all possess a slightly shiny upper leaf surface, a pubescent style, very slight difference in pubescence on outer surface of tepals between inner and outer tepals (much less than common in the genus), and frequently an obtuse leaf base. Visibly pubescent styles are very uncommon in *Pleurothyrium* and are an important reason for placing these collections in one species. *Pleurothyrium cinereum* is included in Little & Dixon (1969) as *Pleurothyrium* sp.

Vegetatively *P. cinereum* strongly resembles *P. steyermarkianum*. The latter species has quite different flowers (with glands forming ridges, not a central dome, and a glabrous style), and its pedicels are strongly triangular in cross section.

The common name used by the Huitot Indians, cited by Klug, is Naime-ey.

The epithet *cinereum* refers to the gray-pubescent style, one of the most distinctive features of this species.

Provisionally placed here is a fruiting collection from the San Martin Province, 20 km NW from Rioja, elevation 1,000 m (*Gentry & Smith 45117*, MO). This collection has the denser indument also found in the Neill collection from Ecuador. In leaf characters it is a good match for *P. cinereum*. The fruit is large (4 × 2–2.5 cm) and the cupule has a double margin. The outer margin is formed by the persistent tepals and the inner margin is erect, ca. 0.5 cm taller than the outer one. Such a pronounced double margin has not been seen in other collections of *Pleurothyrium*. Remnants of stamens found on the cupule clearly point to *Pleurothyrium*; they have four lateral anther cells. The Neill collection includes one weakly double-margined cupule; cupules from Esmeraldas are less mature and do not show a double margin. If the Gentry collection is not an aberration, *P. cinereum* is the only *Pleurothyrium* species with a double-rimmed cupule.

**Pleurothyrium costanense** van der Werff, Ann. Missouri Bot. Gard. 74: 408. 1987. TYPE:

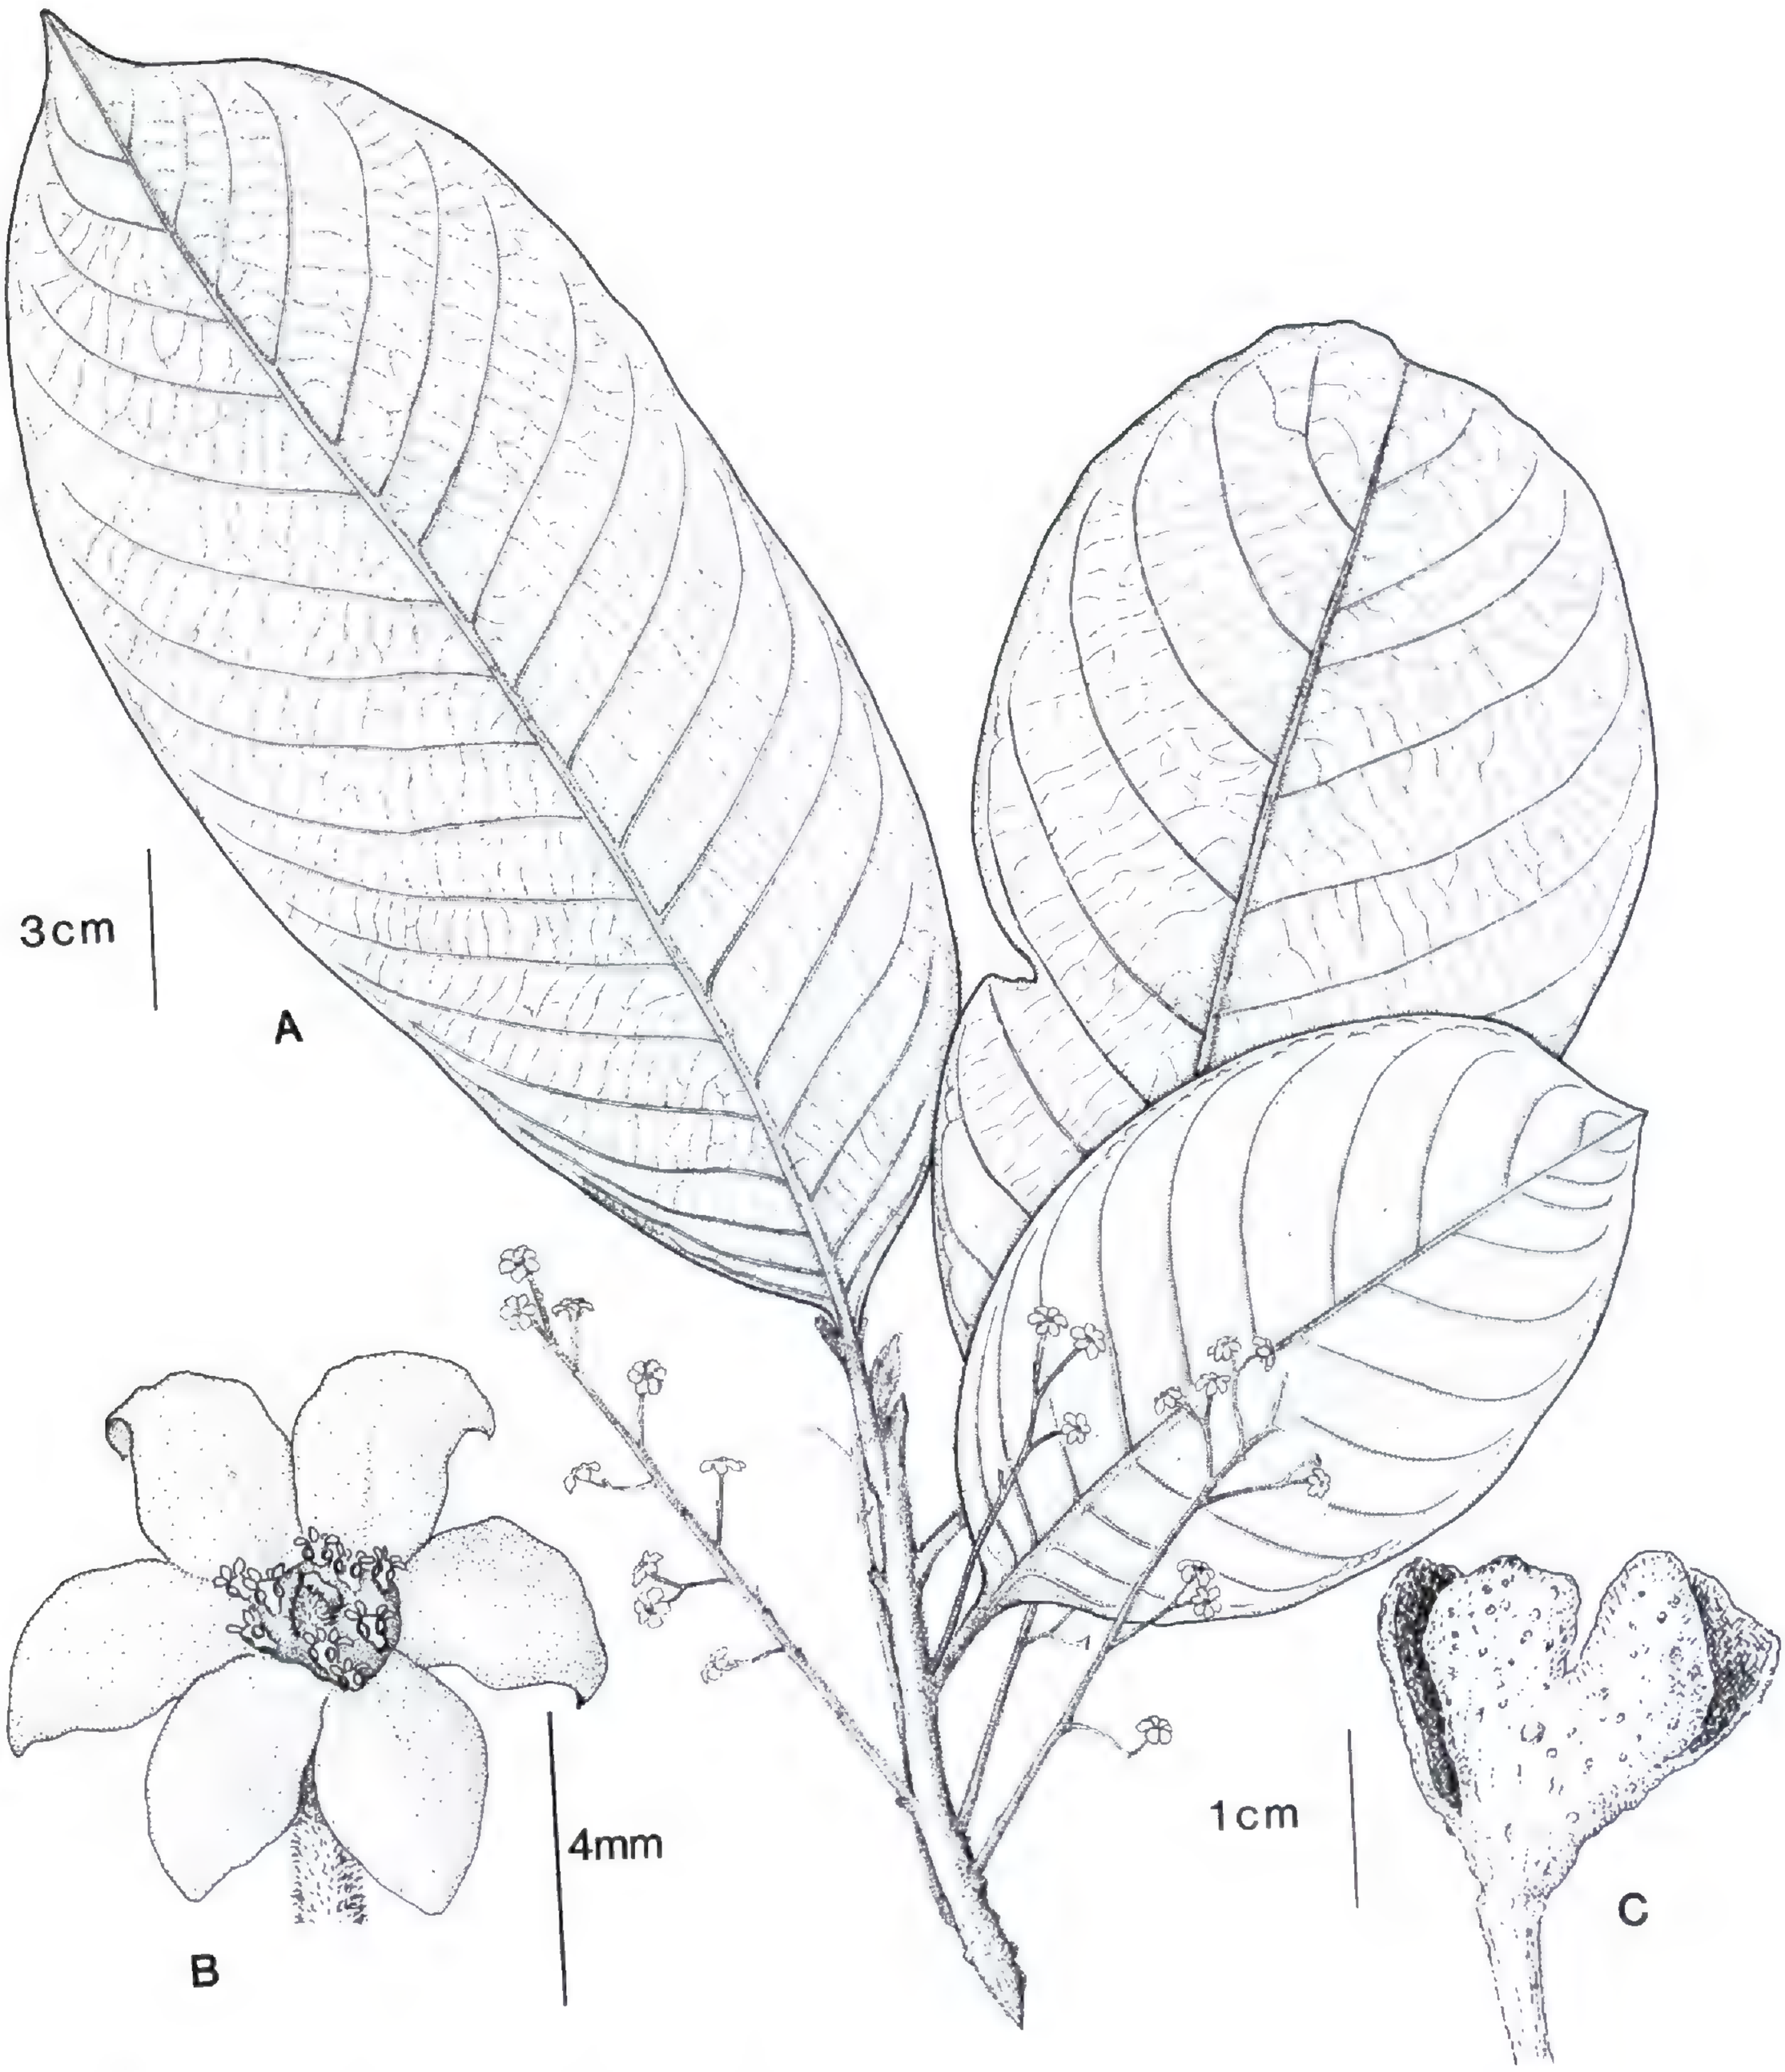

FIGURE 16. *P. costanense.*—A. Habit.—B. Flower.—C. Cupule.

Venzuela. Falcón: Sierra de San Luis, above La Chapa, *van der Werff 3654* (holotype, U; isotype, CORO). Figures 13, 16.

Tree, to 20 m tall. Twigs somewhat angular, ferruginous tomentose, but glabrescent with age, ca. 6 mm diam. 5 cm below apex, solid. Terminal bud ferruginous tomentose. Leaves alternate, chartaceous, 20–35 × 8–17 cm, elliptic to broadly elliptic, the base obtuse or acute, the apex rounded to shortly acuminate; upper surface with variable amounts of tomentose pubescence on midrib and lateral veins, othewise glabrous; lower surface with a ± dense cover of erect, ferruginous hairs, this becoming tomentose on midrib and lateral veins. Venation immersed on lower surface, but midrib, lateral veins, and tertiary venation raised on lower surface; lateral veins 10–17 on each side, arching near the margin toward the tip and becoming loop-connected in the distal half of the lamina. Petioles

1.7–3 cm long, ferruginous tomentose. Inflorescences in the axils of foliage leaves or cataphylls, ferruginous tomentose, 10–20 cm long, the branchlets 2–3 times cymosely branched. Flowers white or buff, 6–9 mm diam. Tepals 6, equal, spreading at anthesis, the outer 3 ferruginous pubescent outside, inner 3 puberulous outside except for a basal, triangular pubescent patch; all tepals papillose inside, elliptic, to 4 mm long. Stamens 9, all 4-celled, the outer 6 with the lower pair lateral-extrorse, the upper pair lateral-introrse, the inner 3 with extrorse or extrorse-lateral (upper pair) cells; filaments short, glabrous. Glands conspicuous, partly enclosing the outer stamens, but not fused. Ovary ellipsoid, with 6 longitudinal lines of hairs, otherwise glabrous, gradually narrowed in the conspicuously pubescent style; pistil ca. 2.8 mm long. Receptacle glabrous inside. Cupule large, warty. Fruits: March–August. Flowers: July–September. Elevation range: 700–2,200 m.

*Collections studied.* VENEZUELA. *Bernardi 6879* (G, MER, NY). ANZOATEGUI: Cerro Peonia, NE of Bergantin, *Steyermark 61393* (F). DISTRITO FEDERAL: mountain slope above Puerto Cruz, *Whitford 49* (A). FALCON: Sierra de San Luis, above la Chapa, *van der Werff 3654* (CORO, U). MERIDA: Andres Bello, La Carbonera, *Marcano Berti 1123* (MER, MO); Andres Bello, San Eusebio, *Quintero 11* (MER). MIRANDA: Paez, Fila La Tigra, 18 km SO de Cupira, *González & Ortega 1215* (G, MO). MONAGAS: Pueblo de Yucucual, *Lau 10* (MO); Montaña de Aguacate, *Steyermark 62230* (F); Caripe, Juasjuillar, *Bosque J-03* (MO), *Bosque J-03A* (MO), *Bosque J-12* (MO). SUCRE: Cerro Espejo, peninsula de Paria, *Steyermark & Rabe 96072* (G, K, NY, US).

*Pleurothyrium costanense* is known from the Cordillera de La Costa, the Sierra de San Luis in Edo. Falcón, and the Venezuelan Andes, where it occurs between 700 and 2,200 m elevation. Most collections are from about 1,000 m. Only one other *Pleurothyrium* species, *P. steyermarkianum* Allen, is known from the Venezuelan Andes, but this species lacks the erect-tomentose pubescence on the lower leaf surface and the young twigs. *Pleurothyrium trianae* is not uncommon at the base of the Andes and Cordillera de La Costa, but this species differs greatly from *P. costanense* in the reflexed margins of the tepals and the dense, but short tomentellous indument on the lower leaf surface, which completely covers the leaf surface.

There is a good deal of variation in the color of the indument in *P. costanense*. Especially the type and *Steyermark 96072* have a light color of indument, whereas some of the other collections are dark ferruginous. In other characters, such as leaf shape, type of indument, raised tertiary venation, and the short, densely pubescent style, these collections agree with each other, and consequently all are placed in the same species.

**Pleurothyrium crassitepalum** van der Werff, sp. nov. TYPE: Colombia. Valle: Río Naya near Puerto Merizalde, elev. 5–20 m, *Cuatrecasas 13986* (holotype, F; isotype, US). Figures 17, 18.

Arbor magna. Ramuli teretes vel subangulares, foliorum cicatribus magnis praediti, hornotini dense, minute, adpresse fusco-pubescentes, annotini glabrescentes. Gemma terminalis dense, adpresse avellino-pubescens. Folia ad apices ramulorum congesta, firme chartacea, elliptica vel elliptico-obovata, 10–17 × 6–9 cm, basi attenuata vel cuneata, apice rotundata vel obtusa, supra glabra, subtus indumento minuto, fere papilloso, praedita; nervis lateralibus 13–16 utroque costae latere, versus marginem sursum curvatis et in dimidio distale folii venam superiorem junctis; supra venatione immersa, subtus costa, nervis lateralibus et venatione tertia elevata. Petioli 11–17 mm longi, ca. 3 mm diametro. Inflorescentiae ex axillis bractearum ortae, dense fusco-tomentulosae, 7–14 cm longae, plerumque racemosae, aliquando ramulis cymae more divisis. Pedicelli 5–11 mm longi, fusco-tomentulosi. Flores extus rufescentes, intus albidi fide coll., ca. 13 mm diametro. Tepala 6, subaequalia, late ovata, exteriora ca. 5 mm longa, interiora ca. 4 mm longa, dense fusco-tomentella in sicco, crassa. Stamina 9, 4-locellata, locellis lateralibus, antheris papillosis, glandulis magnis connatis stamina cingentibus. Ovarium glabrum, ellipsoideum, ca. 1 mm longum, style glabro, ca. 1.5 mm longo, stamina non superante. Tubus floralis glaber. Fructus ignotus.

Large tree, Twigs solid, terete or somewhat angular, with large scars of old leaves, the tips densely, but minutely, brown appressed pubescent, glabrescent on older parts, 5–6 mm diam. 5 cm below apex. Terminal bud with a dense, appressed tan pubescence. Leaves clustered near the tips of branches, firmly chartaceous, elliptic to elliptic-obovate, 10–17 × 6–9 cm, the base attenuate or cuneate, the tip rounded or obtuse, the upper surface glabrous, the lower surface covered with a short, minute, almost papillose indument; lateral veins 13–16 on each side, arching upwards near the margin and connected with the superior vein in the upper half of the lamina, the marginal vein well-developed; venation immersed on the upper surface, but midrib, lateral veins and tertiary venation raised on lower surface. Petioles 11–17 mm long, flattened on the upper side, ca. 3 mm in diameter, with a similar indument as twigs. Inflorescences in axils of cataphylls near the tips of branches, densely brown-tomentulose, 7–14 cm long, mostly racemose, but occasionally with branchlets once cymosely branched, with 10–20 flowers, bracts not present at anthesis. Pedicels 5–11 mm long, densely brown tomentulose. Flowers dark reddish brown outside, white inside fide collector, ca. 13 mm diam. Tepals 6, subequal, all

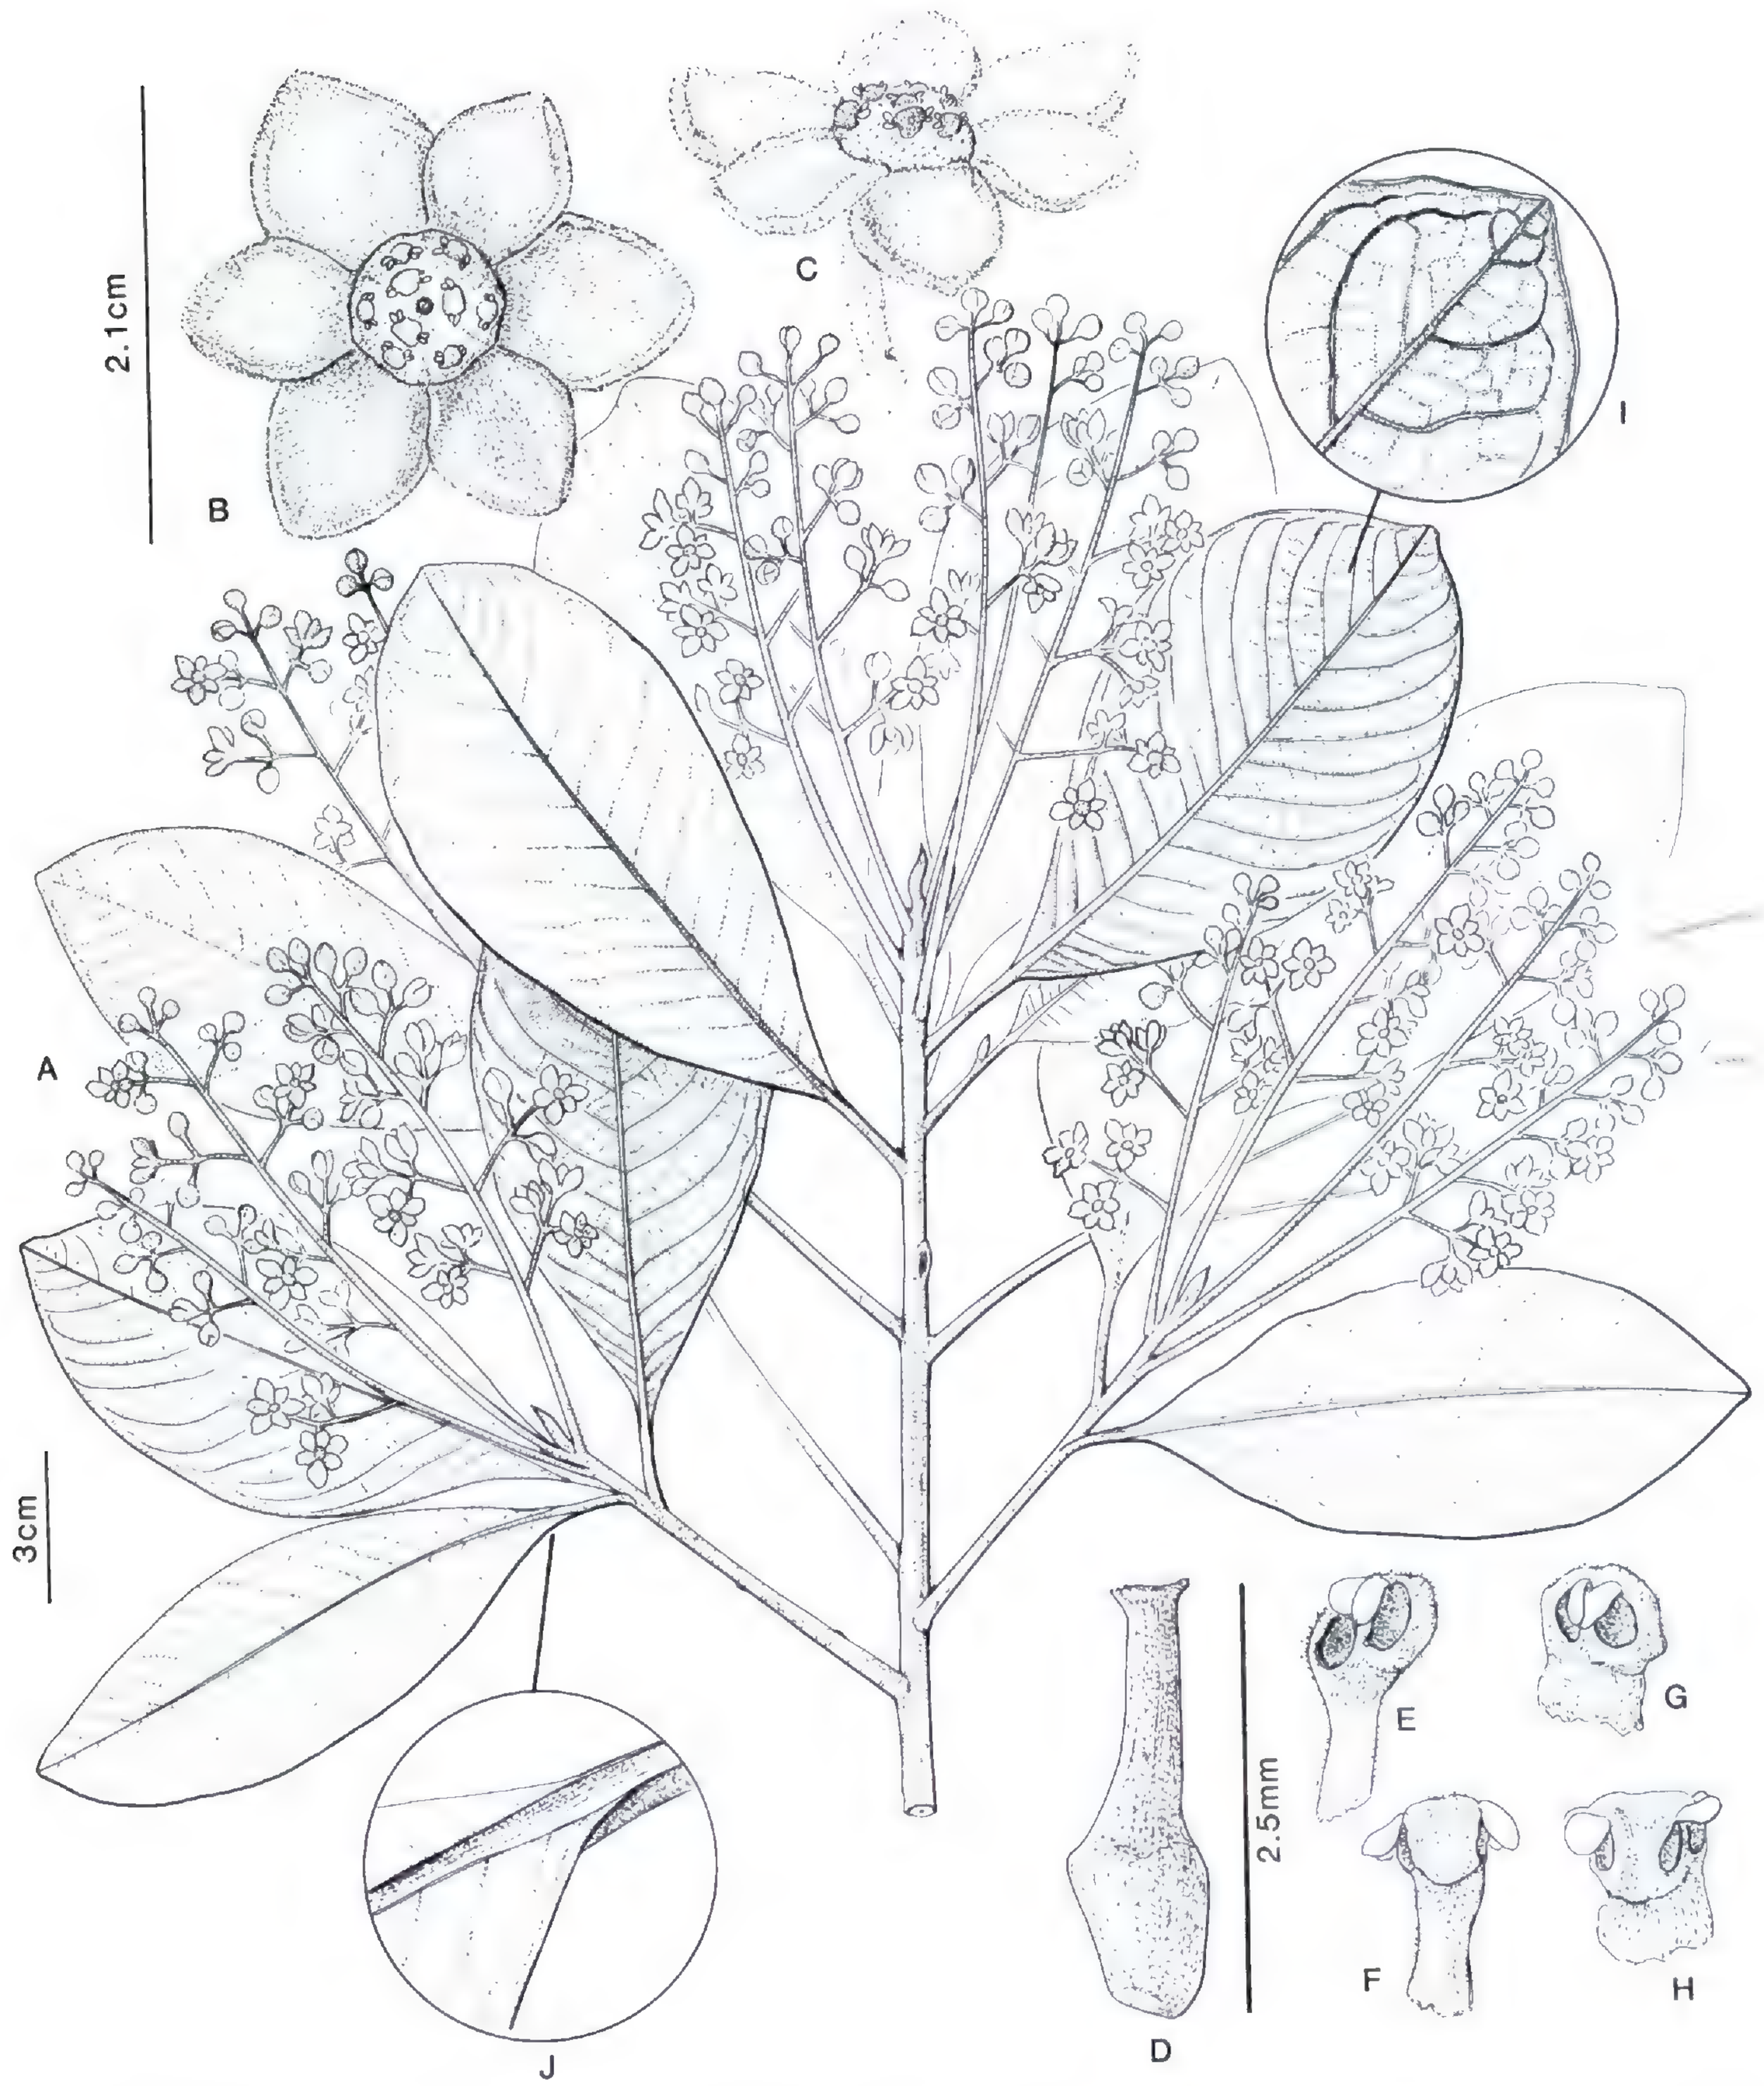

FIGURE 17. *P. crassitepalum.*—A. Habit.—B, C. Flowers.—D. Pistil.—E, F. Lateral and frontal view of outer stamen.—G, H. Lateral and frontal view of inner stamen.—I. Detail of lower leaf surface.—J. Base of leaf.

broadly ovate, the outer 3 ca. 5 mm long, the inner 3 ca. 4 mm long, all on both surfaces densely brown tomentellous, thick. Stamens 9, all 4-celled, the cells lateral and opening back-to-back, the anthers papillose; glands strongly enlarged, forming a central dome, enclosing the outer anthers and fused. Ovary glabrous, ellipsoid, ca. 1 mm long, style glabrous, ca. 1.5 mm long, not surpassing stamens; stigma not or hardly enlarged. Floral tube glabrous. Fruit unknown. Flowers: February. Elevation range: 5–20 m.

*Collection studied.* COLOMBIA: VALLE: Puerto Merizalde, Río Naya, Costa del Pacifico, *Cuatrecasas 13986* (F, US).

*Pleurothyrium crassitepalum* is one of several *Pleurothyrium* species known only from the type. Distinctive characters are the thick tepals, which

FIGURE 18. Distribution of *P. crassitepalum* (★), *P. giganthum* (●), *P. glabrifolium* (○), and *P. golfodulcense* (■).

appear almost double-margined, the very short and dense pubescence on the leaves, which is unusual in the group of species with large flowers and relatively few-flowered inflorescences, and the raised tertiary venation on the lower leaf surfaces. The clustered leaves with rounded tips are also useful characteristics. Common names for this species are nadde, nande, and palo blanco. The wood is used for making boards.

**Pleurothyrium cuneifolium** Nees, Syst. Laur.: 352. 1836. *Ocotea triangulata* Kostermans, J. Sci. Res. (Jakarta) 1: 122, 1952. TYPE: Brazil. Amazonas: Tefé (Ega), *Poeppig 2908* (holotype not designated; B, G—2 sheets, GZU, LE). Figures 19, 20.

*Pleurothyrium chrysophyllum* Nees, Syst. Laur.: 351. 1836. SYNTYPES: Peru. Cuchero, *Poeppig 1718* (B, as no. 1719, GZU, LE, US); Peru. Chachapoyas, Yambrasbamba, *Matthews 1432* (E, K).

*Pleurothyrium macranthum* Nees, Linnaea 21: 512. 1848. SYNTYPES: Peru. *Poeppig 1790* (not seen); *Poeppig 2125* (G, LE).

Tree, to 20–25 m. Twigs angular or ridged when young, becoming ± terete with age, often fistulose, often lenticellate, the young parts minutely tomentellous, glabrescent with age; diameter of young twigs 4–8 mm, depending on how strongly fistulose the twigs are. Terminal bud densely brown tomentellous. Leaves alternate, chartaceous, (narrowly) elliptic to (narrowly) elliptic-obovate, 15–30 × 7–15 cm, the base cuneate, acute or abruptly rounded, the tip obtuse or acute, lateral veins 12–18 on each side, arching upward near the margin and weakly loop-connected in the distal half of the lamina, immersed on the upper surface, midribs and lateral veins raised on lower surface, upper surface glabrous or nearly so, lower surface glabrous, papillose or tomentellous, the indument wearing off with age. Petioles 1.3–2.0 cm long, canaliculate, with similar indument as twigs. Inflorescences in axils of cataphylls, or infrequently in

FIGURE 19. *P. cuneifolium*.—A. Habit.—B. Detail of normal inflorescence.—C. Stunted inflorescence with main axis inhabited by ants.—D. Androecium and glands.—E. Pistil.—F. Young fruits.—G. Hollow twig, showing holes used by ants.

axils of normal leaves, brown-tomentellous, 10–27 cm long, the lateral branchlets to four times cymosely branched but sometimes (when inflorescence fistulose) reduced to short spurs with clustered flowers, many-flowered, bracts often persistent during anthesis, ovate, to ca. 5 mm long, tomentellous on both surfaces. Pedicels of variable length, the lateral flowers of a cyme often nearly sessile, but flowers on fistulose inflorescences with pedicels of up to 7 mm long, with same indument as inflorescence. Flowers white, yellow to yellowish red, from 7 to 14 mm diam. Tepals 6, equal, ± erect, elliptic or elliptic-ovate, 3–7 mm long, the outer 3 (minutely) tomentellous outside, inner 3 with a basal, triangular, (minutely) tomentellous patch, otherwise glabrous, all tepals glabrous inside (rarely papillose), the margins plane or inrolled, not reflexed. Stamens 9, 4-celled, the lower 2 cells lateral-extrorse, the upper 2 lateral-introrse; glands strongly enlarged, surrounding the base of the outer stamens, fused. Pistil 2–3 mm long, the ovary about as long as the style or slightly shorter, sometimes well defined, sometimes gradually narrowed into the style, the lower ⅓–⅔ glabrous, the remainder (and the style) papillose, the stigma often platelike. Floral tube glabrous inside, rarely pubescent. Cupule cup-shaped, (sometimes?) with 6 thick lobes, warty, ca. 2 cm wide, 1 cm high. Fruit ovoid, ca. 2 cm long. Fruits: February–March. Flowers: nearly year-round. Elevation range: 100–1,800 m.

As accepted here, *P. cuneifolium* is a wide-ranging species, known from Colombia, Ecuador, Peru, and Brazil, and occurs in the Amazonian lowlands and up to 1,800 m in the Peruvian Andes. Given its wide distribution and presence in different habitats, it is not surprising to find that it is a variable species. The two species placed in synonymy under *P. cuneifolium*, *P. chrysophyllum* and *P. macranthum*, were not published at the same time by Nees and he did not discuss the characters that separate the three species. Meissner (1864) regarded *P. chrysophyllum* as scarcely more than a variety of *P. cuneifolium*, differing in a denser indument, slightly smaller flowers, shorter pedicels, more branched inflorescences, and flowers with a linear bract near their base. *Pleurothyrium macranthum* differed, fide Meissner (1864), in its larger flowers. Mez (1889) placed *P. macranthum* under *P. cuneifolium*, but kept *P. chrysophyllum* apart; he separated the two on the relative length of the style and ovary: the style longer than the ovary in *P. cuneifolium* and shorter in *P. chrysophyllum*. I found this not a reliable character: in most flowers I dissected the style was about as long as the ovary, and it seemed that often in old flowers the apical part of the style and the stigma had fallen off, which makes it unsuitable as a character to separate two taxa. MacBride (1938) did not mention *P. macranthum* and separated *P. cuneifolium* and *P. chrysophyllum* by the density of their indument on the leaves. The denser indument occurs mostly on specimens from higher elevations, such as the syntypes of *P. chrysophyllum* and several collections from the Oxapampa area (1,500–1,800 m), but *Ayala 574* (Quistacochas, near Iquitos, 140 m) is equally tomentellous. Because minutely tomentellous specimens have been collected near Oxapampa and in the lowlands, and no other characters are restricted to the collections with denser indument, I reduce *P. chrysophyllum* to synonymy. The larger number of collections now available show that there are no discontinuities in flower size, and thus *P. macranthum* cannot be recognized as a distinct taxon. The largest flowers, with tepals to 7 mm long, are found on three Klug collections (*3195*, *3228*, and *3567*), which have strongly fistulose branches and fistulose inflorescences. The branchlets of the inflorescences have, in these collections, been reduced to short spurs bearing a cluster of flowers. This inflorescence shape is quite similar to that of the type of *P. poeppigii* and, indeed, the Klug collections had in some herbaria been annotated as *P. poeppigii*. However, the flowers of *P. cuneifolium* are clearly larger, lack reflexed margins of their tepals, and are glabrous on the inner surface of the tepals.

Included in *P. cuneifolium* are a few collections with entirely glabrous leaves, for instance, *Lawrance 780. Neill 7019* provides the link between the collections with glabrous leaves and tomentellous leaves; it has young, tomentellous and older, glabrous leaves.

Unfortunately, fruiting material of this species it not well known. A common name in the Oxapampa region is roble zapallo, because the cupule has six thick ribs, like the ribs on a squash. This is both unusual for Lauraceae and easy to see on fresh material, but disappears largely on dried specimens. It seems that this cupule type also occurs in lowland populations (Palcazu valley). Flowering material of the roble zapallo fits very well in *P. cuneifolium*.

Infrequently found in Lauraceae are the strikingly lenticellate twigs of many collections of *P. cuneifolium*; other useful characters for *P. cuneifolium* are the fistulose twigs, tomentellous inflorescences, (usually) glabrous inner face of tepals, and the more or less erect tepals (especially the inner ones) at anthesis. Although *P. cuneifolium* lacks reflexed margins of the tepals, I do not think its closest relatives are among the other species with plane tepals. Leaf shape, venation, the more or less erect tepals, and indument of the pistil all suggest a relationship with the species with reflexed margins of tepals, such as *P. trianae* and *P. poeppigii*. Probably also closely related is *P. obovatum*,

a species with fistulose twigs (and sometimes fistulose inflorescences), more or less erect tepals at anthesis, and some lenticels on the small piece of twig I have seen.

A few specimens of *Pleurothyrium cuneifolium* lacked a fistulose stem and would key to *P. trianae*, while very few collections of *P. trianae* had a fistulose stem and would key to *P. cuneifolium*. Apart from the characters used in the key, these two species can be separated as follows: *P. cuneifolium* has longer tepals (3–7 mm vs. ca. 2 mm), larger and more persistent bracts protecting the flower buds, and has the inner surface of the tepals usually glabrous (papillose in *P. trianae*).

**Pleurothyrium giganthum** van der Werff, sp. nov. TYPE: Ecuador. Los Ríos: Río Palenque Science Center, km 56 Quevedo–Sto. Domingo, *Dodson 18217* (holotype, QCNE). Figures 18, 21.

Arbor, ad 30 m alta. Ramuli angulares, solidi, fusco-tomentosi, cicatricibus conspicuis et plerumque cataphyllis adpressis praaediti. Cataphylla 1–2.5 cm longa. Gemma terminalis fusco-tomentosa, ad 7 mm longa. Folia ad apices ramulorum aggregata, chartacea, 30–60 × (10–)15–24 cm, obovata vel obovato-elliptica, sensim versus basim attenuata, basi rotundata, apice apiculata vel rotundata; supra costa nervisque fusco-pubescentibus, lamina pilis paucis erectis, maturitate deciduis praedita, infra costa nervisque fusco-tomentosis, lamina pilis erectis praedita; nervis lateralibus 15–20 utroque costae latere, supra immersis, subtus costa nervisque elevatis, reticulatione minus elevata; venatione in dimidio distale brochidodroma. Petioli crassi, fusco-tomentosi, 5–10 mm longi. Inflorescentiae ex axillis cataphyllorum ortae, foliis perbreviores, fusco-tomentosae, racemosae. Flores virides. Tepala 6, subaequalia, tres interiora basi magis angustata, omnia margine albida, intus et extus pubescentia. Stamina nova, glandulis magnis connatis stamina cingentibus. Ovarium et receptaculum glabrum. Fructus immaturus in cupula inclusus; cupula immatura hexangularis, lenticellata, sensim in pedicello attenuata.

Tree, to 30 m tall. Twigs roundly angular, solid, brown-tomentose, diameter 7–9 mm ca. 5 cm below the tip with conspicuous scars of fallen leaves, often with cataphylls at the base of the most recent growth, these cataphylls appressed and 1–2.5 cm long. Terminal bud brown-tomentose, ca. 7 mm long, narrower than the twig. Leaves clustered near the tips of the branches, chartaceous, 30–60 × (10–)15–24 cm, obovate or obovate-elliptic, gradually narrowed toward the base, the base abruptly rounded, the tip shortly acute to rounded, lateral veins 15–20 on each side, immersed on the upper surface, the midrib strongly raised on the lower surface, lateral veins and tertiary venation also raised on lower surface; lateral veins arching upward near the margin and becoming loop-connected in the distal half; upper surface drying dark green, with brown-tomentose pubescence along the midrib, less so along the lateral veins, the lamina with scattered, erect hairs, which wear off with age; lower surface with brown-tomentose midrib and lateral veins, the lamina with erect hairs, which leave the surface readily visible. Petioles brown-tomentose, 5–10 mm long and 4–6 mm thick. Inflorescences racemose, in the axils of cataphylls below the leaves, ca. 6 cm long, much shorter than the leaves, brown-tomentose, the flowers subtended by brown-tomentose bracts ca. 5 mm long. Pedicels ca. 1.2 cm long, brown-tomentose, gradually widened toward the buds, 3-angled, the ridges continuing as a low keel on the 3 outer tepals. Flowers ca. 2 cm diam., light green with whitish margins. Tepals 6, subequal, the outer 3 ca. 10 × 9 mm, the inner 3 ca. 7 × 7 mm, more constricted at their base than the outer 3, broadly ovate to broadly elliptic, pubescent on both surfaces. Stamens 9, the valves back to back, glands strongly enlarged, completely enclosing the stamens and fused. Ovary (in young fruit) subglobose, glabrous; floral tube glabrous inside. Young fruits fully enclosed in cupule, this lenticellate, gradually narrowed into pedicel, ca. 2.5 cm long, and strongly 6-angled. Fruits: May. Flowers: January, September.

*Collections studied.* ECUADOR. LOS RIOS: Rio Palenque Science Center, *Dodson 10181* (MO), *van der Werff 12362* (MO); Rio Palenque Science Center, *Dodson 13632, 18217* (both QCNE), *Dodson 6302, van der Werff 9471* (both MO).

*Pleurothyrium giganthum* is only known from one or two trees at the Río Palenque Science Center. Characteristic for this species are the large, clustered leaves, the conspicuous cataphylls, and the erect pubescence on the lower leaf surface. This species was first collected flowering in January 1983, but the collected flowers were later lost. Immature fruits were collected in May 1987, also indicating January–February as the flowering season. Since 1987, C. Dodson regularly checked the only known tree for flowers and finally, in September 1990, the tree became deciduous and flowered briefly when the new foliage developed.

The specific epithet is based on the Greek words gigas (giant) and anthos (flower) and refers to the very large flowers of this species.

This species was included in the *Flora of Río Palenque* (Dodson & Gentry, 1978) as *Ocotea* sp. nov.

**Pleurothyrium glabrifolium** van der Werff, sp. nov. TYPE: Ecuador. Napo: Río Payamina, 2–10 km S of the road Coca–Loreto, *Cerón*

*& Palacios 3017* (holotype, MO; isotypes, AAU, C, COL, G, HBG, K, LE, NY, QAME, QRS, U, US). Figures 18, 22.

Arbor, ad 15 m. Ramuli teretes, solidi, ad apicem brunneo-tomentosi, glabrescentes. Gemma terminalis brunneo-tomentosa. Folia alterna, subcoriacea, elliptica, 14–25 × 6–9 cm, basi acuta, apice acuminata, glabra; supra glanduloso-punctata, venatione immersa; subtus costa nervisque elevatis, reticulatione paullo elevata; nervis utroque costae latere 12–16, in dimidio distale venatione brochidodroma. Petioli 1.5–3 cm longi, canaliculati, indumento ramulis similes. Inflorescentiae ex axillis bractaerum ortae, 7–16 cm longae, brunneo-tomentellae, paniculatae, bracteis ad anthesim deciduis. Flores 6–7 mm diametro. Tepala 6, aequalia, ovata, ca. 3 mm longa, 3 exteriora extus tomentella, intus glabra, 3 interiora extus basi tomentella, demum glabra, intus glabra. Stamina 9, 4-locellata, locellis lateralibus, filamentis quam antheris brevioribus; glandulis magnis, connatis, stamina cingentibus. Pistillum glabrum, 1 mm longum, stylo breve, stigmate peltata. Receptaculum glabrum. Fructus ignoti.

Tree, to 15 m tall. Twigs terete, solid, the very tip and terminal bud brown-tomentose, older parts becoming glabrous, ca. 4 mm diam. 5 cm below apex. Leaves alternate, subcoriaceous, elliptic, 14–25 × 6–9 cm, the base acute, tip acuminate, glabrous on both surfaces, the upper surface gland-dotted, venation immersed on upper surface, costa and lateral veins raised on lower surface, the tertiary venation less so; lateral veins 12–16 on each side, curving upward near the margin and becoming loop-connected in the distal half of the lamina. Petioles 1.5–3 cm long, canaliculate, with similar tomentum as the twig. Inflorescences in axils of cataphylls, 7–16 cm long, brown-tomentellous, pa-

FIGURE 22. *P. glabrifolium.*—A. Habit.—B. Flower.—C. Cross section of flower.—D. Detail of inflorescence.—E. stamen.—F. Pistil.

niculate, many-flowered, the branchlets 1–2 times cymosely branched, bracts mostly deciduous at anthesis. Pedicels 2–3 mm long, brown-tomentellous. Flowers 6–7 mm diam., whitish. Tepals 6, equal, ovate, ca. 3 mm long, tomentellous outside, but inner 3 with glabrous margin and tip; glabrous inside. Stamens 9, glabrous, 4-celled, the cells lateral; filaments shorter than the anthers, ca. 0.2 mm long; glands enlarged, fused, completely enclosing the stamens. Pistil glabrous or nearly so, ca. 1 mm long, the style very short, stigma platelike. Floral tube shallow, glabrous; ovary largely covered by the enlarged glands. Fruits unknown. Flowers: December. Elevation range: 250–300 m.

*Collections studied.* ECUADOR. NAPO: Río Payamino, 2–10 km S of Carretera Coca–Loreto, *Ceron & Palacios 3017* (AAU, C, COL, G, HBG, K, LE, MO, NY, QAME, QRS, U, US); El Chuncho, 6 km from Río Payamino, *Palacios 2288* (MO).

*Pleurothyrium glabrifolium* is only known from two collections, made in the same area in the lowlands of eastern Ecuador. The combination of glabrous inner surface of tepals, glabrous and alternate leaves is characteristic for this species. The only other Amazonian species with the inner surface of the tepals glabrous is *P. panurense*, but that species has clustered leaves with a minute, whitish, and dense indument on the lower leaf surface. The completely glabrous stamens and pistil of *P. glabrifolium* are an uncommon character in *Pleurothyrium*.

**Pleurothyrium glabritepalum** van der Werff, sp. nov. TYPE: Colombia. Choco: hills behind Bahia Solano (Puerto Mutis), *Gentry & Forero 7201* (holotype, MO; isotypes, HBG, U). Figures 20, 23.

Arbor, ad 8 m alta. Ramuli solidi, teretes, porphyreo-tomentosi, glabrescentes. Gemma terminalis parva, porphyreo-tomentosa. Folia alterna, subchartacea, elliptica, 10–18 × 3.5–6 cm, basi acuta, apice acuminata, acumine 1–2 cm longo, supra glandulo-punctata et pilis dispersis praedita sed secus costam nervosque laterales indumento densiore, subtus pilis subdispersis arrectis praedita, indumento paginam non tegente, sed secus costam nervosque tomentoso. Nervi laterales 5–8 utroque costae latere, venatione brochidodroma in dimidio distale, supra immersa subtus costa nervisque elevatis, venatione tertia paullo elevata. Petioli 10–15 mm longi, teretes. Inflorescentiae ex axilis bractearum ortae, 2–4 cm longae, 1–3-florae, porphyreo-tomentosae, sub anthesi bracteis deciduis. Flores ca. 13 mm diametro. Tepala 6, subaequalia, ovata, 3 exteriora 5.5 mm longa, extus tomentulosa, intus glabra, 3 interiora 4.5 mm longa, extus basi tomentulosa, demum glabra, intus glabra. Stamina 9, glabra, 4-locellata, locellis lateralibus, glandulis incrassatis stamina cingentibus, coalitis, ovarium depresse globosum, glabrum, ca. 1 mm diametro, tubus floralis glaber. Fructus ignotus.

Tree, at least 8 m tall fide collectors. Twigs solid, terete, brown-tomentose when young, glabrescent, 2–3 mm diam. ca. 5 cm below the tip. Terminal bud small, brown-tomentose. Leaves alternate, thinly chartaceous, elliptic, 10–18 × 3.5–6 cm, the base acute, the tip acuminate, the acumen 1–2 cm long, the upper surface with gland dots and scattered brown hairs, these much denser along midrib and lateral veins, the lower surface with a rather sparse, erect pubescence, the hairs somewhat wrinkled and not covering the leaf surface; indument brown-tomentose along midrib and lateral veins; lateral veins 5–8 on each side, venation immersed on upper surface, midrib and lateral veins raised on lower surface, the tertiary venation slightly so, lateral veins arching upward near the margin and weakly loop-connected in the distal half of the lamina. Petioles 10–15 mm long, terete, with similar pubescence as twigs. Inflorescences in axils of cataphylls, 1–3-flowered, 2–4 cm long, brown-tomentose, bracts lacking at anthesis. Pedicels 4–5 mm long, tomentose. Flowers green with tan center (fide collectors), ca. 13 mm diam. Tepals 6, subequal, the outer three 5.5 mm long, the inner three 4.5 mm long, the outer three tomentulose outside, inner three with a basal, triangular tomentulose patch, otherwise glabrous; all tepals with a glabrous inner surface. Stamens 9, 4-celled, glabrous, the cells lateral and opening back-to-back, glands strongly enlarged, surrounding the stamens, fused; ovary depressed globose, glabrous, ca. 1 mm diam., receptacle glabrous inside. Fruit unknown. Flowers: January. Elevation range: below 250 m.

*Collection studied.* COLOMBIA. CHOCO: hills behind Bahia Solano (Puerto Mutis), *Gentry & Forero 7201* (HBG, MO, U).

*Pleurothyrium glabritepalum*, named after the glabrous inner surface of the tepals, is only known from the type collection. Useful characters for its identification are the following: the more or less erect pubescence, which is also present on the upper leaf surface, the gland dots on the upper leaf surface, the alternate, acuminate thin leaves, the few-flowered inflorescences, and the glabrous inner surface of the tepals. The leaves have, for the genus, few lateral veins and a marginal vein is weakly developed.

**Pleurothyrium golfodulcense** Burger & Zamora, Fieldiana Botany, New Series, 23: 115.

FIGURE 23. *P. glabritepalum.*—A. Habit.—B. Flower.—C. Leaf base, showing indument.—D. Leaf apex.

1990. TYPE: Costa Rica. Puntarenas: Alto de las Mogas, *Sanchez, Zamora & Brenes 1228* (holotype, CR not seen; isotype, F not seen). Figures 18, 24.

Tree, to 15 m tall. Twigs terete, solid, gray pubescent, 2–3 mm diam. ca. 5 cm below tip. Terminal bud densely gray-pubescent. Leaves alternate, thinly chartaceous to coriaceous, 10–20 × 4–7 cm, elliptic to elliptic-obovate, base acute or obtuse, apex acuminate, acumen to 2 cm long, upper surface glabrous, except for the ± pubescent midrib, gland-dotted, lower surface glabrous or with minute appressed hairs, but midrib and to a lesser degree lateral veins pubescent; lateral veins 6–9; loop-connected in distal half of lamina, venation immersed on upper surface, midrib and lateral veins raised on lower surface. Petioles 6–22 mm long. Inflorescences in axils of cataphylls or normal leaves, to 10 cm long, racemose, ferruginous pubescent, the lateral branches often subtended by an elliptic bract, to 6 mm long, pubescent on both surfaces; pedicels to 14 mm long, often with a bracteole halfway between inflorescence axis and flower. Flowers white, rotate, 9–12 mm diam. Tepals 6, equal, elliptic, 4–6 mm long, ca. 3 mm wide, gray to ferruginous pubescent outside, papillose inside. Stamens 9, 4-celled, the cells lateral to apical, opening back-to-back, the glands strongly enlarged and, together with the stamens, forming a dome 2.5 mm wide and 1 mm high, the glands enclosing the stamens, but not fully fused. Pistil 2.2 mm

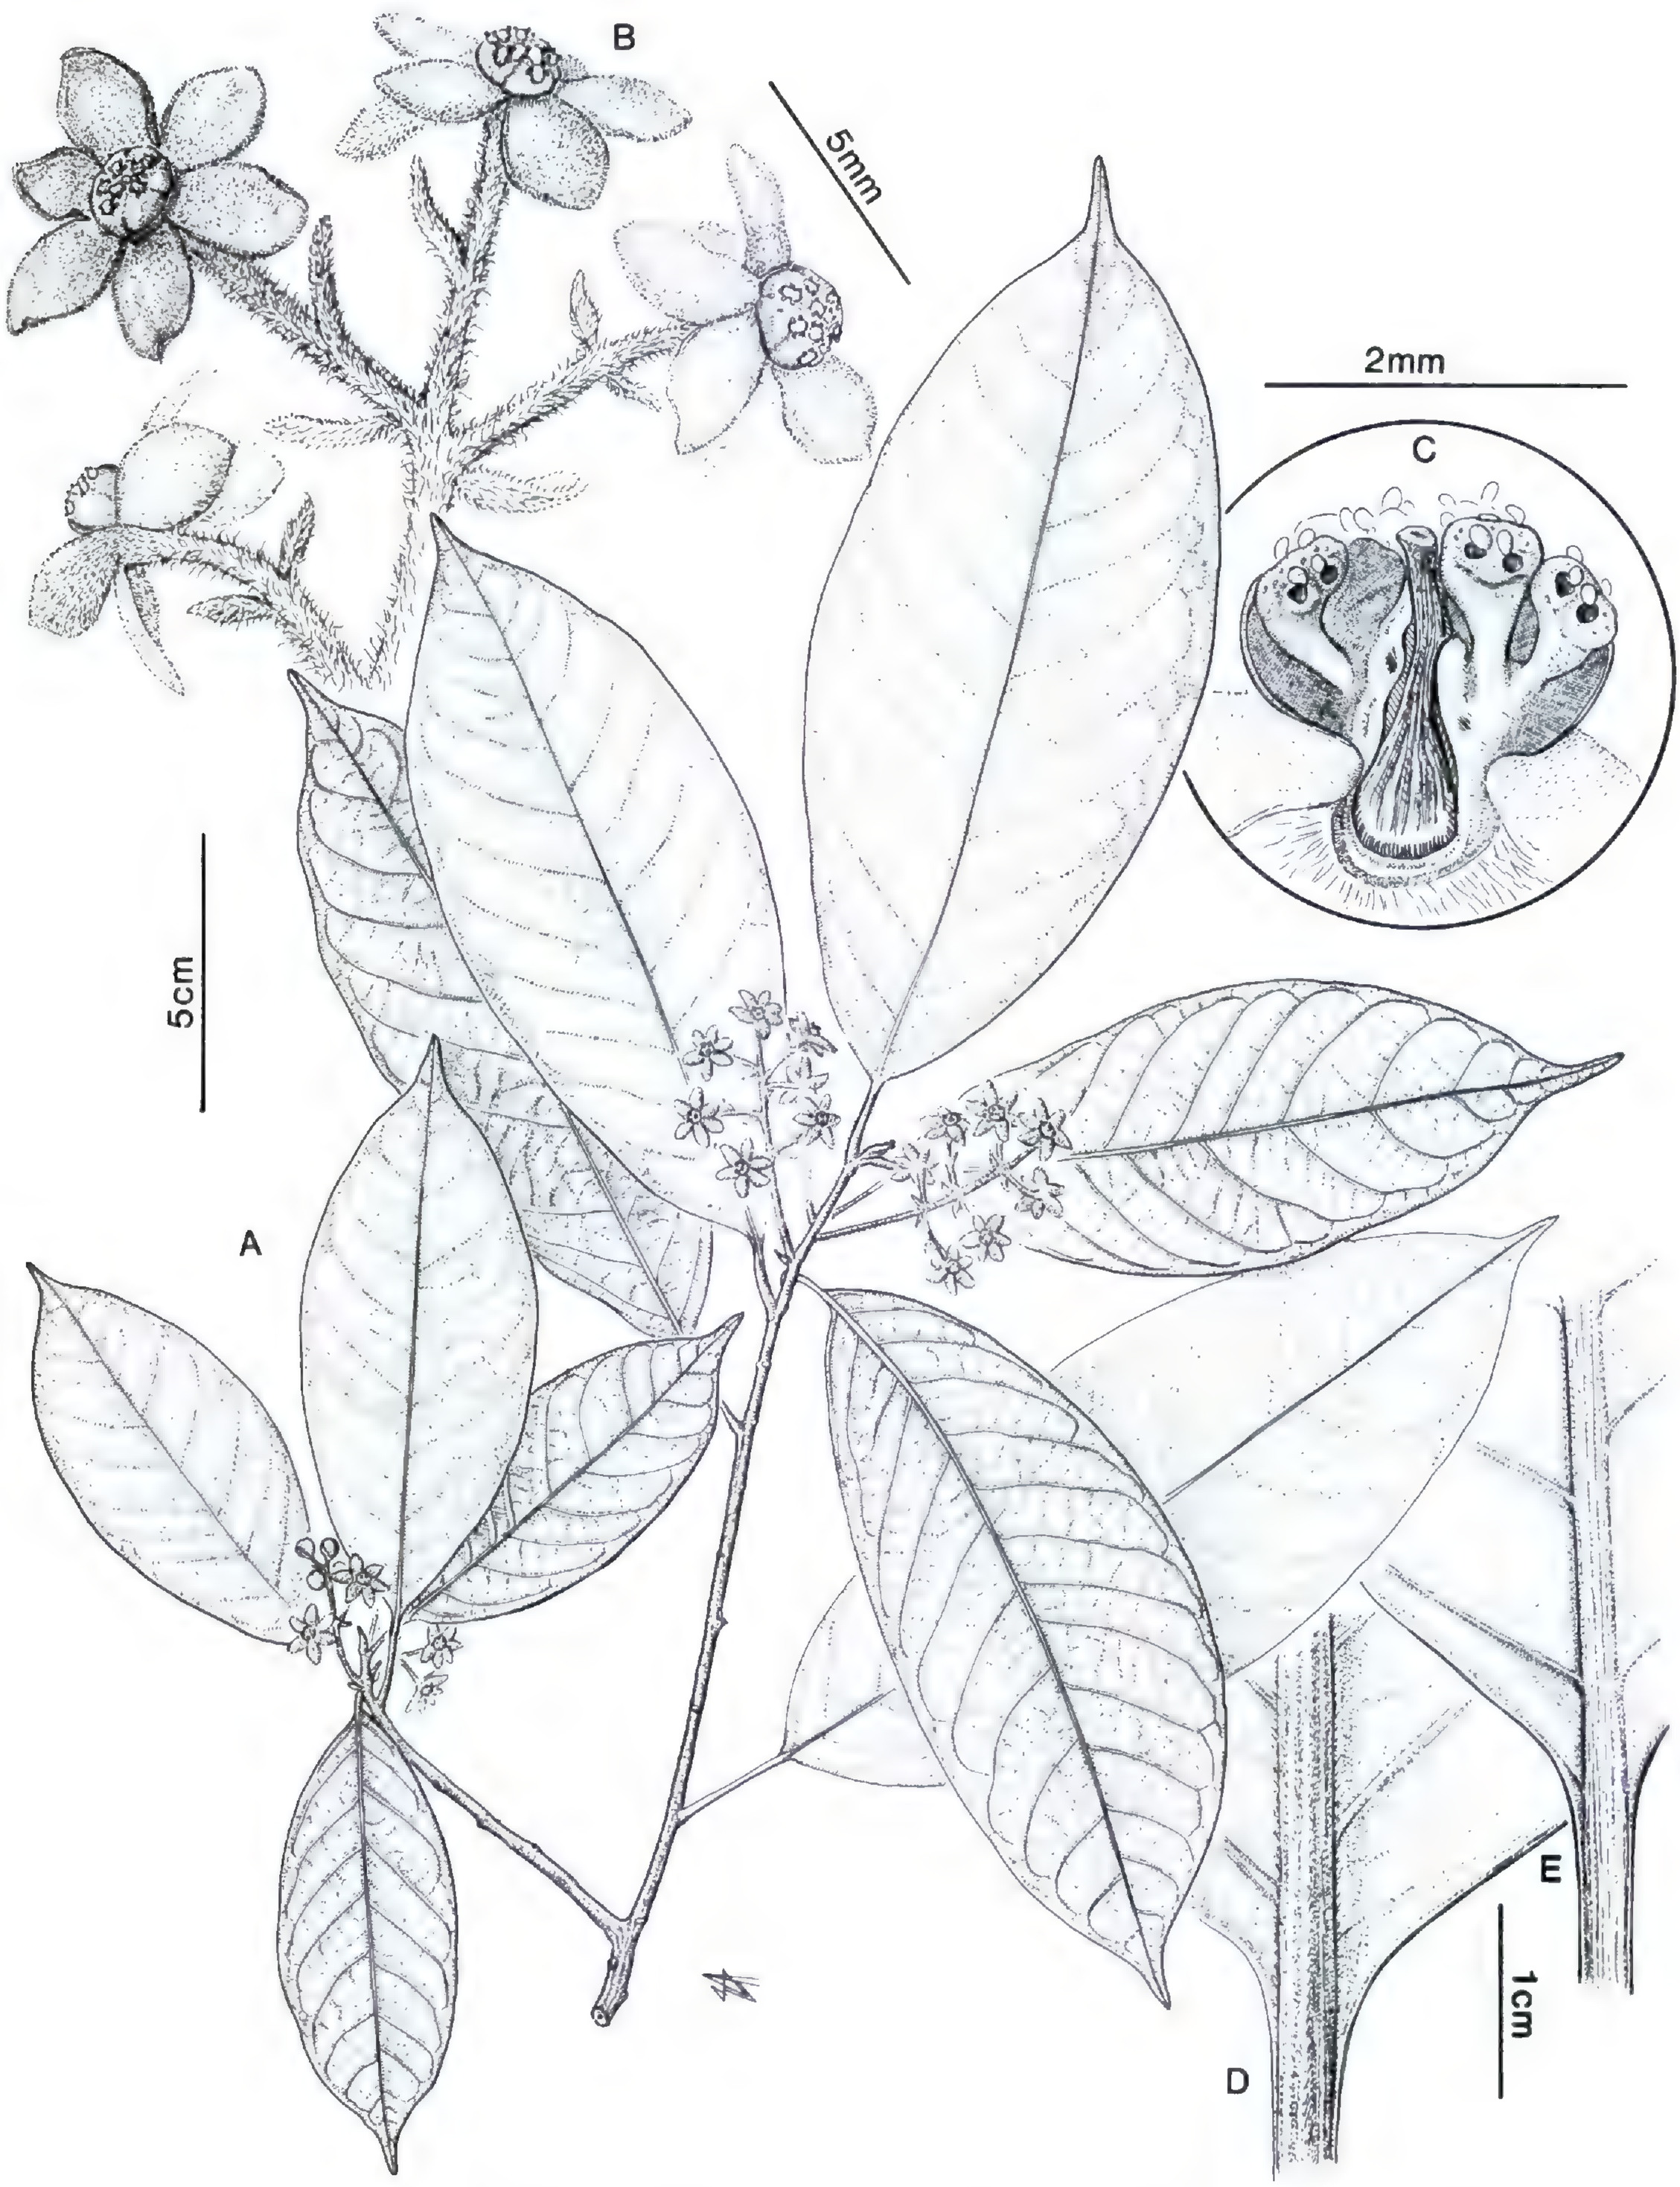

FIGURE 24. *P. golfodulcense.*—A. Habit.—B. Part of inflorescence.—C. Cross section of flower.—D, E. Lower and upper surface of leaf base.

long, ovary ca. 1 mm long, pubescent, style sparsely pubescent. Receptacle pubescent inside. Cupule with coarse warts, 2 cm tall, 2 cm wide. Fruit unknown. Flowers: January–February. Elevation range: 200–800 m.

*Collections studied.* COSTA RICA. PUNTARENAS: forested slopes above Golfito, *Burger 4690* (CR, F, MO). PUNTARENAS: forested hills above Palmar Norte, *Allen 5885* (GH, UC); Parque Nacional Corcovado, Los Patos Forest, *Kernan 184* (CR, MO), *Kernan 187* (CR, MO); Osa, Rancho Quemado, *Jimenez 648* (MO).

*Pleurothyrium golfodulcense* is restricted to the Osa peninsula and adjoining area in Costa Rica. I have accepted a rather wide concept of this species and include here, for instance, *Kernan 184*, which differs from typical *P. golfodulcense* in its thinner leaves, shorter petioles and gray vs. ferruginous pubescence. In leaf size and shape, venation, pubescent pistil and receptacle, gland-dotted leaves, petiole length, and bracts pubescent on both surfaces it fits in *P. golfodulcense*, and because it was collected together with typical *P. golfodulcense* (*Kernan 187*) and young leaves of *Allen 5885* are as thin as those of *Kernan 184*, I prefer to include *Kernan 184* in *P. golfodulcense*.

The closest relatives of *Pleurothyrium golfodulcense* are probably the Panamanian species *P. racemosum* and *P. pilosum* and the Ecuadorian-Colombian *P. tomiwahlii* (see discussion under *P. tomiwahlii*).

**Pleurothyrium grandiflorum** van der Werff, Ann. Missouri Bot. Gard. 74: 408. 1987. TYPE: Colombia. Chocó: Río Mecana, *Juncosa 1675* (holotype, MO). Figures 25, 26.

Tree, 15 m. Twigs ridged, becoming terete, solid, very finely appressed puberulent, ca. 3 mm diam. 5 cm below the tip. Terminal bud appressed puberulent, shiny. Leaves alternate, thinly chartaceous, 15–24 × 4–7 cm, elliptic or narrowly elliptic, the base sharply acute or slightly decurrent on petiole, the tip acute, the upper surface nearly glabrous, but with some fine appressed hairs, especially on the midrib; the lower surface with scattered, minute, appressed hairs, these more numerous along lateral veins and midrib; venation on upper surface immersed, but slightly raised on lower surface; lateral veins 15–20 on each side, arching upward near the margin and becoming loop-connected in the upper half of the lamina. Petioles 1–1.5 cm long, with same kind and density of pubescence as twigs. Inflorescences to 10 cm long, with same kind and density of pubescence as twigs, racemose, few-flowered (usually 2 flowers present on each inflorescence), bracts not present at anthesis. Pedicels to 6 mm long, appressed puberulous. Flowers yellow, 1.5–1.7 cm diam., fragrant (same odor as in some euglossine bee-pollinated flowers, fide collector). Tepals 6, subequal, the inner three narrower than the outer three, the inner surface with a dense, short pubescence. Stamens 9, 4-celled, the outer six with lateral cells, the inner three with extrorse cells, anthers glabrous, filaments not discernible in the glandular mass. Pistil 1.3 mm long, glabrous, the ovary partly sunken in the pubescent floral tube and covered by the glabrous glandular mass. Staminal glands strongly enlarged, fused, forming a thick wall outside the stamens. Fruit unknown. Flowers: January. Elevation range: below 100 m.

*Collection studied.* COLOMBIA. CHOCO: Río Mecana, *Juncosa 1675* (MO).

*Pleurothyrium grandiflorum* represents the extreme in the tendency toward large flowers and few-flowered inflorescences in the genus. Its venation type, with a rather weakly developed marginal vein, is not specialized and its pubescence type is also rather nondescript, quite unlike the brown-tomentose pubescence which is common in *Pleurothyrium*, but rarely found in the closely related *Ocotea* and *Nectandra*. *Pleurothyrium grandiflorum* is only known from the type collection in the Chocó, an area known to be rich in endemic species.

**Pleurothyrium hexaglandulosum** van der Werff, Ann. Missouri Bot. Gard. 75: 417. 1988. TYPE: Panama. Colón: Río Guanche, 5 km upstream from road to Portobelo, *Hammel & Trainer 14781* (holotype, MO; isotypes, BR, PMA). Figures 26, 27.

Small tree, to 5 m tall. Twigs terete, densely tomentellous, solid, diameter 5 cm below tip 5 mm. Leaves alternate, chartaceous, 30–45 × 10–15 cm, obovate, gradually narrowed toward the base, the base abruptly rounded to subcordate, the tip acuminate, the upper surface glabrous, the lower surface with some small appressed hairs, especially along midrib and lateral veins; lateral veins 14–18 on each side, immersed on upper surface, raised on lower surface, the veins arching toward the tip near the margin and prominently loop-connected in the upper two-thirds of the lamina. Petioles tomentellous, ca. 5 mm long, swollen, to 5 mm thick. Inflorescences in axils of cataphylls, to 65 cm long, brown puberulous, paniculate, the branchlets 3–4 times cymosely branched, the basal

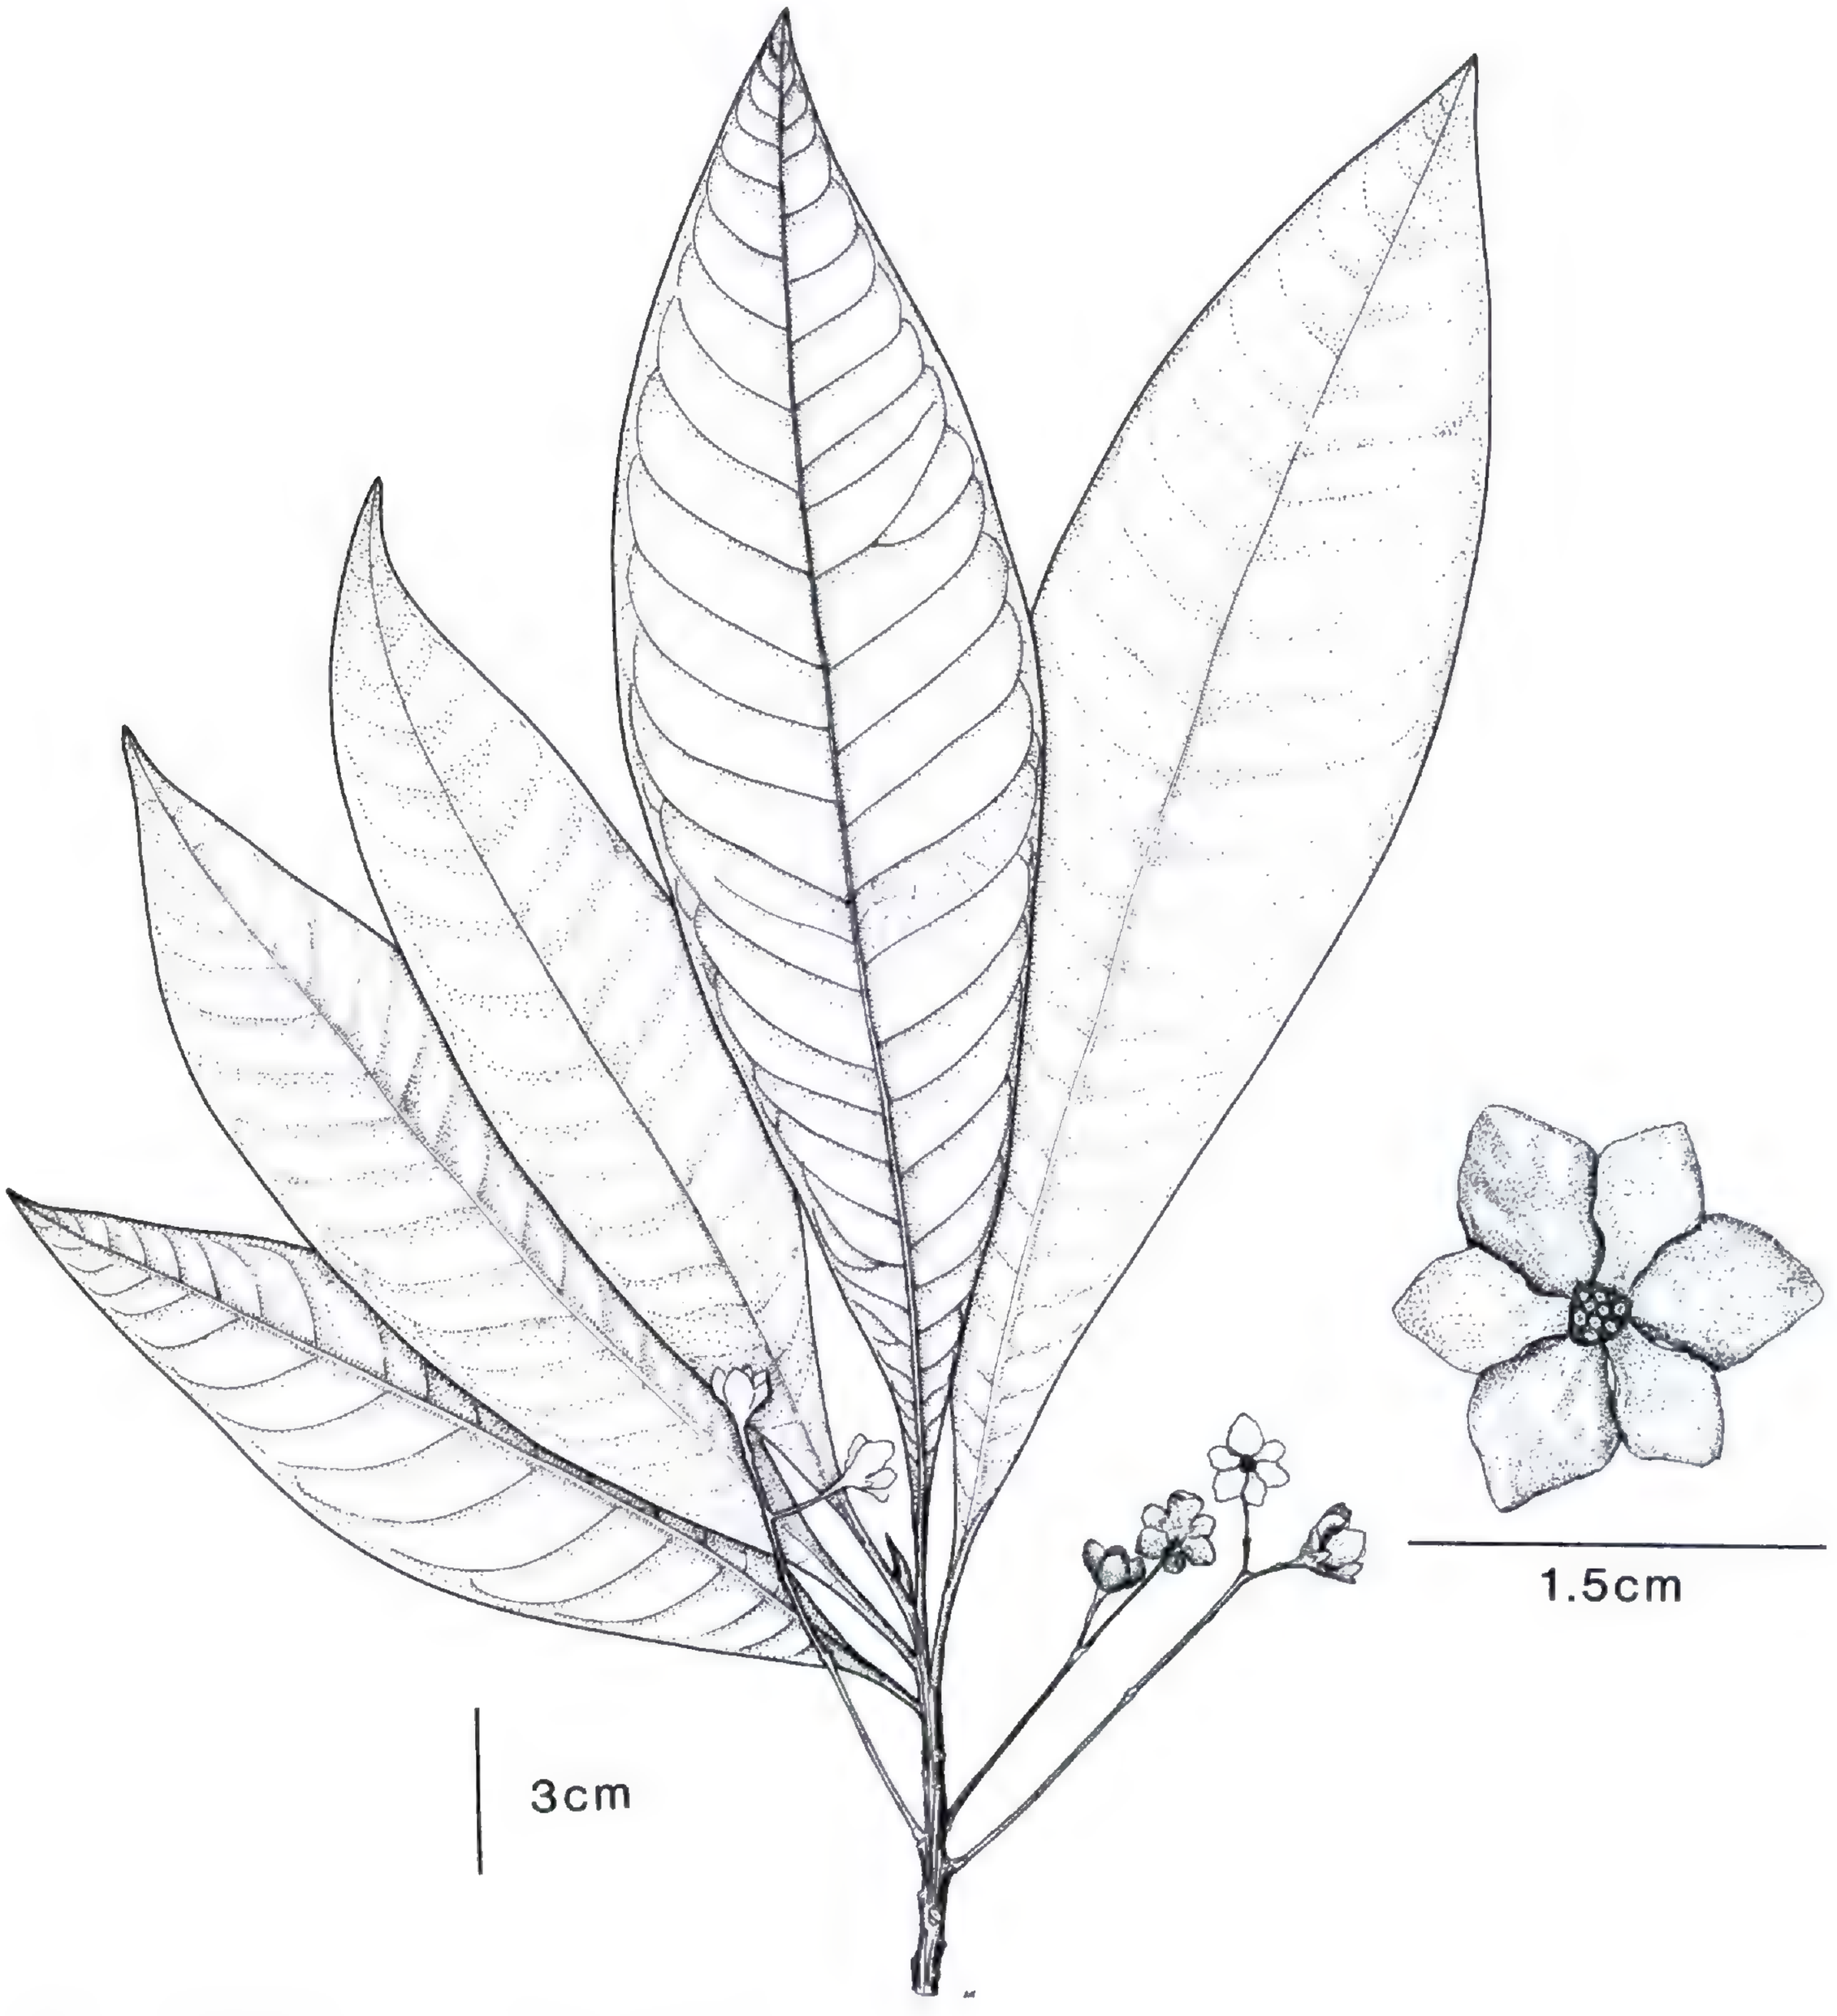

FIGURE 25. *P. grandiflorum*. Habit and flower.

branchlets to 25 cm long, the upper ones gradually shorter. Bracts absent at anthesis. Pedicels 1.5 (–2) cm long, densely gray-pubescent. Flowers ca. 10 mm diam., green, turning yellow. Tepals 6, equal, ca. 4 mm long, glabrous inside except where glands and stamens were not pressed against tepals, thus showing a narrow line of hairs in the center of the lower part of the tepal, this expended in a diamond-shaped pattern in the upper part; margin of tepals flat. Stamens 9, 4-celled, the outer six with introrse-lateral cells, the inner three with extrorse-lateral cells; in young flowers the anthers bent down and not raised above the glandular mass, but stamens becoming straight in older flowers with anthers clearly raised above the glands; filaments pubescent on the back. Glands conspicuously enlarged, but not fused, although enclosing the outer stamens. Ovary broadly ovoid, 1 × 1.5 mm, with short, gray pubescence, partly enclosed in the pubescent floral tube. Style ca. 0.5 mm long, with some gray pubescence. Glands and stamens deciduous in older flowers, leaving the ovary fully ex-

FIGURE 26. Distribution of *P. grandiflorum* (★), *P. hexaglandulosum* (●), *P. insigne* (○), and *P. intermedium* (■).

posed. Fruits unknown. Flowers: March. Elevation range: 150–200 m.

*Collections studied.* COSTA RICA. PUNTARENAS: Osa Peninsula, *Croat & Grayum 59792* (MO). PANAMA. COLON: Rio Guanche, ca. 5 km upstream from road to Portobelo, *Hammel & Trainer 14781* (BR, MO, PMA).

*Pleurothyrium hexaglandulosum* is only known from the type collection. The collection *Croat & Grayum 59792*, from the Osa Peninsula, Costa Rica, is tentatively placed here, although it differs in a number of minor characters. The twigs are almost glabrous, the inflorescences much shorter (to 15 cm long) and less pubescent, the tepals papillose, not pubescent, and the pedicels are shorter. On the other hand, the Costa Rican collection has the short, swollen petioles, the leaf shape, the pattern on the inner face of the tepals (though not as sharply outlined), and the androecial structure of the type of *P. hexaglandulosum*. Because the differences are quantitative and the leaf shape, thick petioles, and lax inflorescences are unmatched in *Pleurothyrium*, I place the Costa Rican collection in *P. hexaglandulosum*. However, if future collections show that the differences between the Panamanian and Costa Rican populations are consistent and not individual variation, it might be best to describe the Costa Rican material as a new taxon.

**Pleurothyrium insigne** van der Werff, sp. nov. TYPE: Ecuador. Napo: Reserva Biológica Jatun Sacha, tree, 12 m, tepals red outside, creamy-white inside, 13 Feb. 1987, *Palacios 1332* (holotype, MO; isotypes, AAU, C, COL, G, HBG, K, KUN, LE, NY, QAME, QRS, U). Figures 26, 28.

Arbor, ad 12 m alta. Ramuli teretes, solidi, ferrugineo-tomentosi, vetustiores glabrescentes. Folia alterna, firme chartacea, 20–60 × 7–15 cm, obovata vel anguste obovata, apice breviter acuminata vel rotundata, basi (acuta)

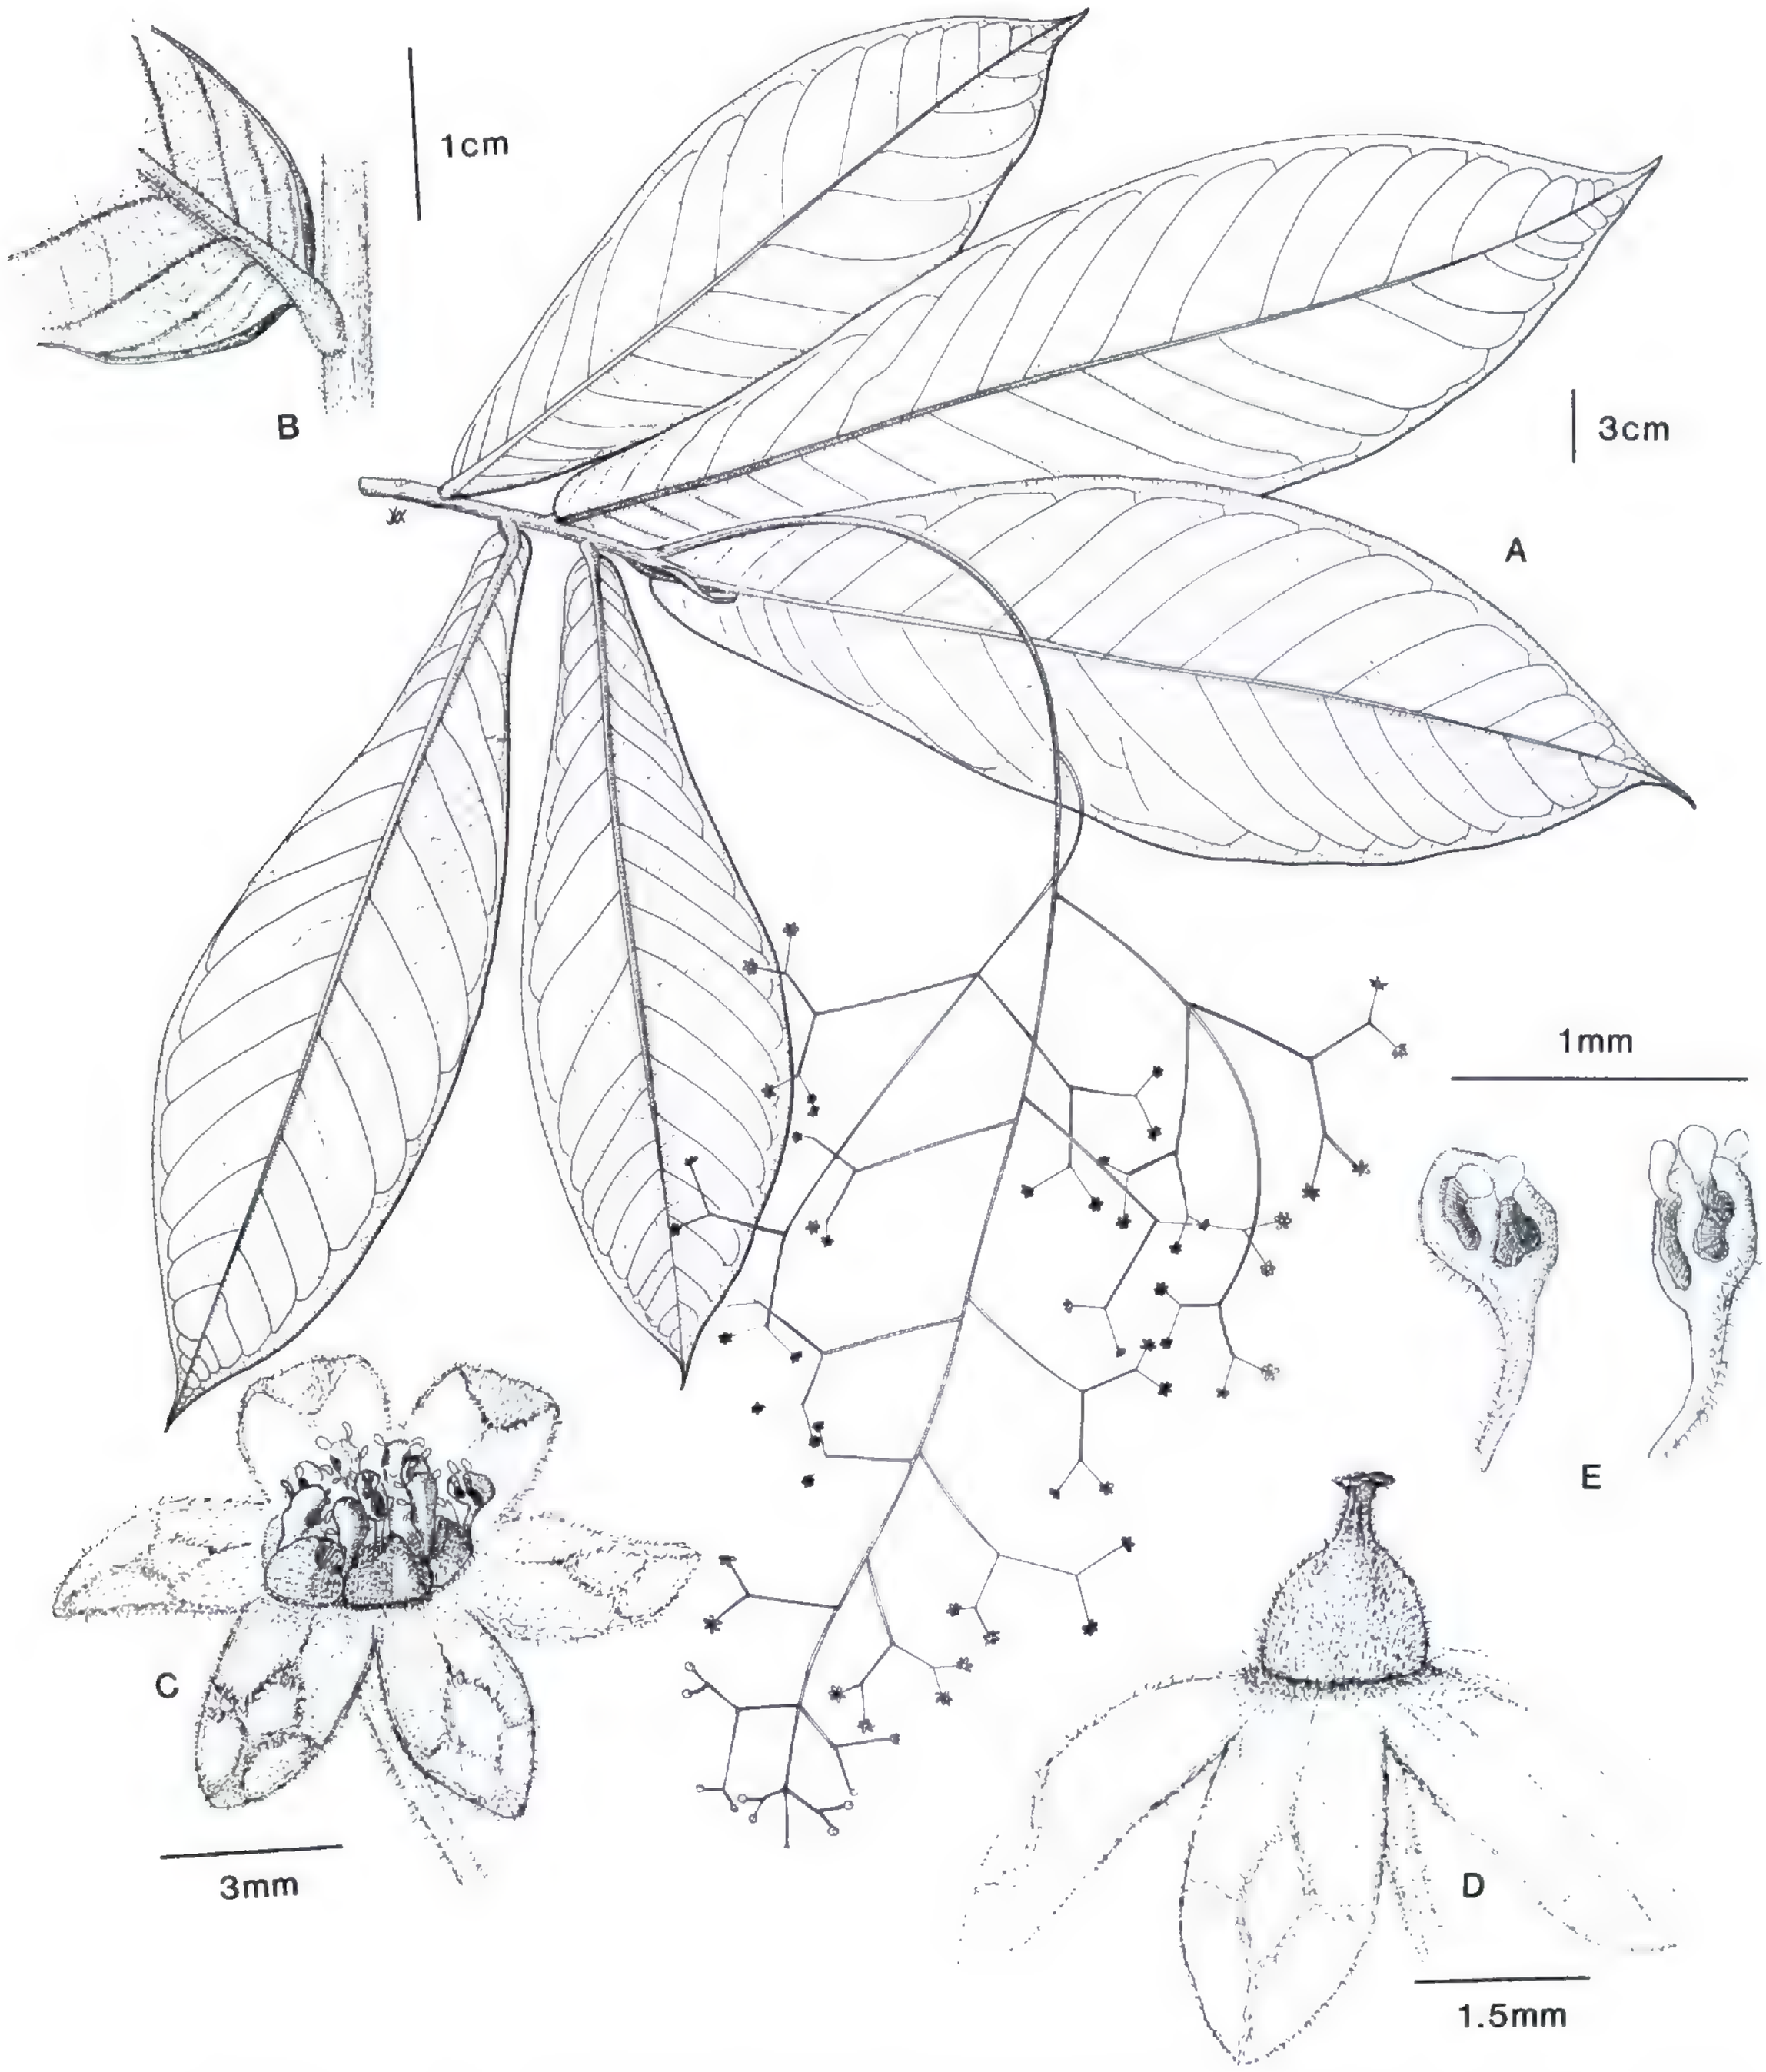

FIGURE 27. *P. hexaglandulosum.*—A. Habit.—B. Base of leaf.—C. Flower.—D. Old flower with androecium fallen off.—E. Stamens.

obtusa vel abrupte rotundata (cordata), supra praeter costae basem pubescentem glabra, subtus pilis erectis parvis praedita, indumento secus costam nervosque densiore castaneoque, venatione supra immersa, subtus costa nervisque elevatis; nervis (14–)18–26(–28) utroque costae latere, ad marginem in venam conspicuam marginalem terminantibus. Petioli 1.5–4 cm longi, ferrugineo-tomentosi. Inflorescentiae ad apices ramulorum ex axillis bractearum ortae, ferrugineo-tomentosae, ad 40 cm longae, paniculatae. Pedicelli ad 1 cm longi. Flores rotati, 12–15 mm diametro. Tepala 6, subaequalia, tres exteriora late elliptica, 5–6 × 4–5 mm, extus tomentella, intus minute papillosa; tres interiora 4–5 × 2.5 mm, extus basi tomentella, demum papillosa, intus papillosa. Stamina 9, 4-locellata, locellis lateralibus, glandulis permagnis, stamina cingentibus, staminodia parva, 3. Ovarium (depresse) globosum, ca. 1.5 mm diametro, basi glabrum, demum ferrugineo-tomentellum; stylo ca. 1 mm longo. Receptaculum intus tomentellum. Cupula verrucosa, 1.5 × 2.5 cm; fructus ellipsoideus, 2.5 × 2 cm.

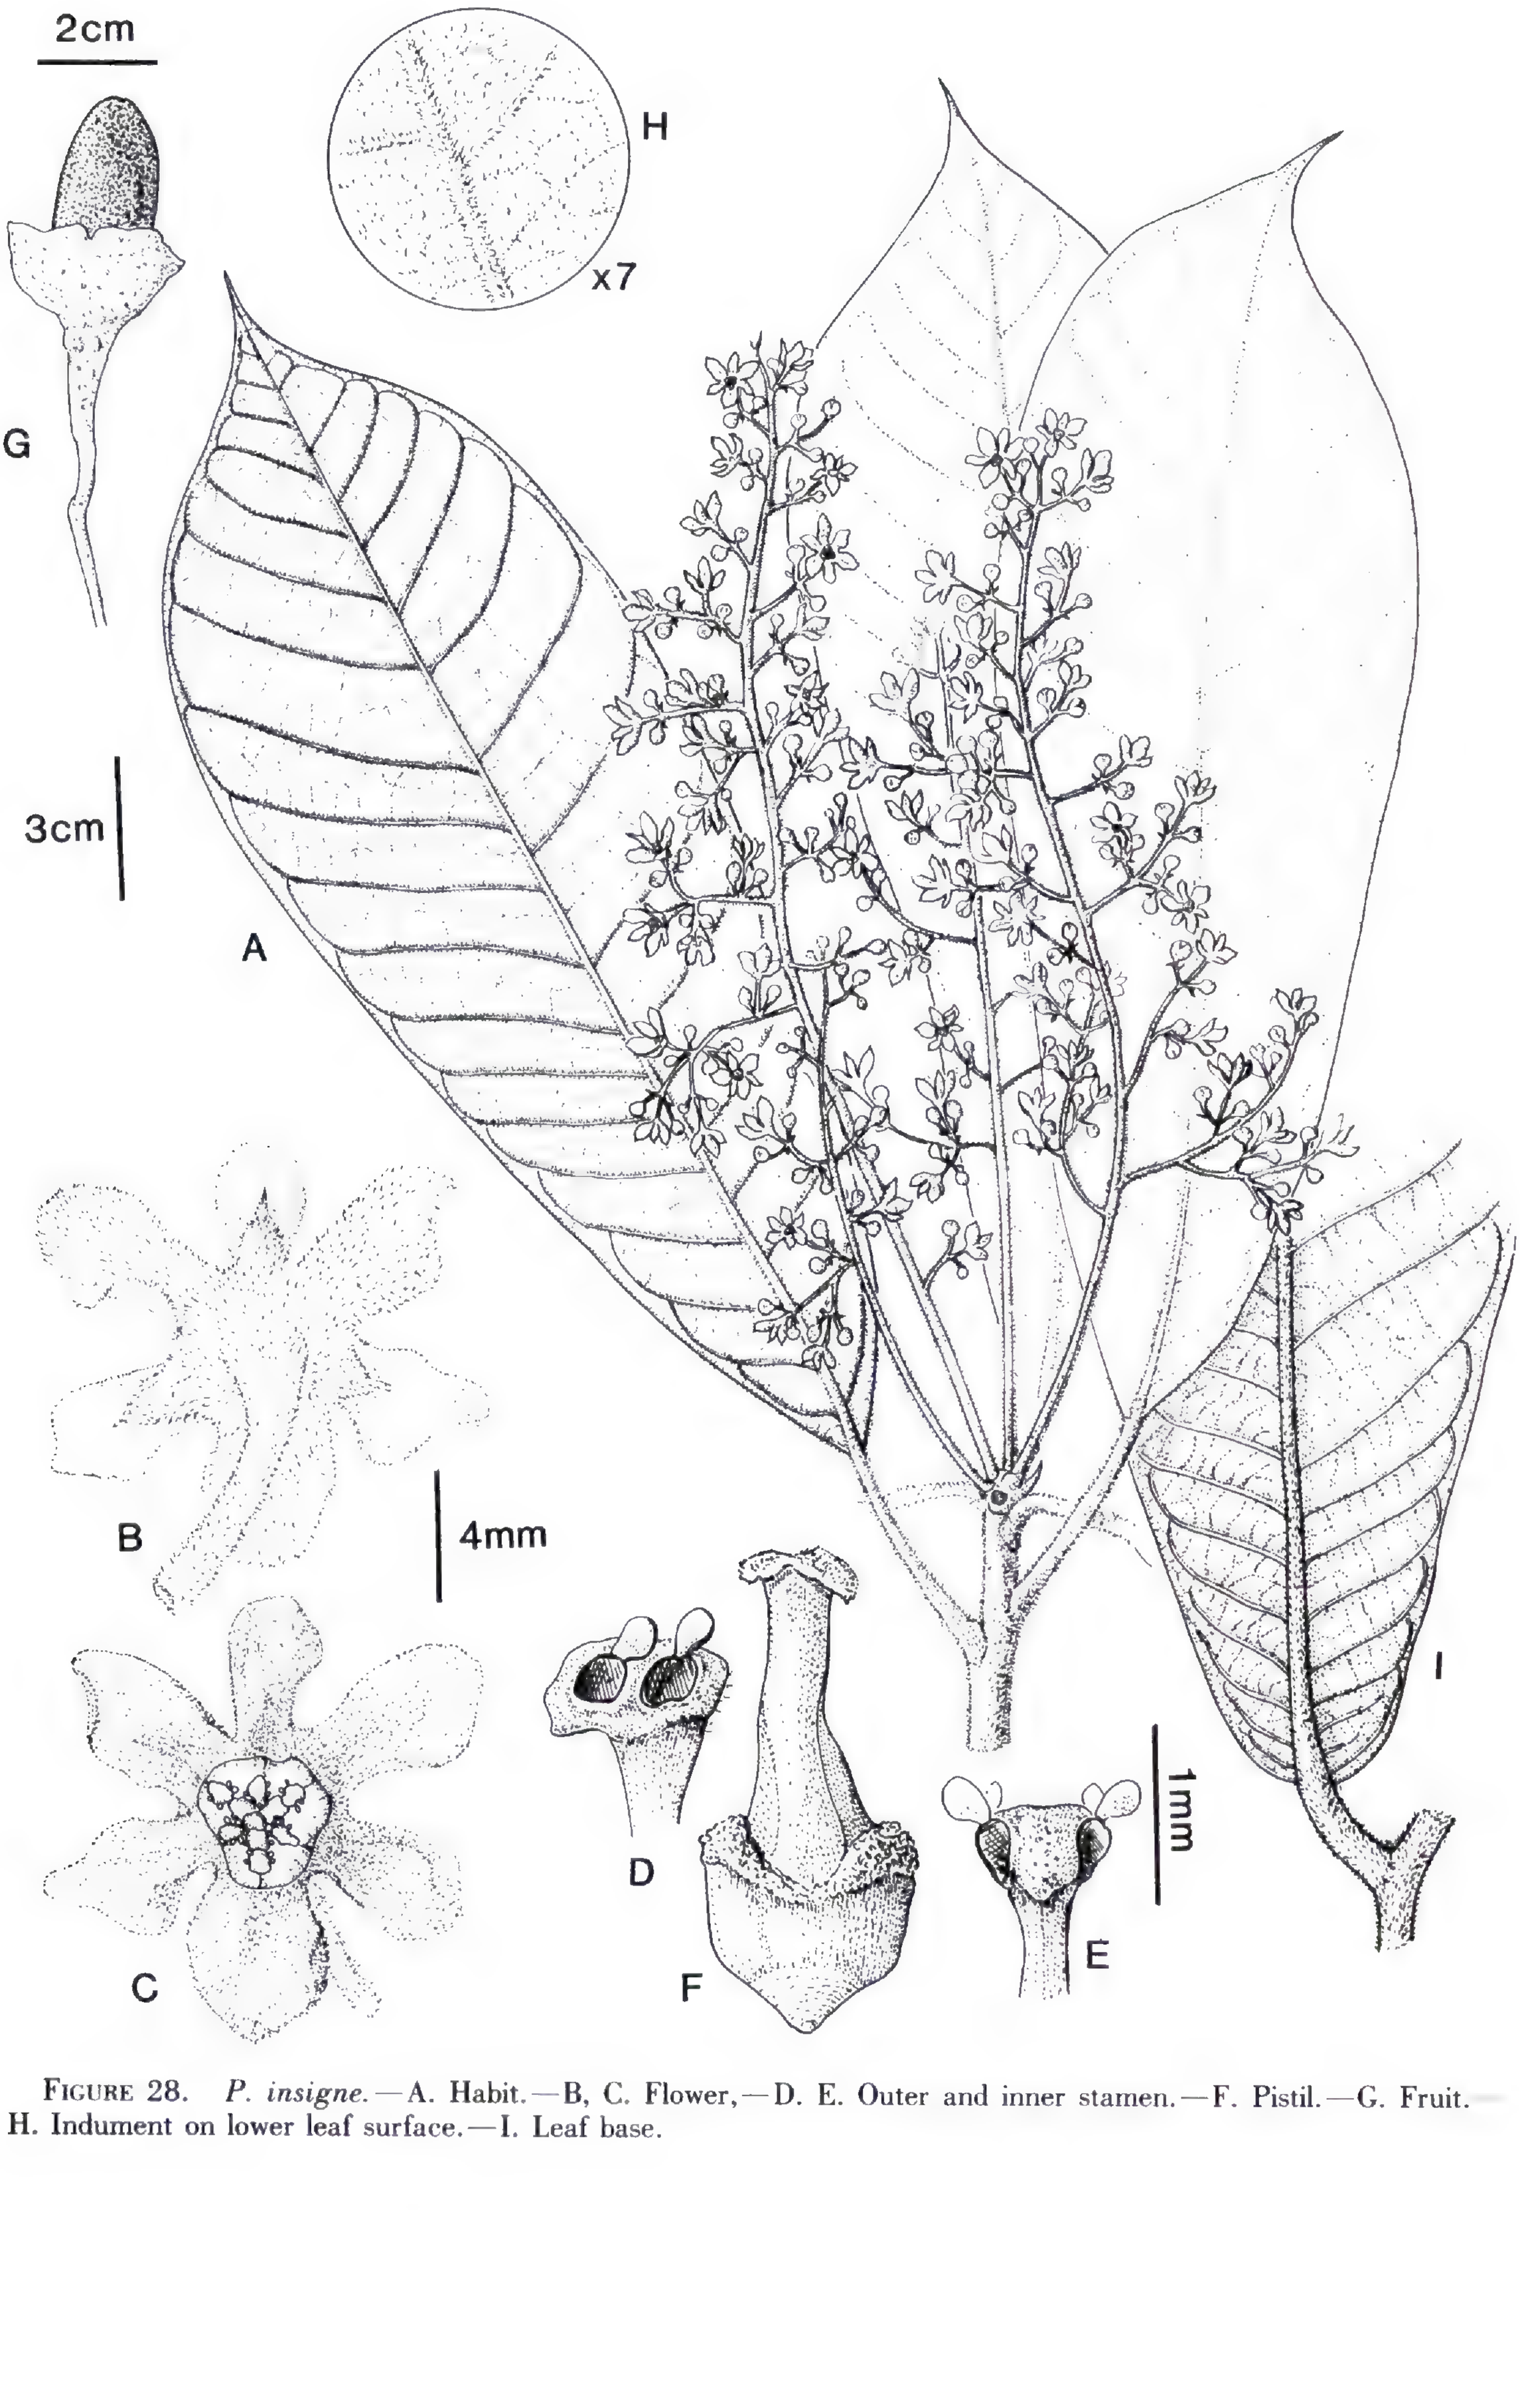

FIGURE 28. *P. insigne.*—A. Habit.—B, C. Flower,—D. E. Outer and inner stamen.—F. Pistil.—G. Fruit.—H. Indument on lower leaf surface.—I. Leaf base.

Small tree, to 12 m tall. Twigs solid, terete, 5–9 mm diam. 5 cm below the tip, ferruginous tomentose, but glabrescent with age. Leaves alternate, firmly chartaceous, 20–60 × 7–15 cm (narrowly) obovate, the base (acute) obtuse, abruptly rounded or cordate, the tip rounded or shortly acuminate; upper surface with some pubescence at the base of the midrib, otherwise glabrous, lower surface with an indument of erect hairs, this much denser on midrib and lateral veins; venation immersed on upper surface, midrib, lateral veins and marginal vein prominently raised on lower surface; lateral veins (14–)18–26(–28), connected by a conspicuous marginal vein. Petioles 1.5–4.0 cm long, to 5 mm diam., castaneous tomentose. Inflorescences clustered near tips of branches in axils of cataphylls, rarely along leafless short-shoots, 15–40 cm long, paniculate, ferruginous tomentose. Bracts of inflorescences, if present, to 4 mm long, ovate, tomentose outside, nearly glabrous inside. Pedicels to 1 cm long. Flowers reddish outside, greenish white inside, the tepals spreading, 12–15 mm diam. Tepals 6, subequal, outer 3 elliptic, 5–6 × 4–5 mm, tomentose outside, papillose inside, inner 3 elliptic, ca. 5 × 2.5–3 mm, outside with a basal, triangular, tomentose patch, otherwise papillose; inside papillose. Stamens 9, 4-celled, the cells lateral; staminodia 3, minute, linear, ca. 0.3 mm long, hidden by stamens and glands. Glands of inner stamens strongly enlarged and enclosing the outer stamens, forming a large mass, but not fully fused. Ovary (depressed) globose, ca. 1.5 mm diam., the base glabrous, upper part pubescent. Style ca. 1 mm long. Floral tube shallow, pubescent within. Cupule 1.5 × 3.5 cm or smaller, warty. Fruit ellipsoid, ca. 2.5 cm long, well exserted from cupule. Fruits: August–February. Flowers: June–November. Elevation range: 100–450 m.

*Collections studied.* BRAZIL. AMAZONAS: Humaita, near Tres Casas, *Krukoff 6232* (A, G, K, MO, NY, S, US). ECUADOR. *Pleurothyrium insigne* is a striking species, easily recognized by its large, obovate leaves with a pronounced marginal vein, the castaneous-tomentose indument of twigs, and the erect hairs on the lower leaf surface. Initially, I divided the specimens included in *P. insigne* between two species, one with abruptly rounded or cordate leaf base and short petioles (to 2 cm long), the other with an obtuse leaf base and longer (3–4 cm) petioles. Because some collections (for instance, *Krukoff 6232*) include specimens with obtuse and abruptly rounded leaf bases and the difference in petiole length is not consistent, I decided to place all specimens in one species, even though the extremes look quite different. The specimens with an abruptly rounded to cordate leaf base are very similar to *P. maximum*; the latter differs only in its glabrous lower leaf surface, smaller flowers, equal tepals, and relatively smaller glands. *Pleurothyrium maximum* is largely recognized because of the floral differences. I consider such differences as fundamental in *Pleurothyrium* and expect that additional collections of *P. maximum* will show that these differences will be consistent.

*Pleurothyrium insigne* is known from several widely scattered localities in Ecuador, Peru, and Brazil. The best collections are from the Jatun Sacha Biological Station, where the species is locally common. All collections from that area have leaves with an obtuse base; Peruvian collections and the sole Brazilian collection can have obtuse or abruptly rounded/cordate leaf bases.

**Pleurothyrium intermedium** (Mez) Rohwer, Mitt. Inst. Allg. Bot. Hamburg 20: 43. 1986. *Nectandra intermedia* Mez, Repert. Spec. Nov. Regni Veg. 16: 308. 1920. TYPE: Brazil. Acre: Seringal São Francisco, *Ule 9408* (holotype, B; isotype, K). Figure 26.

Tree or shrub, 5–20 m tall. Twigs terete, solid, sparsely pubescent to glabrous, diameter 5 cm below the apex ca. 3 mm. Terminal buds densely appressed yellowish pubescent, the bud contrasting with the dark twig. Leaves alternate, chartaceous, elliptic to obovate-elliptic, 9–16 × 3–5 cm, the base acute, the tip obtuse, upper surface glabrous, the venation immersed, the lower surface glabrous or nearly so, the midrib raised, lateral veins weakly raised; lateral veins 10–12 on each side, arching upward near the margin, not or very weakly connected with the superior vein. Petioles ca. 1.5 cm long, with similar tomentum as twigs. Inflorescences in axils of deciduous bracts, ca. 12 cm long, paniculate, the branchlets with racemosely arranged cymes, often the two lateral flowers of a cyme missing; main axis sparsely pubescent, the

FIGURE 29. *P. marginale.*—A. Habit.—B. Flower.—C. Base of leaf underside, showing indument.

branchlets denser pubescent, pedicels almost white pubescent, 2–3(–5) mm long. Flowers yellowish green, ca. 3 mm diam., the tepals ± erect at anthesis. Tepals 6, equal, ovate, ca. 2 mm long, puberulous outside, papillose inside, the margin reflexed. Stamens 9, 4-celled, the cells lateral, filaments glabrous, about as long as the anthers, glands enlarged, but not fused and not surrounding the outer stamens, but visible as large lobes separating the outer stamens; anthers raised above the level of the glands. Ovary glabrous, ovoid, gradually narrowed into the short style, stigma platelike; pistil 1.8 mm long. Floral tube glabrous inside. Fruit unknown. Flowers: August. Elevation range: 100–200 m.

*Collections studied.* BOLIVIA. SANTA CRUZ: Ichilo, Reserva Forestal Chore, Camp. Arroyo Perdido, *Neill 9435* (MO, QCNE), *Neill 9439* (MO, QCNE). BRAZIL. AMAZONAS: Seringal São Francisco, *Ule 9408* (B, K). PERU. MADRE DE DIOS: Tambopata, Hermosa Chica, *Pesha 10* (MO).

*Pleurothyrium intermedium* is only known from the type collection, two recent collections from Bolivia, and one recent collection from Peru. It belongs to the group of species with erect tepals at anthesis and is most closely related to two other, equally poorly known, species from Brazil (*P. amplifolium* and *P. undulatum*). More collections are needed for a better understanding of the status of those three species.

**Pleurothyrium marginale** van der Werff, sp. nov. TYPE: Colombia. Valle: Río Cajambre near Barco on the Pacific coast, elev. 5 80 m, *Cuatrecasas 17196* (holotype, US; isotype, F). Figures 29, 30.

FIGURE 30. Distribution of *P. marginale* (★), *P. maximum* (●), *P. nobile* (○), and *P. obovatum* (■).

Arbor, ad 20 m. Ramuli teretes, solidi, minute fusco-puberuli, glabrescentes. Folia alterna, firme chartacea, elliptica, 8–14 × 3–5 cm, basi acuta vel attenuata, apice acuminata, supra glabra vel paucis pilis adpressis munita, subtus sparse adpresse strigosa, indumento densiore secus costam nervosque laterales; nervis lateralibus 8–12 utroque costae latere. Venatio brochidodroma, supra immersa, subtus costa, nervis lateralibus et venatione tertia elevata. Petioli 15–22 mm longi. Inflorescentiae ex axillis bractearum ortae, fusco-tomentulosae, 4–6 cm longae, racemosae, uni- vel biflorae, bracteis sub anthesi absentibus. Pedicelli ca. 4 mm longi, pedunculi ca. 9 mm longi, fusco-tomentulosi. Tepala 6, subaequalia, 3 exteriora late ovata, ca. 5 mm longa, 3 interiora rhomboidea, basi late et breviter stipitata, ca. 4 mm longa, in sicco utrinque fusco-tomentella. Stamina 9, 4-locellata, locellis lateralibus, antheris glabris, glandulis incrassatis, coalitis, stamina cingentibus. Ovarium ellipsoideum, glabrum, ca. 0.8 mm longum; stylum glabrum, ca. 1 mm longum, stigma peltatum. Tubus floralis glaber. Fructus perjuvenalis in tubo florale inclusus; fructus adultus ignotus.

Tree, 20 m tall. Twigs terete, solid, minutely brown-puberulous, glabrescent, ca. 3 mm diam. 5 cm below the tip. Leaves alternate, not clustered, firmly chartaceous, elliptic, 8–14 × 3–5 cm, the base acute to attenuate, the tip acuminate, the upper surface glabrous or with some minute hairs, especially near the base of the midrib, the lower surface with scattered, minute, appressed hairs, these denser along midrib and lateral veins; venation brochidodromous, immersed on upper surface, midrib and lateral veins raised on lower surface, a marginal vein well developed; lateral veins 8–12 on each side. Petioles 15–22 mm long, flattened on upper surface, pubescence similar to that of twigs. Inflorescences in axils of cataphylls, brown-tomentulose, 4–6 cm long, racemose, 1–2-flowered (but probably several flowers fallen off), bracts absent at anthesis. Flowers yellow fide collector, ca. 12 mm diam. Pedicel ca. 4 mm long, peduncle ca. 9 mm long, brown-tomentulose. Tepals 6, subequal, the outer three broadly ovate, ca. 5 mm long, the inner three mostly rhombic with a short, broad stalk, ca. 4 mm long; both inside and outside brown tomentellous in sicco. Stamens 9, 4-celled, the cells lateral, opening back-to-back, anthers glabrous; glands enlarged, fused, enclosing the stamens. Ovary ellipsoid, ca. 0.8 mm long, glabrous, style glabrous, ca. 1 mm long, stigma platelike. Floral tube

glabrous inside. Very young fruit fully enclosed in the enlarged floral tube; mature fruit unknown. Flowers: April. Elevation range: below 100 m.

*Collection studied.* COLOMBIA. VALLE: Costa del Pacifico, Río Cajambre, *Cuatrecasas 17196* (F, US).

A species only known from the type collection, *Pleurothyrium marginale* derives its name from its well-developed marginal vein. This species can be readily identified also by the sparse, appressed indument on the lower leaf surface and the few-flowered inflorescences. The collector indicated that the tree had tall buttresses (as in *Cecropia*) and canary-yellow wood. Buttresses are rare among neotropical Lauraceae: I have only seen them in a *Caryodaphnopsis* species from Peru. Yellow wood is a common feature in *Aniba*, but is infrequent outside this genus. The wood is used for making boards and canoes; the common name is palo blanco.

**Pleurothyrium maximum** O. C. Schmidt, Notizbl. Bot. Gart. Berlin-Dahlem 10: 235. 1928. *Ocotea maxima* (O. C. Schmidt) Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. TYPE: Peru. Amazonas: mouth of Río Santiago, Pongo de Manseriche, terra firma forest, 160 m elev., *Tessman 4040* (holotype, B; isotypes, G, NY). Figure 30.

Small tree, 4–6 m tall. Twigs terete, solid, ferruginous tomentose, glabrescent in age, 5–6 mm diam. a few cm below the tip. Leaves alternate, chartaceous or firmly chartaceous, 30–50 × 7–15 cm, obovate to narrowly obovate, gradually narrowed toward the base, the base abruptly rounded to cordate, the tip acute to acuminate, glabrous above, the lower surface with a few scattered, minute, appressed hairs, otherwise glabrous; midrib and lateral veins immersed on upper surface, prominently raised on lower surface, the tertiary venation weakly raised. Lateral veins 20–30 on each side, near the margin connected by a conspicuous marginal vein. Petioles 1–2 cm long, 4–5 mm diam., with similar pubescence as the twigs. Inflorescences slender, lax, 40–65 cm long, ferruginous tomentose, the branchlets once or twice cymosely branched, in axils of cataphylls at tips of twigs, bracts mostly lacking at anthesis. Pedicels 5–9 mm long, ferruginous tomentose. Flowers rotate, ca. 8–9 mm diam. dark green-red-brown outside, dark green inside, the glands bright green, stamens yellowish. Tepals 6, equal in shape and size, 2.5 × 1.5 mm, the margin flat, the outer three ferruginous tomentellous outside, the inner three with a basal, triangular, tomentellous patch, otherwise glabrous; all tepals glabrous inside except for a narrow line of short hairs in the center of the lower part, this expanded into a diamond-shaped outline in the upper part. Stamens 9, 4-celled, the outer six with 2 cells lateral and 2 cells introrse, the inner three with one pair lateral and one extrorse; glands enlarged, protruding between and ± enclosing the outer stamens, but definitely free. Immature ovary globose to ovoid, 1–1.5 mm long, covered with short brown hairs; style glabrous. Floral tube inside covered with short reddish hairs. Fruit and cupule unknown. Flowers: September–November. Elevation range: below 200 m.

*Collections studied.* PERU. AMAZONAS: mouth of Río Santiago, Pongo de Manseriche, *Tessmann 4040* (B, G, NY), *Tessmann 4529* (B, G, NY).

*Pleurothyrium maximum* is only known from two collections from the area where the Río Santiago joins the Río Marañon, in northern Peru. It is vegetatively similar to *P. insigne*, which see for further discussion. *Pleurothyrium maximum* also resembles *P. williamsii*, which differs in its narrower leaves (5 cm above the base, 2–3.5 cm wide vs. 5–6 cm wide), shorter indument on twigs (or glabrous) and inflorescences, thinner leaves that dry dark green, and shorter inflorescences (but few inflorescences are known). In *P. maximum* the glands of the stamens are free and do not form a wall surrounding the stamens, while in *P. williamsii* the glands do form a wall, with only a faint line indicating the boundaries of the individual glands.

**Pleurothyrium nobile** A. C. Smith, Phytologia 1: 120. 1935. *Ocotea nobilis* (A. C. Smith) Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. TYPE: Brazil. Amazonas: near mouth of Rio Embira, *Krukoff 5121* (holotype, NY not seen; isotypes, A, B, G, K, MO, S, US). Figure 30.

Tree, 25 m tall. Twigs solid, terete or ridged, glabrous, 6–7 mm diam. 5 cm below the apex. Terminal bud brown-tomentellous. Leaves alternate, stiffly chartaceous, elliptic, 15–30 × 6–12 cm, the base obtuse to rounded, the tip acute, glabrous on both surfaces, venation immersed on upper surface, midrib and lateral veins raised on lower surface, tertiary venation weakly raised on lower surface, lateral veins 7–10 on each side, arching upward near the margin, but not or very weakly connected with the superior vein. Petioles 2–3 cm long, glabrous, canaliculate. Inflorescences in axils of cataphylls, to 12 cm long, minutely

puberulous, glabrescent, paniculate, the branchlets 3–4 times cymosely branched, few-flowered, bracts not present at anthesis. Pedicels 3–4 mm long. Flowers ca. 10 mm diam. Tepals 6, equal, brown-puberulous on outside, minutely brown-papillose to glabrous inside, ovate, ca. 4 mm long. Stamens 9, 4-celled, the cells lateral, anthers and upper part of filaments brown-papillose, glands large, completely surrounding the stamens but not fully fused. Ovary ovoid, ca. 2 mm long, the lower part glabrous, the upper part brown-papillose, except for six large glabrous spots, where glands were in contact with ovary; style poorly differentiated, brown-papillose, 0.2 mm long. Floral tube glabrous inside. Cupule and fruits unknown. Flowers: June–July. Elevation range: 200–300 m.

*Collections studied.* BRAZIL. AMAZONAS: mouth of Rio Embira, *Krukoff 5121* (A, B, G, K, MO, NY, S, US). PERU. HUANUCO: Puerto Inca, Dtto. Llullapichis, *Kroll 285* (MO), *Kroll 422* (MO). LORETO: Coronel Portillo, Km 98 carretera Pucallpa–Huanuco, *M. Castillo 12* (F, K, MO, NY, US, WIS), *M. Castillo 15* (F, K, US).

*Pleurothyrium nobile* is rarely collected and is known only from five collections. The type collection was made in varzea forest, two later collections (both from the same tree) in dry tropical forest, and two from wet forest. The recent collections have smaller, less-branched inflorescences, but the collections agree well in leaf shape, type of indumentum, and floral characteristics. Smith (1935) cited *Krukoff 4800* as a paratype of *P. nobile*. Because this collection has a whitish, very short appressed indument on lower leaf surface, acuminate leaf tips, and slender inflorescences, I include it in *P. panurense* (Meissner) Mez. The common name for the species in Peru is *lobo moena*.

**Pleurothyrium obovatum** van der Werff, sp. nov. TYPE: Ecuador. El Oro: 15 km NW of Paccha on the road to Pasaje, 1,800 m elev., *Brandbyge 42366* (holotype, AAU). Figures 30, 31.

Arbor parva, ad 10 m alta. Ramuli teretes, fistulosi. Gemma terminalis ferrugineo-tomentella. Folia alterna, perobovata, 40–45 × 16–20 cm, firme chartacea, basi acuta, apice rotundata vel breviter acuminata, glabra. Nervi laterales ca. 20 utroque costae latere, venatione leviter brochidodroma. Inflorescentiae ex axillis bracteārum ortae, interdum fistulosae, ferrugineo-tomentelli, 20–30 cm longae, paniculatae. Flores ca. 11 mm diametro. Tepala 6, aequalia, elliptica, dense tomentella vel papillosa. Stamina 9, 4-locellata, locellis interioribus extrorsis, superioribus lateralibus, antheris erectis, super glandulas prominentibus. Glandulae liberae. Ovarium ellipsoideum, glabrum, stylo ca. 1 mm longo, papillis ferrugineis praedito. Tubus floralis glaber. Fructus ignoti.

Small tree, to 10 m tall. Twigs terete, fistulose, with scattered small, erect ferruginous hairs, diameter of twigs 5 cm below tip ca. 9 mm. Terminal bud minutely, but densely, ferruginous tomentellous. Leaves alternate, strongly obovate, 40–45 × 16–20 cm, firmly chartaceous, gradually narrowed to the acute base, the tip blunt or with a very short acumen, glabrous on both surfaces, midrib slightly raised or immersed, otherwise venation immersed on upper surface, midrib prominently raised on lower surface, lateral veins and tertiary venation progressively less raised. Lateral veins ca. 20 on each side, near the margin arching upward and in the distal half of the lamina connected with the superior vein, but a marginal vein not well developed. Petioles ca. 2 cm long, glabrous or with some scattered ferruginous hairs, 5 mm diam. Inflorescences in axils of cataphylls, sometimes fistulose, ferruginous-tomentellous, 20–30 cm long, paniculate, the lateral branches 2–3 times cymosely branched, many-flowered, bracts deciduous at anthesis. Pedicels ca. 3 mm long, gradually widened in floral tube. Flowers outside ferruginous brown, inside whitish, ca. 11 mm diam., rotate. Tepals 6, equal, 4 mm long, elliptic, densely tomentellous or papillose on both surfaces, the margins plane. Stamens 9, 4-celled, the lower pair extrorse, the upper pair lateral, the cells large; anthers erect and raised well above the glands. Glands not completely enclosing the outer stamens, not fused. Ovary ellipsoid, ca. 1.5 mm long, glabrous, gradually narrowed into the style, this ca. 1 mm long and with some ferruginous papillae; stigma platelike. Floral tube glabrous inside. Very young fruit fully enclosed in floral tube. Fruits and cupules unknown. Flowers: September. Elevation range: 1,000–1,800 m.

*Collections studied.* ECUADOR. AZUAY: Cuenca, El Sillado, Parque Molleturo, *Ortiz-Proyecto Molleturo 192* (MO). EL ORO: Pasaje, 15 km NW of Paccha on road to Pasaje, *Brandbyge 42366* (AAU). LOJA: 15 km E of Alamor on road to Celica, *Brandbyge 42343* (AAU).

*Pleurothyrium obovatum* is only known from three recent collections in southern Ecuador. The fistulose (lenticellate?) branches, relatively small glands of the stamens, and floral shape indicate a close relationship to the *P. cuneifolium* group. *Pleurothyrium obovatum* is, however, easily recognized by the ferruginous indument, which becomes floccose on older twigs, and obovate, glabrous leaves. The large, erect anthers are another character of this species. The leaves of the two Brandbyge collections are more narrowed toward the base than the Ortiz collection, and it is likely

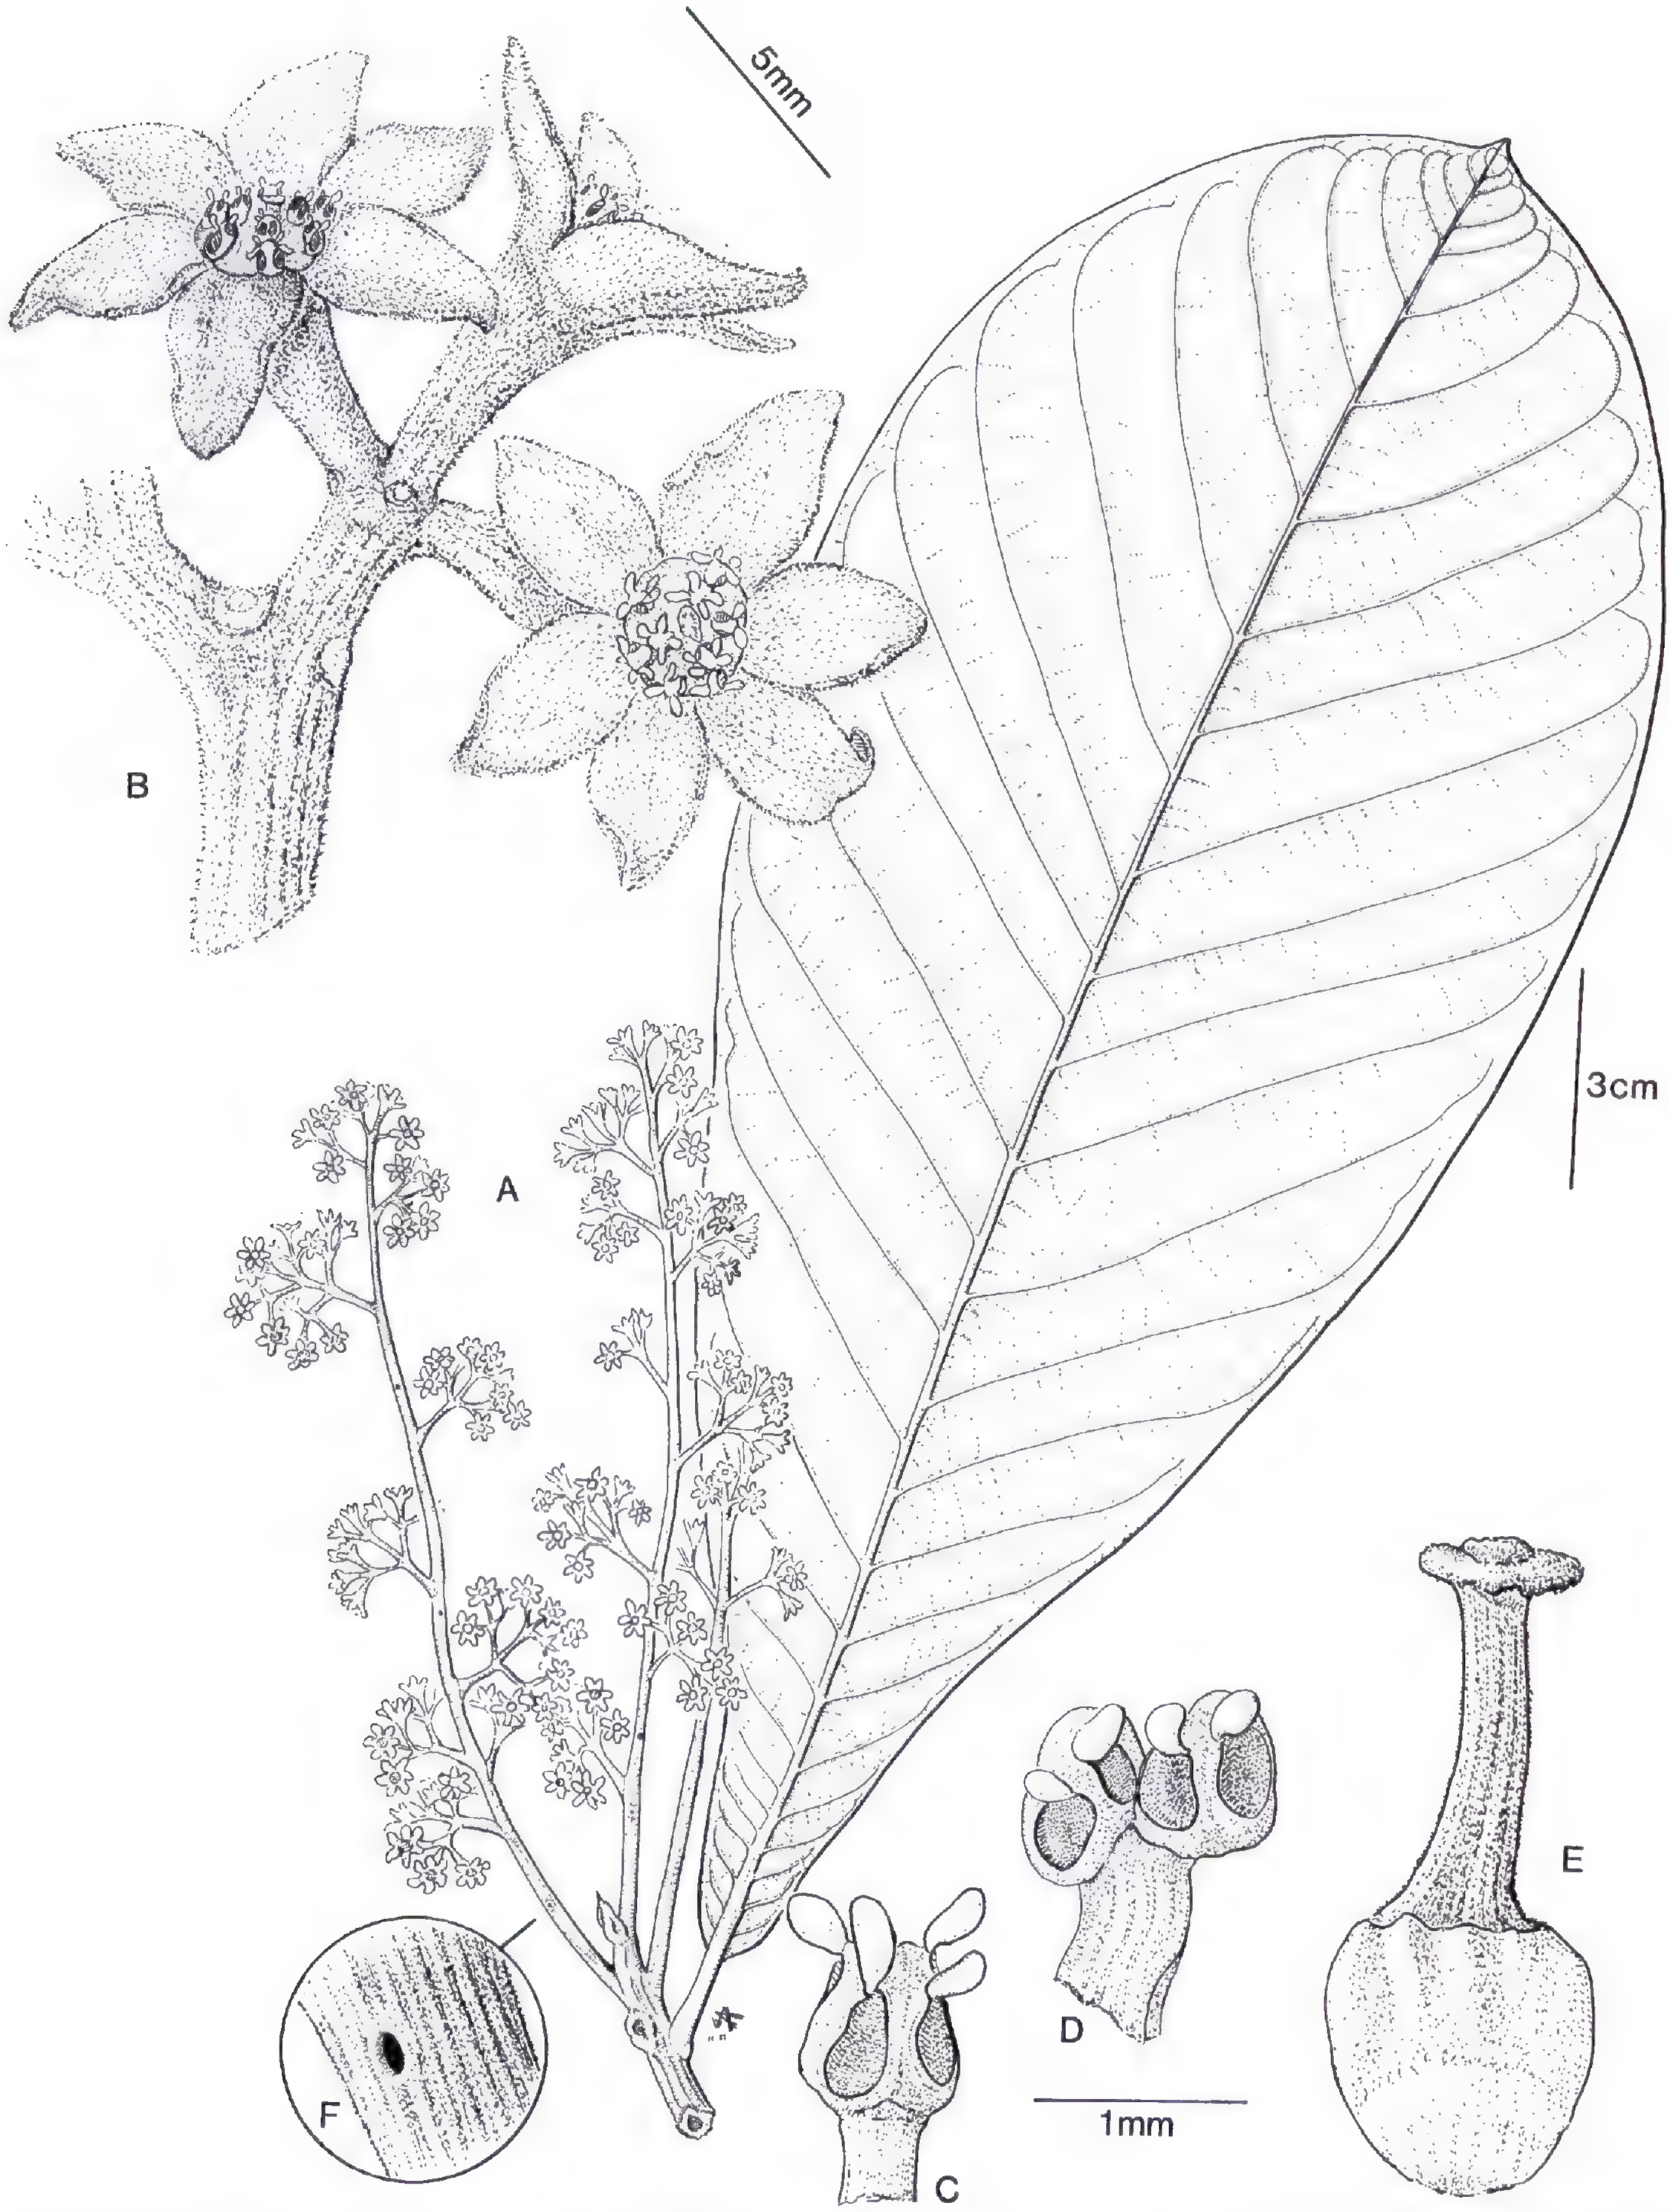

FIGURE 31. *P. obovatum.*—A, Habit.—B. Flowers.—C. Stamen (Whorl I).—D. Stamens (Whorls I and III) with fused filaments.—E. Pistil.—F. Detail of inflorescence axis, showing hole used as passage by ants.

FIGURE 32. Distribution of *P. palmanum* (★), *P. panurense* (●), and *P. prancei* (○).

that the few collections do not show the full range of morphological variation.

**Pleurothyrium palmanum** (Mez & J. D. Smith) Rohwer, Mitt. Inst. Allg. Bot. Hamburg 20: 41. 1986. *Ocotea palmana* Mez & J. D. Smith, Bot. Gaz. (Crawfordsville) 33: 258. 1902. TYPE: Costa Rica. San José: La Palma, *Tonduz CR 12652 = J. D. Smith Herb. 7374* (B, GH, US: also reported in K, M; holotype not designated). Figure 32.

Trees, to 20 m tall. Twigs solid, ridged or terete, tomentulose with brown or yellow-brown hairs. Terminal bud tomentulose. Leaves alternate, clustered near the tips of branches, chartaceous, 15–28 × 7–15 cm, obovate or broadly obovate, the base cuneate or acute, the tip rounded or with a very short, blunt acumen, upper surface with short, brown pubescence along midrib, otherwise glabrous, lower surface densely yellow-brown to brown-tomentulose, sometimes with taller hairs mixed in, lateral veins 5–9 on each side, these arching toward the tip and becoming weakly loop-connected in the distal half of the lamina; venation immersed on the upper surface or the midrib slightly raised, midrib and lateral veins elevated on lower surface, tertiary venation slightly raised. Petioles 1–2 cm long, terete, with similar pubescence as twigs. Inflorescences in axils of cataphylls, 4–10 cm long, paniculate, the branchlets once cymosely branched, rarely depauperate and racemose, with up to 20 flowers, brown-tomentellous, bracts subtending flowers sometimes persisting, these elliptic, to 4 mm long, tomentellous on both surfaces. Pedicels ca. 3 mm long, tomentellous. Flowers ca. 10–12 mm diam. Tepals 6, equal in size, ca. 5 mm long, elliptic, the outer three tomentellous outside, inner three papillose except for the tomentellous base; all tepals papillose inside. Stamens 9, 4-celled, the cells lateral, the valves nearly back-to-back; filaments and anthers each ca. 1 mm long, papillose; glands large, partially fused, but not enclosing all outer stamens. Style ca. 1.5 mm long, papillose;

ovary globose, glabrous, ca. 1 mm long, enclosed in the glabrous floral tube. Cupule and fruit unknown. Flowers: November. Elevation range: 1,000–1,600 m.

*Collections studied.* COSTA RICA. LA PALMA: *Rowlee 233* (F, US), CARTAGO: *Barbour 1011* (F, MO). PUNTARENAS: Reserva Biológica Monteverde, Powell Trail, Pacific slope, *Haber 9526* (MO). SAN JOSE: La Palma, *Tonduz 12652* (B, GH, US). PANAMA. CHIRIQUI: Palo Alto, just E of Boquete, *Stern et al. 1064* (MO).

*Pleurothyrium palmanum* is a rarely collected species. The concept of this species accepted here is different from that in Burger & van der Werff (1990); one of the two flowering collections cited in that publication (*Barbour 1012*) is here excluded from *P. palmanum*. It differs in its indument (lower leaf surface is nearly glabrous, not entirely covered by a brown-tomentellous indument) and flower structure (glands are fused and enclosing stamens, not only partly fused and not enclosing stamens). The only flowering collections I have seen are the type and *Haber 9526*. The glands in *P. palmanum* are not strongly enlarged and the stamens are erect, with the lower pair of locelli lateral and the upper introrse. The available collections are quite variable in leaf size. The type has large (18–28-cm-long) leaves; *Barbour 1011*, a sterile collection, has leaves to 15 cm long, while *Stern et al. 1064* (from Chiriquí, Panama) and *Haber 9526* have even smaller leaves, to 10 cm long. Because *Haber 9526* and the type have the same flower type, leaf shape (± obovate), and indument, I attach no taxonomic value to the striking variation in leaf size. The collection *Barbour 1012* remains unplaced. As mentioned earlier, I exclude it from *P. palmanum*, but the specimens (a MO and a US sheet) have few flowers, some of which had been dissected by earlier botanists and were unrecognizable, while others were covered with fungus or were otherwise damaged. Vegetatively, *Barbour 1012* somewhat resembles *P. golfodulcense*.

**Pleurothyrium panurense** (Meissner) Mez, Jahrb. Bot. Gart. Berlin 5: 468. 1889. *Nectandra panurensis* Meissner, D.C. Prodr. 15(1): 157. 1864. *Ocotea panurensis* (Meissner) Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. TYPE: Brazil. Amazonas: near Panure along the Rio Uaupés, *Spruce 2449* (B, BM, BR, E, G, K; holotype not designated). Figures 32, 33.

Tree, to 20 m tall. Twigs solid, terete, minutely brown-tomentellous, ca. 4 mm diam. 5 cm below the apex. Terminal bud brown-tomentellous. Leaves clustered near tips of branches, chartaceous, 15–30 × 6–10 cm, elliptic to elliptic-obovate, the base obtuse or rounded, the tip acuminate; upper surface glabrous, lower surface covered with a very fine, almost appressed whitish tomentum, this partially wearing off on older leaves; lateral veins 12–16, arching upward near the margin and loop-connected in the upper half of the laminae, venation immersed on upper surface, costa and lateral veins raised on lower surface. Petioles 5–14(–24) mm long, with similar indument as twigs. Inflorescences in the axils of cataphylls, brown-tomentellous, 5–10 cm long, paniculate, the branchlets 1–2 times cymosely branched, 15–30-flowered, bracts deciduous at anthesis. Pedicels to 5 mm long. Flowers white, ca. 8 mm diam. Tepals 6, equal, outer three gray-tomentellous outside, inner three with a basal triangular tomentellous patch, otherwise glabrous, elliptic, ca. 3 mm long. Stamens 9, 4-celled, all with 2 cells extrorse, the other pair lateral; stamens scarcely raised above the glandular mass that completely surrounds the stamens; ovary glabrous, globose, ca. 1.3 mm long, enclosed mostly in the rather deep, glabrous floral tube, the upper part covered by the glands; style ca. 0.5 mm long, papillose; stigma platelike. Cupule deeply cup-shaped, 2–2.5 cm wide, ca. 1.5 cm long, warty, gradually narrowing into the pedicel. Fruit ellipsoid, ca. 2.3 cm long, 1.4 cm wide. Fruits: December–April. Flowers: May–June. Elevation range: 100–200 m.

*Collections studied.* BRAZIL. AMAZONAS: near mouth of Rio Embira, *Krukoff 4783* (G, NY); mouth of Rio Embira, tributary of River Tarauaca, *Krukoff 4800* (A, F, G, MO, NY); Rio Apitua tributary of Rio Purus, 120 km S of Labrea, *Prance 13927* (NY); Panure ad Rio Uaupes, *Spruce 2449* (B, BM, BR, E, G, K). PERU. LORETO: Maynas, Mishana, Río Nanay, *Ayala 5734* (MO); Maynas, vicinity of Iquitos, *Revilla 3687* (MO); Maynas, Pto. Almendras, *Vásquez 10233* (MO); San Antonio, Río Pintuyacu, *Vásquez et al. 7468* (MO). UCAYALI: Coronel Portillo, Leoncio Prado (Yarina Cocha), *Vásquez 4970* (MO).

*Pleurothyrium panurense* is a rarely collected species, known with certainty from six collections: the type collection, four recent collections from Peru, and a collection from Brazil. All collections, including the type (indicated on the K sheet), come from inundated forest. Allen (1964) listed two additional collections of *P. panurense*, *Froes 20526* and *21295* (both NY), and presented a description of cupule and fruit based on *Froes 20526*. I assign these collections to *P. vasquezii* because the pubescence on the lower leaf surface consists of scattered, erect hairs (not a finely appressed, whitish indument) and because the leaves are not clustered.

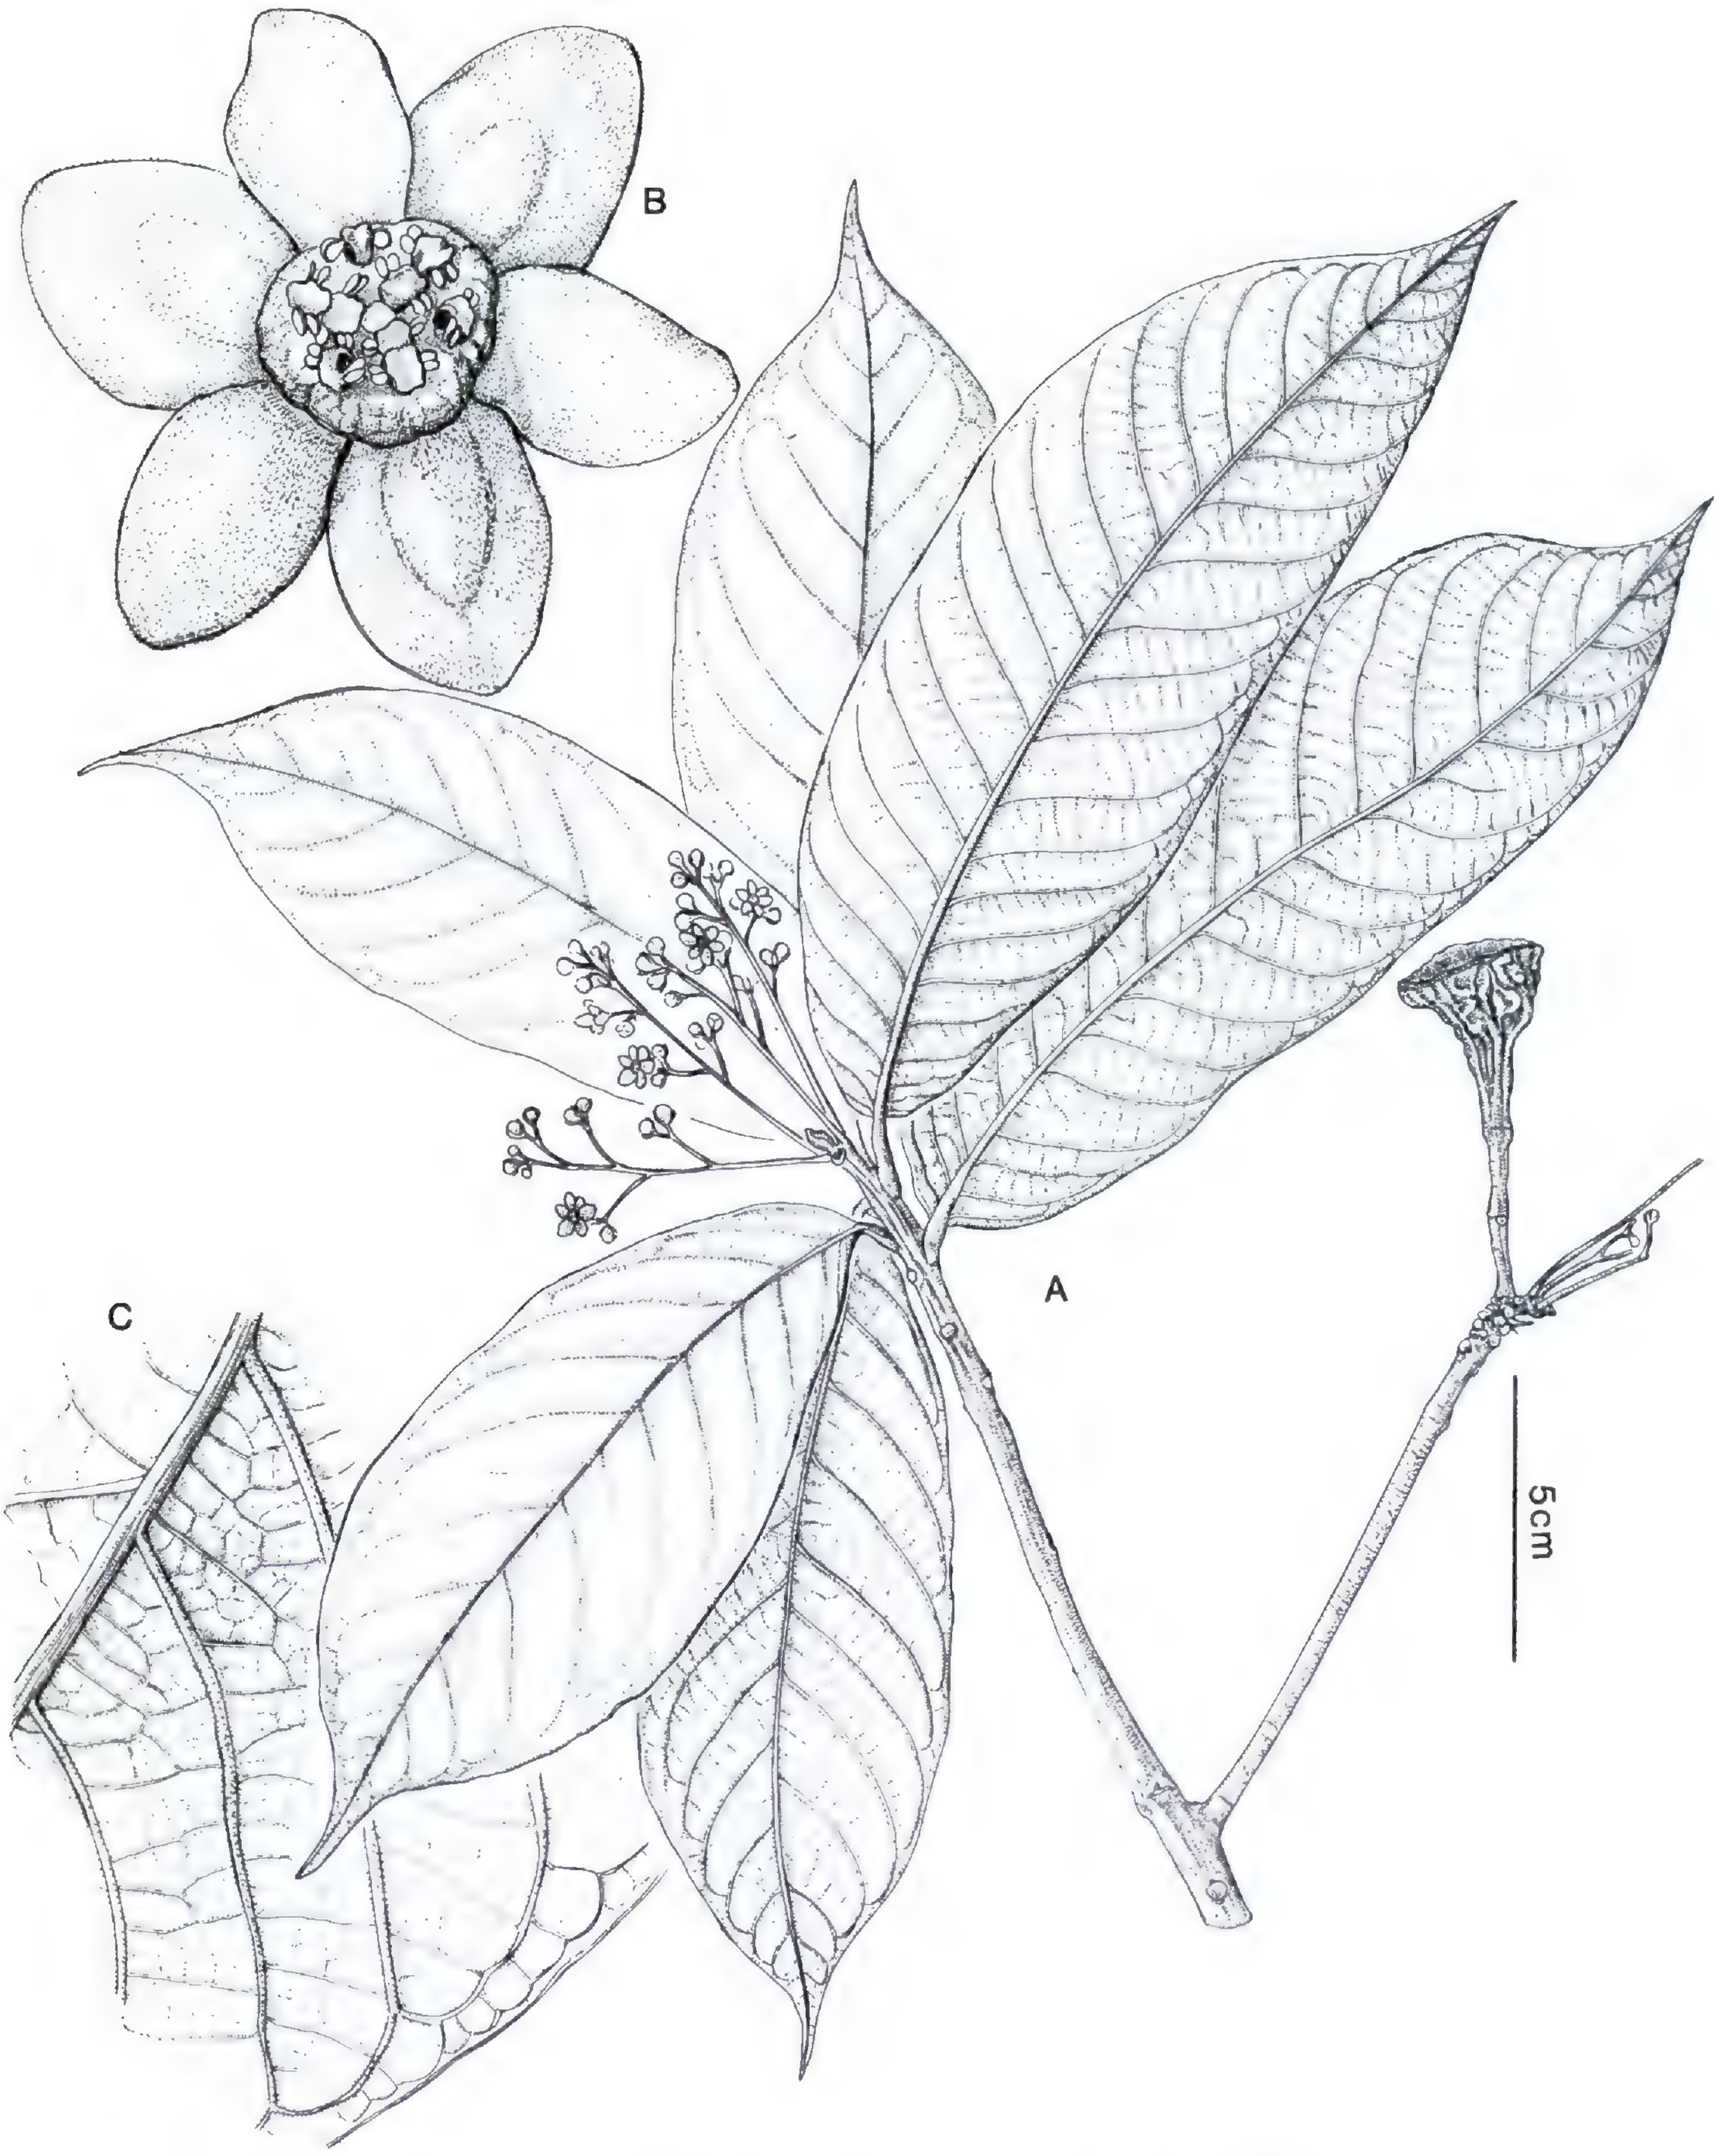

FIGURE 33. *P. panurense*.—A. Habit.—B. Flower.—C. Detail of lower leaf surface.

Also, the marginal vein is more strongly developed, and the pubescence on the young twigs is ferruginous-tomentose rather than light-brown tomentellous. Thus, Allen's description of cupules and fruits of *P. panurense* should be ignored.

Actually, *Pleurothyrium panurense* can be readily identified by the following combination of characters: short (to 10-cm-long) inflorescences, inner face of tepals glabrous, leaves clustered, leaves with an obtuse or rounded base, and leaves with a whitish indument on lower leaf surface. The flower size is normal for the genus and the glands are well developed.

It is likely that *Prance et al. 13927* (NY) be-

FIGURE 34. Distribution of *P. parviflorum* (★), *P. pauciflorum* (●), and *P. pilosum* (○).

longs here, too. However, the leaves are rather narrow and not clustered; the indument agrees with *Pleurothyrium panurense*. Unfortunately, the specimen is sterile.

*Krukoff 4800* and *Vasquez 4970* are provisionally placed here. They differ from *P. panurense* in their acute leaf bases and longer petioles (18–24 mm vs. 5–13 mm in typical *P. panurense*), but agree well in inflorescence and floral characters. Both collections were made in flooded forest. Although it is possible that future collections will show these collections to be different from *P. panurense*, I prefer to include them for the time being in *P. panurense*. *Krukoff 4800* was cited by A. C. Smith as a paratype of *P. nobile*, but it differs from that species in its indument.

**Pleurothyrium parviflorum** Ducke, Arch. Jard. Bot. Rio de Janeiro 5: 114. 1930. *Ocotea parviflora* (Ducke) Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. TYPE: Brazil. Amazonas: Igarapé do Lago de Serpa prope Itacoatiara, ad ripas inundatas, *Ducke RB 19935* (holotype, RB; isotypes, B, U). Figures 34, 35.

*Pleurothyrium densiflorum* A. C. Smith, Bull. Torrey Bot. Club 58: 109. 1931. *Ocotea compactiflora* Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. TYPE: Peru. Loreto: Mishuyacu, *Klug 1372* (holotype, NY not seen; isotype, US).

Tree, to 30 m tall, but usually not exceeding 20 m. Twigs slightly angular or terete, fistulose, glabrous or nearly so, ca. 5 mm diam. a few cm below the tip. Terminal bud covered with gray, fine appressed hairs. Leaves alternate, chartaceous, 10–20 × 3.5–9 cm, elliptic, the base acute to truncate, apex acute, glabrous or nearly so on both surfaces. Lateral veins 10–15 on each side, curving toward the tip near the margin, but not uniting with the superior veins; veins immersed on upper surface, midrib and lateral veins raised on lower surface. Petioles 10–15 mm long, glabrous, somewhat canaliculate. Inflorescences in axils of leaves or cataphylls, glabrous or with some minute appressed pubescence, 5–15 cm long, the branches up to 4 times cymosely branched, frequently flat-

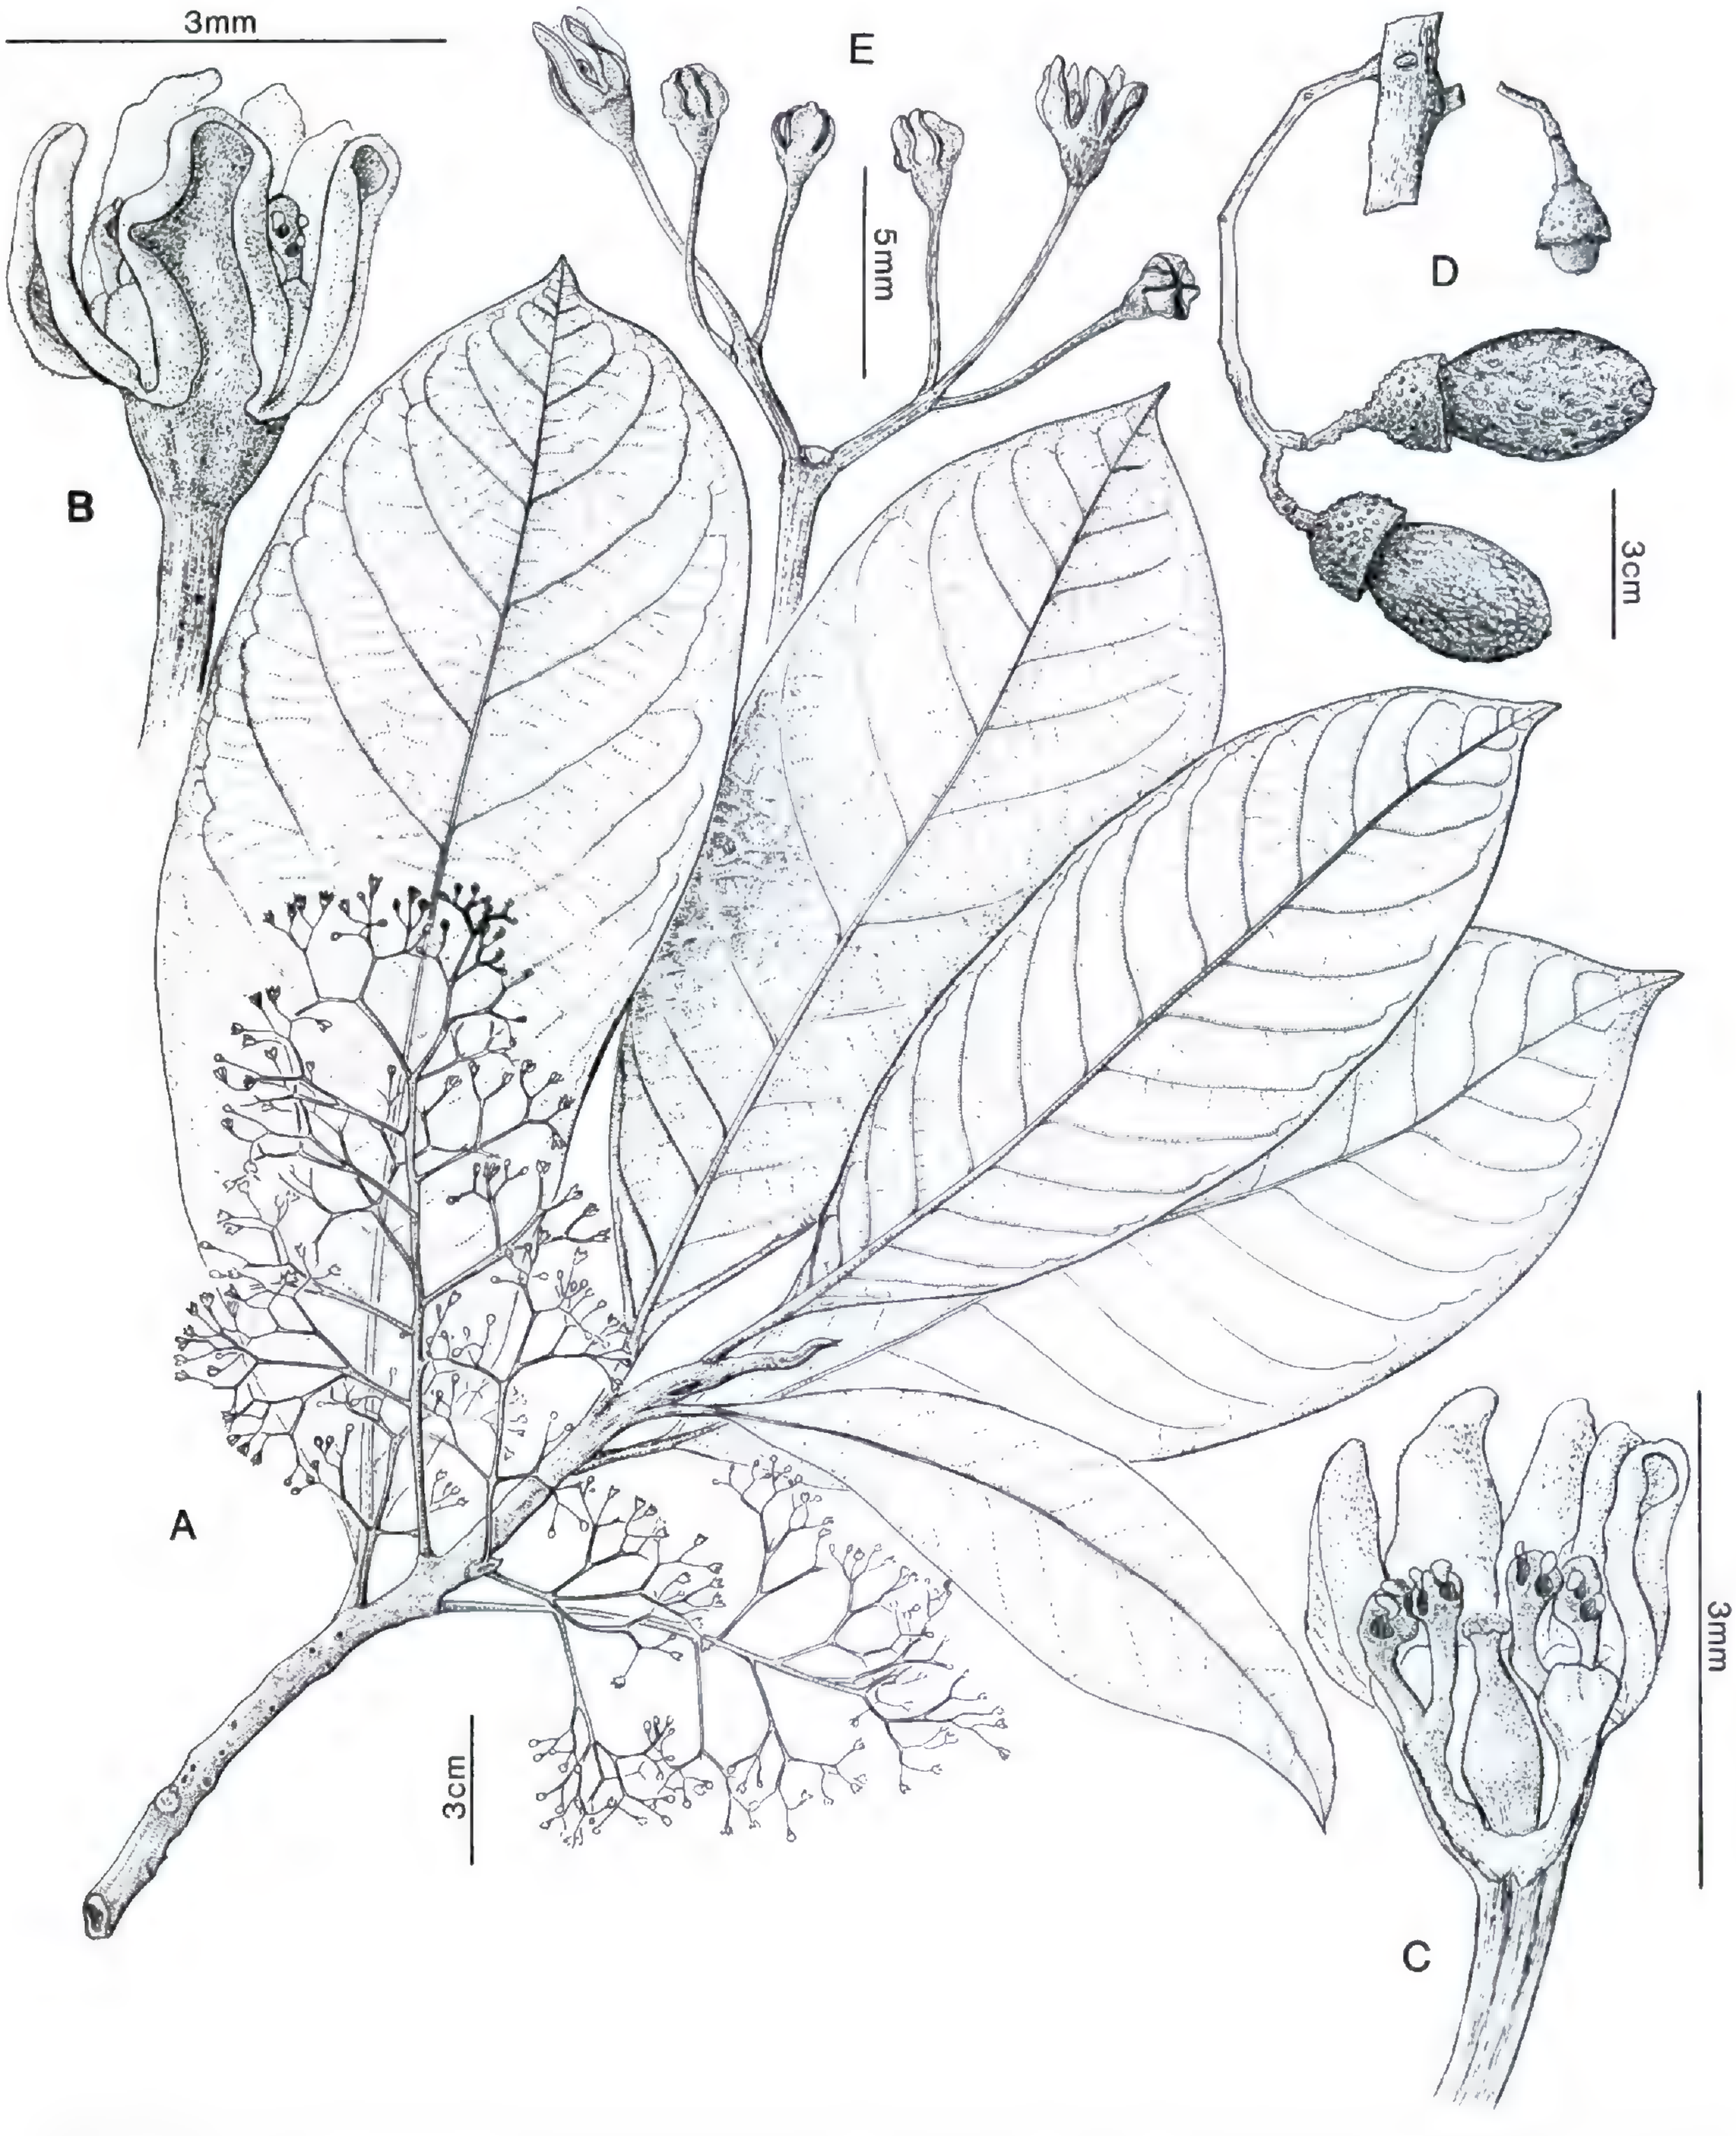

FIGURE 35. *P. parviflorum.*—A. Habit.—B. Flower.—C. Cross section of flowers.—D. Fruit.—E. Part of inflorescence.

tened, many-flowered; bracts absent at anthesis, but present in younger parts of inflorescences, linear, to 2.5 mm long, glabrous or with some minute appressed pubescence, the margin ciliate. Pedicels 3–5(–7) mm long. Flowers green or greenish white, ca. 5 mm diam. Tepals 6, equal, narrowly elliptic, ca. 2 mm long, the margins reflexed, glabrous or minutely papillose outside, papillose on inner surface. Stamens 9, ca. 0.9 mm long, 4-celled, the cells lateral, filaments glabrous, as long as anthers. Glands almost completely encircling the outer stamens, but not fused. Ovary glabrous, ellipsoid, ca. 0.7 mm long, gradually narrowed into the 0.4-mm-long, glabrous style. Floral tube deep, fully en-

closing the ovary, glabrous. Cupule with large lenticels, completely enclosing the fruit when young, at maturity bowl-shaped, 2.5 cm wide, 1 cm high, sometimes smaller and shallower; fruit ellipsoid, 3.6 × 2.7 cm, well exserted. Fruits: December–April. Flowers: April–August. Elevation range: 100–300 m.

*Pleurothyrium parviflorum* is one of the most frequently collected *Pleurothyrium* species. It is apparently a common tree in seasonally flooded forest (tahuampa) in Amazonian Peru and has been reported also from Brazil (Estado Acre and Amazonas) and Ecuador. This species can be easily identified by its habitat preference, and the combination of hollow stems (sometimes inhabited by ants), nearly glabrous inflorescence, glabrous leaves, and the reflexed margin of the tepals. There are a few other *Pleurothyrium* species with hollow twigs and tepals with reflexed margin and of those, *Pleurothyrium poeppigii* Nees can be confused with *P. parviflorum*. However, *P. poeppigii* has a dense, minute cover of hairs on the lower leaf surface, stiffer leaves, pubescent flowers and inflorescences, and smaller glands that do not enclose the outer stamens. One collection, *Nuñez 5901* (MO), is intermediate between the two. It resembles *P. parviflorum* in the lack of pubescence and the texture of the leaves and size of the glands, but has the stiffer, narrower infloresences and pubescence of the flowers found in *P. poeppigii*. Common name: Yacu Moena (= Moena del agua).

**Pleurothyrium pauciflorum** van der Werff & Hammel, sp. nov. TYPE: Costa Rica. Puntarenas: Cantón de Osa, ca. 2 km NE of the union of Río Pavón and Río Rincón, tree, 30 m, fl., *Hammel et al. 17909* (holotype, MO; isotypes, BM, CR, MEXU, USJ). Figures 34, 36.

Arbor, ad 35 m. Ramuli teretes, solidi, ferrugineo-tomentelli. Gemma apicalis ferrugineo-tomentella. Folia alterna, firme chartacea, 16–35 × 7–12 cm, oblonga vel elliptica, basi acuta vel obtusa, apice acumine ad 2 cm longo praedita, nervis lateralibus 14–20 utroque costae latere, brochidodroma in dimidio distale, supra glabra vel basi sparse tomentella, subtus pilis plus minusve erectis praedita, indumento secus nervos densiore, secus nervos majores tomentello; supra nervis immersis, subtus costa nervisque lateralibus prominenter elevatis, reticulatione paullo elevata. Petioli 1.8–3.2 cm longi. Inflorescentiae in bracteorum axillis ortae, ad 3 cm longae, pauciflorae. Pedicelli ad 2 mm longi. Flores ad 8 mm diametro, tepalis semi-erectis. Tepala 6, aequalia, crassa, 4–5 mm longa, ca. 4 mm lata, intus paullo papillosa, tres exteriora extus tomentella, tres interiora basi tomentella, demum papillosa. Stamina 9, 4-locellata, locellis lateralibus, glandulis perauctis, staminibus cingentibus. Pistillum ca. 3 mm longum, ovario pubescente sensim in stylum glabrum attenuato; receptaculo pubescente. Infructescentiae 2.5–4.5 cm longae; cupulae crassae, verrucosae, 2 cm longae, 3 cm latae, 1.5 cm profundae, tepalis frequenter persistentibus. Fructus ellipsoideus, 3 × 1.5 cm.

Tree, to 35 m tall. Twigs terete, solid, ferruginous-tomentellous, 4–6 mm diam. ca 5 cm below apex. Terminal buds ferruginous-tomentellous. Leaves alternate, grouped near tips of branches, firmly chartaceous, 16–35 × 7–12 cm, oblong or elliptic, the base acute or obtuse, tip acuminate, acumen to 2 cm long, but frequently damaged,

FIGURE 36. *P. pauciflorum.*—A. Habit.—B. Inflorescence with flower.—C. Fruit.

lateral veins 14–20 on each side, curving strongly upward near the margin and becoming loop-connected in upper half of the leaf, upper leaf surface glabrous or with traces of a tomentellous indument along midrib, the lower surface with ± erect hairs, this indument denser along veins and becoming tomentellous along major veins; veins immersed on upper surface, midrib and lateral veins prominently raised on lower surface, the tertiary venation slightly raised, but readily visible because of its indument. Petioles 1.8–3.2 cm long, upper surface flat, with similar indument as on twigs. Inflorescences in axils of (tardily) deciduous bracts, to 3 cm long, with up to 7 flowers (usually 3 or 1), ferruginous-tomentellous, bracts at base of inflorescences frequently present at anthesis, ovate or elliptic, to 5 mm long, pubescent on both surfaces. Pedicels ca. 2 mm long, ferruginous-tomentellous. Flowers ca. 8 mm diam., the tepals half-erect or somewhat spreading, never fully rotate; in old flowers tepals erect. Tepals 6, equal in size and shape, thick, 4–5 mm long, ca. 4 mm wide, all tepals inside slightly papillose, the outer 3 outside ferruginous-tomentellous, inner 3 with a basal triangular tomentellous area, otherwise slightly papillose. Stamens 9, all 4-celled, the cells lateral, glands strongly enlarged, enclosing stamens and fused. Pistil ca. 3 mm long, the pubescent ovary gradually narrowed into the glabrous style; receptacle ± pubescent. Infructescences 2.5–4.5 cm long, usually with 1 fruit; cupule thick, warty, ca. 2 cm tall, 3 cm wide and 1.5 cm deep, the tepals often persisting on the margin; fruit ellipsoid, ca. 3 × 1.5 cm. Fruits: June. Flowers: October. Elevation range: 50–200 m.

*Collections studied.* COSTA RICA. PUNTARENAS: Osa, *Hammel 17009* (MO); Osa, Reserva Indigena Guaimi, *Hammel 17909* (BM, CR, MEXU, MO, US).

*Pleurothyrium pauciflorum* can be readily identified by the ferruginous-tomentellous branchlets and the short, few-flowered inflorescences. Depauperate specimens of *P. golfodulcense* may also have short inflorescences, but this species has twigs covered with more or less appressed, ascending hairs, lacks erect hairs on the lower leaf surface, and has rotate flowers. It is uncommon to find a *Pleurothyrium* species with strongly enlarged glands that has half-erect tepals instead of rotate flowers. The androecium was, in all flowers seen, more or less covered by the tepals. Also, the tepals were, in comparison to other *Pleurothyrium* species, quite thick and fleshy. It would be interesting to discover what insect might pollinate this species; the arrangement of tepals suggests a beetle.

**Pleurothyrium pilosum** van der Werff, sp. nov.
TYPE: Panama. San Blas: Cangandi, 9°24′N, 70°24′W, hills near village, *de Nevers, Herrera & Charnely 7520* (holotype, MO; isotypes, CAS, PMA). Figure 34.

Arbor. Ramuli angulares, lateritio-tomentosi, cicatricibus conspicuis praediti. Gemma terminalis brevis, crassa, lateritio-tomentosa. Folia ad apices ramulorum congesta, chartacea, 15–25 × 7–13 cm, obovata, basi obtusa vel rotundata, apice rotundata vel breviter acuminata, nervis lateralibus 6  9 utroque costae latere, basalibus sub angulo acutiore quam venis distalibus abeuntibus, supra costa nervisque immersis, subtus elevatis, reticulatione paullo elevata; supra glabra, subtus dense pilosa, indumento secus costam nervosque tomentoso. Petioli 1.5–3 cm longi, lateritio-tomentosi. Inflorescentiae axillis cataphyllorum ortae, ad 15 cm longae, lateritio-tomentosae. Flores non visi. Tepala 6, late elliptica, 3 mm longa, intus et extus pubescentia. Stamina pubescentia, 9, 4-locellata, locellis lateralibus, glandulis magnis, stamina fere cingentibus, liberis. Pistillum glabrum, receptaculum pubescens. Fructus immaturus in cupula profunda, hexangulare inclusus.

Tree. Twigs angular, reddish brown tomentose, with conspicuous scars of old leaves, solid, 6 mm diam. ca. 5 cm below the tip. Terminal bud short, thick, reddish brown tomentose. Leaves clustered near tips of branches, chartaceous, 15–25 × 7–13 cm, obovate, the base obtuse to rounded, tip rounded or very shortly acuminate, lateral veins 6–9 on each side, the lowest pair leaving the midrib at the very base of the lamina and under a smaller angle than the more distal lateral veins, lateral veins approaching the leaf margin very closely and strongly arching upward, but only the upper 2 or 3 veins loop-connected, midrib and lateral veins immersed on upper leaf surface, but prominently raised on lower surface, the tertiary venation slightly raised; upper surface glabrous or with very few scattered reddish hairs, lower surface densely covered with erect, reddish hairs, these not obscuring the surface, the indument becoming tomentose along lateral veins and midrib. Petioles flattened above, 1.5–3 cm long, reddish brown tomentose. Pubescence on twigs and veins on lower leaf surface described by collectors as orange. Inflorescences in axils of cataphylls, at tips of branches, to 15 cm long, reddish brown tomentose, branchlets once cymosely branched or flowers racemosely arranged. Open flowers not seen. Tepals (based on remnants on young fruits) broadly elliptic, densely pubescent on both surfaces, 3 mm long. Stamens pubescent, 9, 4-celled, cells lateral; glands en-

larged, forming a dome and largely enclosing stamens, free (the glandular mass is broken up in fruiting stage). Ovary and style glabrous; receptacle pubescent inside. Young fruits enclosed in cupule, cupule with 6 ribs, to 1.5 cm long. Young fruits: March. Elevation range: ca. 30 m.

*Collection studied.* PANAMA. SAN BLAS: Cangandi, *de Nevers et al. 7520* (CAS, MO, PMA).

*Pleurothyrium pilosum*, only known from the type collection from San Blas, Panama, is closely related to *P. racemosum*, another Panamanian species only known from the type. These two species have in common a glabrous ovary and style, pubescent receptacle, clustered leaves, the basal lateral vein leaving the midrib under an acute angle at the very base of the lamina, and lateral veins that approach the leaf margin very closely. Although some of these characters occur also in other *Pleurothyrium* species, the ascending basal lateral veins are unique to these two species. *Pleurothyrium pilosum* differs from *P. racemosum* in its larger leaves (to 25 vs. 14 cm), in its leaf shape (obovate vs. oblong), indument of lower leaf surface (pilose vs. with scattered curled hairs or subglabrous) and indument of twigs (longer, red-brown vs. shorter plain brown).

Unfortunately, the only collection of *Pleurothyrium pilosum* is in young fruit. The description of floral parts is based on dried remnants on the young fruits, and I am not certain that the dimensions are correct. Because the type collection was made from a marked tree in a permanent quadrat, it is likely that the tree will be recollected in the future.

**Pleurothyrium poeppigii** Nees, Syst. laur.: 349. 1836. *Octoea poeppigii* (Nees) Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. TYPE: Peru. Maynas: *Poeppig addenda 301* (B, G, GZU, L, holotype not designated). Figure 37.

*Pleurothyrium krukovii* A. C. Smith, Phytologia 1: 121. 1935. *Ocotea krukovii* (A. C. Smith) Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. TYPE: Brazil. Acre: near mouth of Rio Macauhan, *Krukoff 5563* (holotype, NY not seen; isotypes A, G, K, MO).

Tree to 30 m tall. Twigs terete or subangular, fistulose, minutely brown-tomentellous or glabrous, 4–7 mm diam. ca. 5 cm below the tip. Terminal bud minutely brown-tomentellous. Leaves alternate, firmly chartaceous or subcoriaceous, 20–30 × 6–10 cm, (narrowly) elliptic to slightly (narrowly) obovate, the base acute, tip rounded or shortly acute, the upper surface glabrous, lower surface minutely tomentellous, papillose or rarely glabrous, lateral veins 14–18 on each side, arching upward near the margin, not or very weakly loop-connected, venation immersed on the upper surface, midrib and lateral veins raised on the lower surface. Petioles 1.5–2 cm long, with similar indument as on twigs, canaliculate. Inflorescences in axils of deciduous bracts, or infrequently in axils of regular leaves, to 18 cm long, minutely tomentellous or subglabrous, the branchlets complanate, to two times cymosely branched, the flowers often appearing densely clustered; bracts deciduous at anthesis. Pedicels 2–3 mm long. Tepals 6, equal, ± erect at anthesis, the margin reflexed, elliptic, ca. 2 mm long, the outer three minutely tomentellous outside, the inner three with a minutely tomentellous, triangular, basal patch, otherwise papillose; all tepals papillose on inner surface. Flower color described as white, green, and dull orangish; odor of melon. Stamens 9, all 4-celled, glabrous, 2 cells ± extrorse, the other 2 ± introrse, filaments about as long as anther, outer stamens separated by the enlarged glands, but glands not surrounding stamens and remaining free. Ovary ellipsoid, mostly included in the glabrous receptacle, glabrous or papillose near the tip, the style about as long as ovary, papillose; pistil ca. 2 mm long. Cupule cup-shaped, ± warty, ca. 1.5 cm high, 1.8 cm wide. Fruits: January, August, and November. Flowers: March, April, August, and December. Elevation range: 400–1,800 m.

FIGURE 37. Distribution of *P. poeppigii* (★), *P. racemosum* (●), *P. steyermarkianum* (○), and *P. synandrum* (■).

As accepted here, *P. poeppigii* is a wide-ranging species occurring in Amazonian Brazil, Bolivia, Peru, Ecuador, and Colombia. Its nearest relative is *P. parviflorum* Ducke, from which it differs in the tomentellous flowers and inflorescences, the narrower inflorescences, the tomentellous lower leaf surfaces, and the more coriaceous and generally larger leaves. The type specimens of *P. poeppigii* and *P. krukovii* are both somewhat atypical for this species. *Poeppig addenda 301*, the type of *P. poeppigii*, has strongly fistulose twigs and even some of the inflorescences are fistulose. These inflorescences are shorter and more compact than nonfistulose inflorescences on other specimens. The flowers of *Poeppig addenda 301* are slightly larger than on the other specimens, and the pedicels are slightly thicker. However, I feel that these differences do not warrant the recognition of two species, and I am inclined to accept most of these differences as a consequence of the strongly fistulose character of twigs and inflorescences. Oddly enough, none of the labels indicate that the twigs were inhabited by ants, although the hollow twigs and the exit holes along the twigs strongly suggest that ants colonize the twigs. See also discussion under *P. cuneifolium*.

The type of *P. krukovii* has, for this species, rather thin and glabrous leaves, characters found in *P. parviflorum*. The inflorescence and the flower buds have, however, the indumentum of *P. poeppigii*. In spite of the fact that A. C. Smith described flowers of *P. krukovii*, none of the isotypes I have seen had flowers, and the microfiche photo of the NY holotype does not show flowers either. *Krukoff 5722*, a paratype, also has glabrous leaves, but has tomentellous flowers. *Krukoff 5255* has stiffer leaves and tomentellous leaves and flowers; it fits my concept of *P. poeppigii* very well. These observations allow two approaches. One is to define three species narrowly: *P. poeppigii*, only known from its type; *P. krukovii*, with very few collections (excluding, for instance, *Krukoff 5255*) and defined by its glabrous, chartaceous leaves and subglabrous inflorescence axes; and a third, undescribed species occurring in Brazil, Peru, Ecuador, and Colombia with subcoriaceous, tomentellous leaves and rather

lax inflorescences. The other approach is to accept *P. poeppigii* in a wider sense, defined by its fistulose stems, tomentellous flowers, narrow inflorescences, and similar floral structure. I take this approach rather than recognizing three poorly defined and hard to identify taxa.

For the same reason, the collection *Cardenas 3966* (F, US) is included in *Pleurothyrium poeppigii*, although its obovate leaves are aberrant for this species. In other characters, such as flower size and structure, fistulose and tomentellous twigs, it fits in *P. poeppigii*, and I am not willing to describe a new taxon with only one collection based solely on a different leaf shape. This is the only collection of *P. poeppigii* from Bolivia.

In addition to *Pleurothyrium parviflorum* Ducke and *P. poeppigii*, *P. cuneifolium* Nees can also have fistulose twigs. This latter species can be recognized by its angular, lenticellate twigs, larger flowers, and tepals that are glabrous on the inner surface.

Although most collections of *Pleurothyrium poeppigii* are from lowland sites, I include here three collections from the Oxapampa area in central Peru from ca. 1,800 m elevation.

**Pleurothyrium prancei** van der Werff, sp. nov. TYPE: Brazil. Acre: vicinity of Serra de Moa, varzea forest, stilt-rooted tree, 8 m tall, *Prance et al. 12392* (holotype, F; isotypes, F, MO, NY, S). Figure 32.

Arbor, ad 8 m. Ramuli parum angulati, cinnamomeo-tomentelli; glabrescentes. Gemma terminalis cinnamomeo-tomentosa. Folia alterna, chartacea, 15–30 × 4.5–9 cm, anguste obovata vel anguste elliptica, basi acuta, apice acuminata, acumine ad 1.5 cm longo, supra glabra, subtus costa et nervis tomentellis, laminis glabris vel paucis pilis praeditis, supra venatione immersa, subtus costa nervisque elevatis, reticulatione paullo elevata; nervis 9 12 utroque costae latere, sursum arcuatis, venatione brochidodroma in dimidio distale. Petioli 2–3 cm longi. Inflorescentiae axillis cataphyllorum ortae, in apicibus ramulorum congestae, cinnamomeo-tomentellae, 10 20 cm longae, ramulis semel, raro bis cymae more furcatis, bracteis sub anthesi deciduis. Pedicelli 5–10 mm longi. Flores intus virides, 8–9 mm diametro. Tepala 6, subaequalia, patentia, margine plano, tres exteriora late elliptica 4 × 3 mm, extus cinnamomeo-tomentella, intus maxime basi pubescentia et zona peranguste centrali papillosa, demum glabra; tres interiora elliptica, 3 × 2 mm, extus parte triangulari basali tomentella, demum glabra, intus dense papillosa. Stamina 9, 4-locellata, locellis lateralibus, filamentis stamina aequantibus, glabris; glandulis incrassatis, vix stamina cingentibus, liberis. Pistillum ca. 2 mm longum, pubescens, ovario sensim in stylum brevem attenuato, stigmate incrassato. Fructus ignotus.

Tree, to 8 m tall, with stilt roots fide collectors. Twigs slightly angular, brown-tomentellous, glabrescent, 4 mm diam. ca. 5 mm below tip. Terminal bud brown-tomentellous. Leaves alternate, chartaceous, 15–30 × 4.5–9 cm, narrowly obovate to narrowly elliptic, the base acute, the apex acuminate, acumen to 1.5 cm long, but usually broken off, glabrous above, midrib and to a lesser degree lateral veins tomentellous below, the lamina glabrous or with a few scattered hairs near the base, venation immersed on upper surface, midrib and lateral veins raised on lower surface, tertiary venation slightly raised; lateral veins 9–12 on each side, arching upward near the margin and loop-connected in the distal half. Petioles 2–3 cm long, ± terete, with a similar indument as on twigs. Inflorescences in axils of cataphylls near tip of twigs, brown-tomentellous, 10–20 cm long, the branchlets once or rarely twice cymosely branched, bracts deciduous at anthesis, those subtending buds ca. 2 mm long, tomentellous outside, glabrous inside. Pedicels 5–10 mm long, brown-tomentellous. Flowers green inside, 8–9 mm diam. Tepals 6, subequal, spreading, the margin plane, the outer 3 broadly elliptic, 4 × 3 mm, brown-tomentellous outside, glabrous inside, except for some hairs near the very base and a narrow, median, papillose strip; inner 3 elliptic, 3 × 2 mm, the outside with a basal, triangular, tomentellous patch, otherwise glabrous, the inside densely papillose. Stamens 9, 4-celled, the cells lateral, opening back-to-back, filaments about as long as anther, glabrous; glands enlarged, protruding between the outer stamens and touching adjoining gland in front of outer stamens, but free. Pistil ca. 2 mm long, the ovary pubescent, gradually narrowed into the short style, stigma enlarged. Floral tube pubescent inside. Fruits unknown. Flowers: April. Elevation range: ca. 100 m.

*Collection studied.* BRAZIL. ACRE: Cruzeiro do Sul, vicinity of Serra da Moa, *Prance 12392* (F, MO, NY, S).

*Pleurothyrium prancei*, only known from the type collection, occurs in varzea (flooded forest) and reportedly has stilt roots, very unusual for a Lauraceae. It is characterized by the combination of glabrous, alternate leaves, a pubescent pistil, and flowers with the outer tepals glabrous inside, and inner tepals papillose inside. *Pleurothyrium prancei* does not seem to have close relatives. *Campbell et al. 8057*, from the upper Rio Moa in Acre, Brazil is possibly this species; the specimen is, however, sterile and hence the identification tentative.

It is a pleasure to name this species after Ghillean Prance, who has contributed so widely to the knowledge of the Amazonian flora.

**Pleurothyrium racemosum** van der Werff, sp. nov. TYPE: Panama. Panama: Cerro Jefe, along summit road and trail into Chagres Valley, elev. 900 m, *McPherson 12120* (holotype, MO; isotypes, BM, F, HBG, MEXU, PMA). Figures 37, 38.

Arbor parva, ad 7 m alta. Ramuli teretes, hornotini castaneo-tomentosi, annotini cinereo-tomentosi. Folia ad apices ramulorum aggregata, firme chartacea, 6 14 × 2.5–4 cm, oblonga vel leviter obovata, basi truncata vel acuta, apice obtusa vel breviter acuta, supra glabra vel basi costae nervorumque paullo castaneo-tomentosa, subtus pilis castaneis praedita basi costae nervorumque et margine tomentosa. Nervi laterales utroque costae latere 6–9, venatione brochidodroma in dimidio distale. Inflorescentiae ex axillis bractearum ortae, castaneo-tomentosae, 3–7 cm longae, ob abortionem florum lateralium racemosae. Tepala 6, aequalia, elliptica, ca. 4.5 mm longa, rotata vel paullo reflexa. Stamina 9, 4-locellata, antheris introrsum flexis, locellis lateralibus, filamentis pubescentibus. Glandulae stamina exteriora cingentes, liberae. Ovarium anguste ellipsoideum, glabrum; stylus glaber, stigmate peltato. Tubus floralis profundus, pubescens. Fructus ignoti.

Small tree, to 7 m tall. Twigs terete, solid, brown-tomentose when young, the tomentum turning gray on older twigs, the demarcation between brown and gray tomentum sharp, diameter of the young twigs ca. 3 mm. Terminal bud brown-tomentose. Leaves clustered near tips of branches, firmly chartaceous, 6–14 × 2.5–4 cm, oblong or somewhat obovate, the base truncate or acute, the tip obtuse or slightly acute, the upper surface glabrous or with some scattered brown hairs, these concentrated along the base of the midrib and lateral veins, the lower surface with more brown hairs becoming tomentose along the base of the midrib, lateral veins and margin. Venation, including midrib, immersed on upper surface, raised on lower surface; lateral veins 6–9 on each side, curving toward the tip near the margin and venation becoming brochidodromous in the distal half of the laminae. Basal veins leaving midrib under a more acute angle than more distal veins, and situated at the very base of the lamina. Petioles brown tomentose, 9–12 mm long. Inflorescences in the axils of cataphylls at the tip of the branches, brown tomentose, 3–7 cm long, racemose, 4–10 flowers per inflorescence; individual flowers representing a dichasium with the lateral flowers undeveloped, this indicated by 2 bracts at the transition from peduncle to pedicel. Peduncle to 10 mm long, pedicel to 3 mm long, both brown tomentose. Flowers brown outside, creamy-white inside, 9 mm diam. Tepals 6, equal in size, 4.5 mm long, elliptic, spreading to reflexed at anthesis; outer tepals brown-tomentose outside, with a triangular, gray-tomentose patch inside, otherwise papillose; inner tepals with a triangular, brown-tomentellous patch, otherwise glabrous outside, gray-tomentellous inside. Stamens 9, all 4-celled, the anthers curved inward, the cells lateral; filaments pubescent. Bases of filaments united, forming a ridge carrying the free parts of the stamens and the glands. Staminal glands enclosing the outer stamens, but not fused. Ovary narrowly ellipsoid, glabrous, 1 mm long; style glabrous, 1 mm long; stigma peltate. Floral tube deep, densely pubescent inside. Fruits and cupule unknown. Flowers: February.

*Collection studied.* PANAMA. PANAMA: Cerro Jefe, *McPherson 12120* (BM, F, HBG, MEXU, MO, PMA).

The type (and only) collection of *Pleurothyrium racemosum* was made on Cerro Jefe in Panama, a low mountain about 800 m high, which has yielded many endemics. The indument on the lower leaf surface can be rather sparse, especially on older leaves, but remnants of the characteristic curled hairs are always present near the base of the leaf and along the major veins. This species is closely related to *P. pilosum*, where differences between these species are discussed.

**Pleurothyrium steyermarkianum** Allen, Mem. New York Bot. Gard. 15: 93. 1966. TYPE: Venezuela. Mérida: La Azulita, forest above Hacienda Agua Blanca, elev. 1,310–1,340 m (fl), *Steyermark 56077* (holotye, F not seen; isotype, VEN). Figures 37, 39.

Tree, to about 20 m tall. Twigs angular, solid, minutely tomentellous when young, becoming glabrous with age, 4–5 mm diam. about 4 cm below apex. Leaves alternate, coriaceous, 12–25 × 5–10 cm, elliptic to broadly elliptic, base acute or obtuse, apex acute or acuminate, glabrous and somewhat shiny above, with scattered, appressed hairs or glabrous below, lateral veins 11–16 on each side, curving upward near the margin and weakly loop-connected in the distal half of lamina, midrib and lateral veins immersed on upper surface, raised on lower surface, tertiary venation scarcely visible on upper surface, slightly raised on lower surface. Petioles canaliculate, 1.1–2.5 cm long. Inflorescences in axils of deciduous bracts, to 16 cm long, minutely and laxly brown-tomentellous, the branchlets 2–3 times cymosely branched, bracts subtending the flower buds broadly ovate, boat-shaped, tomentellous outside and glabrous inside. Pedicels to 2 mm long, tomentellous, thick, acutely triangular in cross section, the three ribs continuing as keels on the outer 3 tepals.

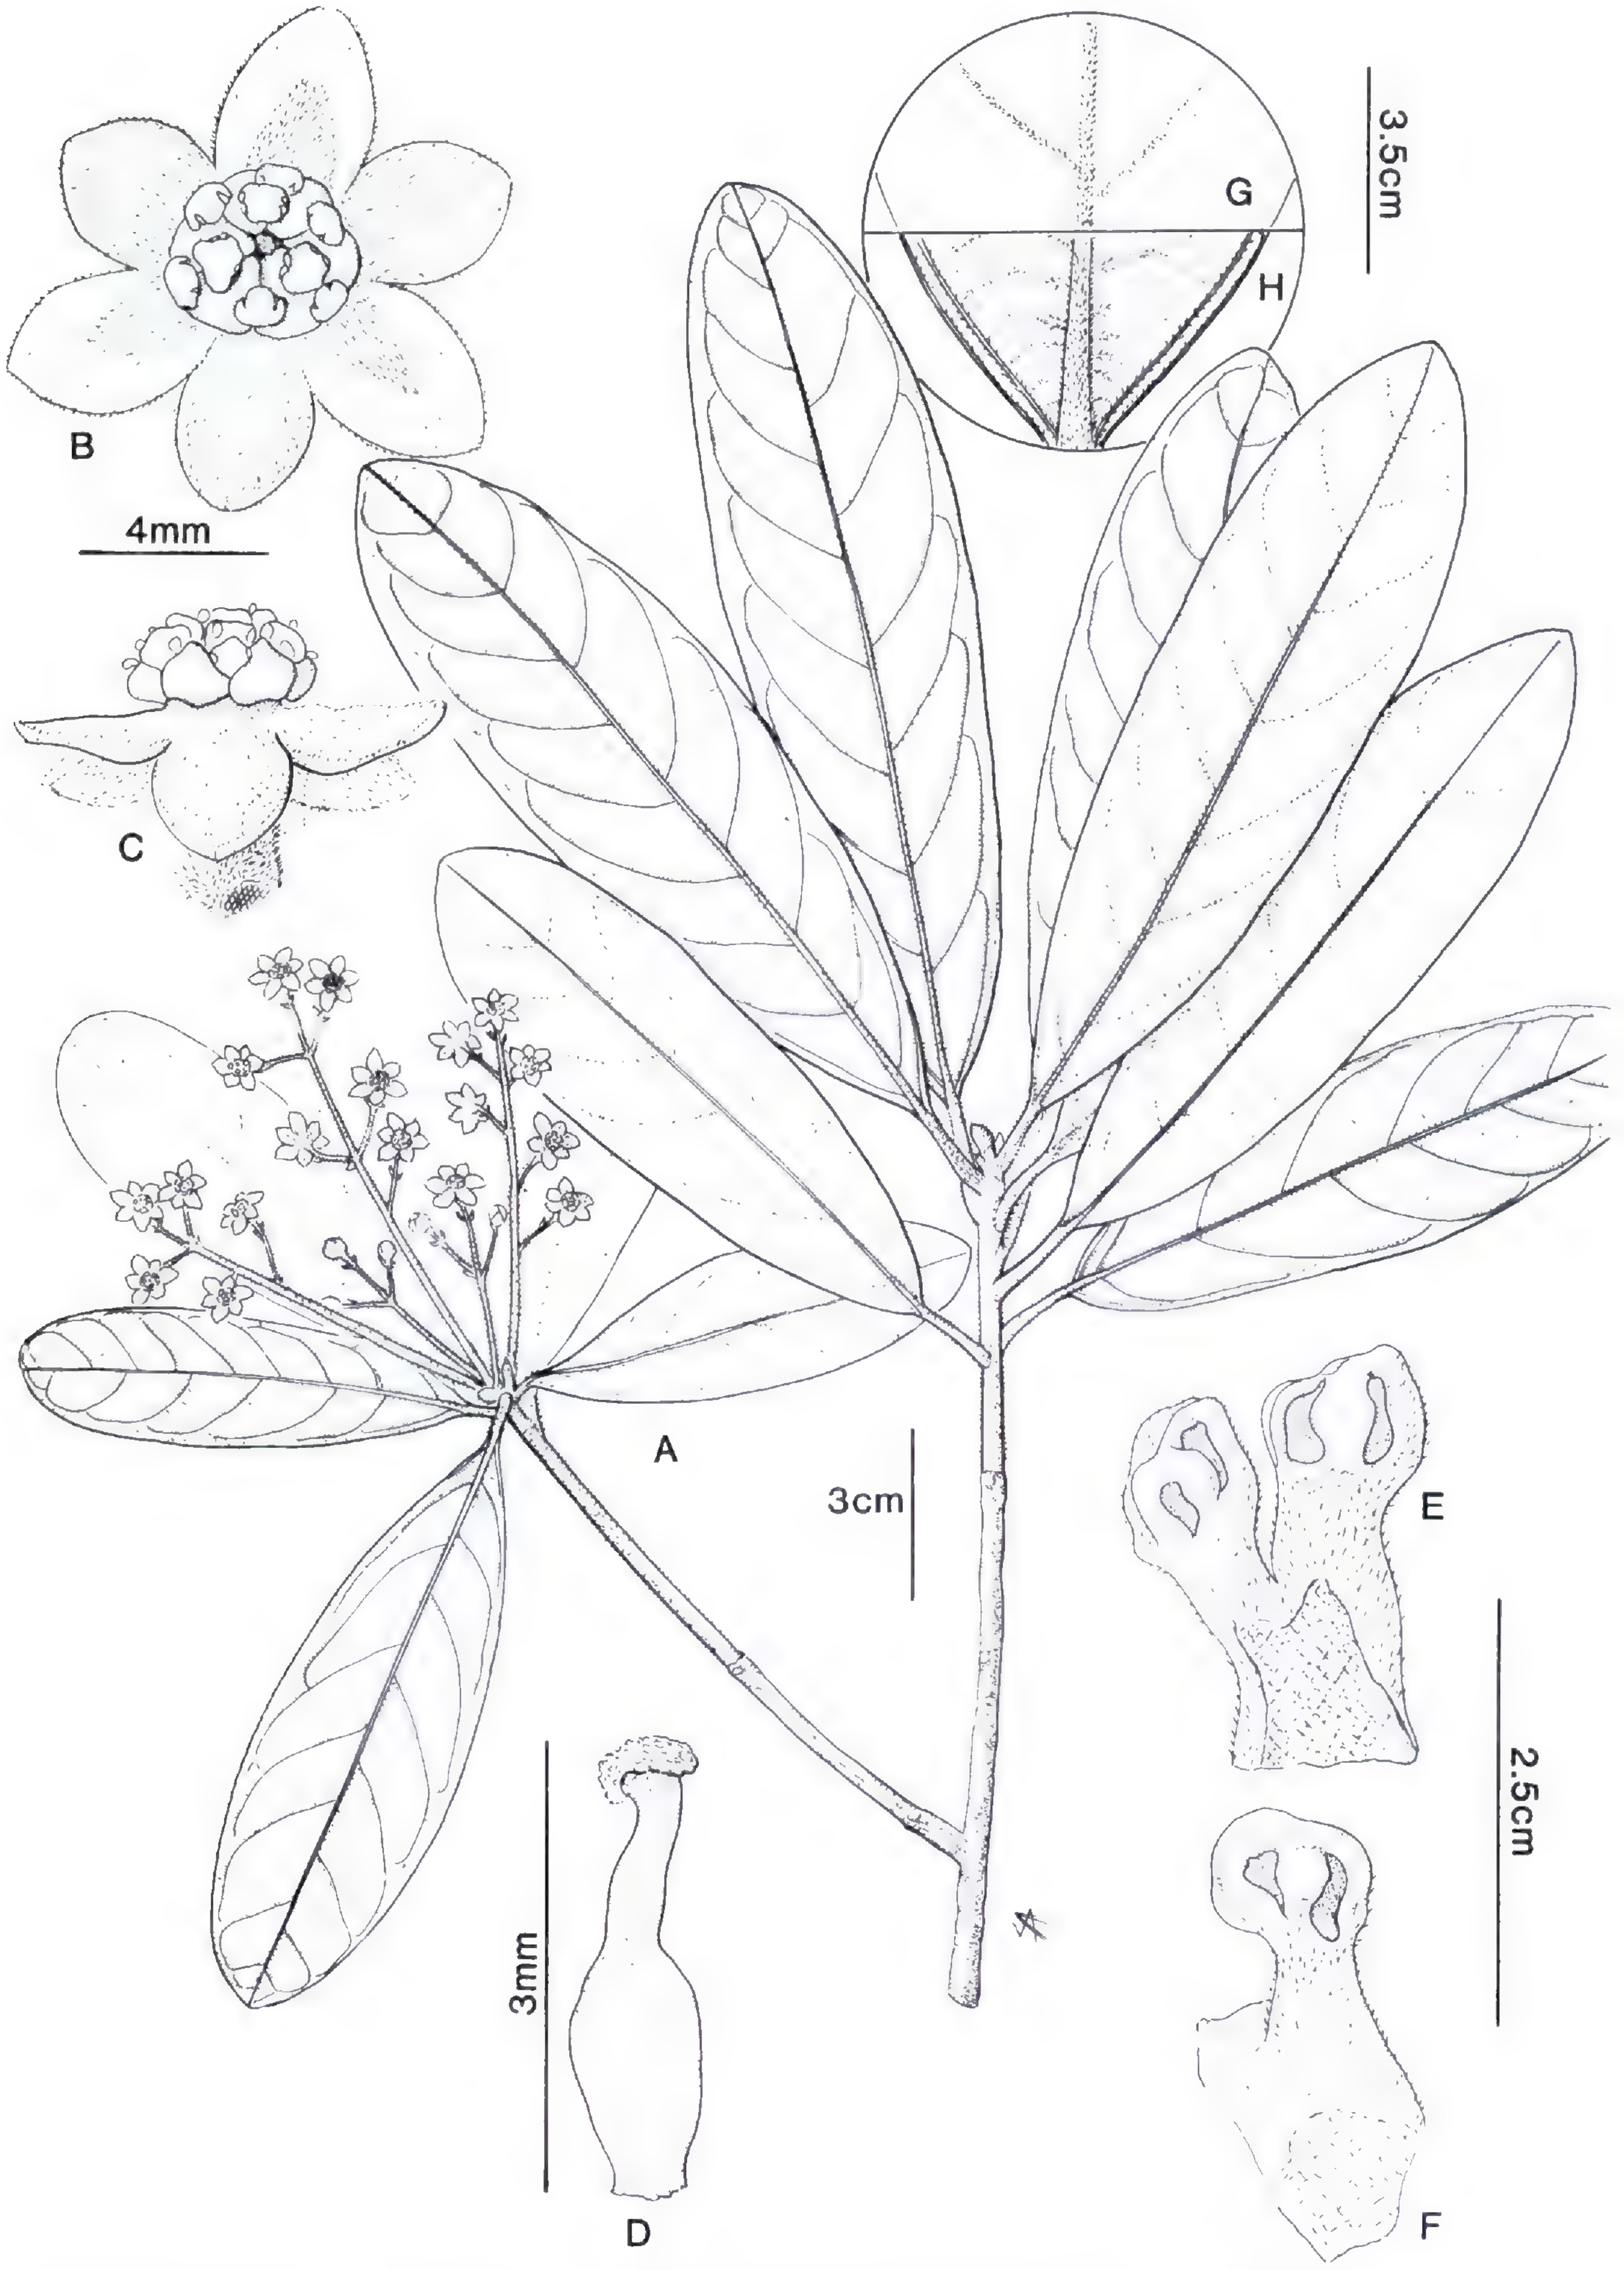

FIGURE 38. *P. racemosum*. —A. Habit. —B. Flower. —C. Flower, side view. —D. Pistil. —E. Stamens I and III. —F. Stamen II. —G. Detail of upper leaf surface. —H. Detail of lower leaf surface.

FIGURE 39. *P. steyermarkianum.*—A. Habit.—B. Flower.—C, D. Stamens.—E. Pistil.—F. Petiole.—G. Reticulation pattern on leaf.—H. Part of inflorescence.—I. Underside of leaf base.—J. Detail of lower leaf surface.

Flowers ca. 8 mm diam., pale yellow-green and fragrant fide collectors. Tepals 6, elliptic, 3–3.5 mm long, papillose inside, the outer 3 tomentellous outside, the inner 3 with a central tomentellous strip, otherwise glabrous outside. Stamens 9, 4-celled, the cells lateral; glands enlarged, forming ridges surrounding the stamens, fused. Pistil and receptacle glabrous, ovary ellipsoid. Cupule cup-shaped, 2 cm wide, 1 cm high; fruit ellipsoid, ca. 2 × 1.5 cm. Flowers: April. Elevation range: 1,300–2,000 m.

*Collections studied.* VENEZUELA. MERIDA: Selva nublada de la Zona La Trampa, *Bernardi 2169* (G, MER, NY); La Azulita, *Steyermark 56077* (VEN).

*Pleurothyrium steyermarkianum* is only known from two collections made in the Andes of Venezuela. The floral structure, especially the way in which the enlarged glands form ridges surrounding the stamens, the triangular or three-ribbed pedicels, and broad bracts of the inflorescence suggest a relationship with *P. cuneifolium* and its allies. However, *P. steyermarkianum* has a characteristic leaf

indument, lacks fistulose twigs, and differs in floral dimensions from *P. cuneifolium*.

When publishing *Pleurothyrium steyermarkianum* (as *P. steyermarkiana*), Allen indicated that the holotype was deposited in NY. This is an error. The holotype was at F and no isotype was found at NY. The F holotype was sent on loan from F to MO, but unfortunately never arrived and presumably is lost. The only specimen of the type collection studied is the VEN isotype.

Allen also indicated the collection *Bernardi 2169* had flowers and fruits. All sheets I have seen, however, have floral buds and fruits; thus, the only specimen of *P. steyermarkianum* with flowers is the VEN isotype.

**Pleurothyrium synandrum** van der Werff, sp. nov. TYPE: Colombia. Valle: Río Calima, La Trojita, *Cuatrecasas 16656* (holotype, F; isotypes, U, US). Figures 37, 40.

Arbor, ad 30 m. Ramuli teretes, ferrugineo-tomentulosi, glabrescentes. Gemma terminalis dense ferrugineo-pubescens. Folia alterna, coriacea, elliptico-ovata vel elliptica, 15–25 × 6–8 cm, basi et apice acuta, supra glabra, subtus ferrugineo-tomentosa vel tomentella, paucis pilis longioribus secus costam et venas laterales praedita; supra venatione immersa, subtus costa venisque lateralibus elevatis; venis lateralibus 18–24 utroque costae latere, marginem versus arcuatis, sed non connexis. Petioli ca. 1 cm longi, ferrugineo-tomentulosi. Inflorescentiae ex axillis bractearum ortae, 8–15 cm longae, ferrugineo-tomentulosae, paniculatae, ramulis 2–3 plo cymae more divisis. Flores pallide flavi, 11–12 mm diametro. Tepala 6, aequalia, 5 mm longa, intus papillosa, exteriora extus pubescentia, interiora minute puberula praeter basim pubescentem. Stamina 9, 4-locellata, 6 exteriora duobus locellis extrorsis, duobus lateralibus, 3 interiora locellis extrorsis, filamentis staminum exteriorum dorsaliter pubescentibus; interiora arcte stylum pubescentem cingentia. Glandulae dilatatae sed stamina exteriora vix ambientes. Cupula 4–5 cm late, 2.5 cm alta, verrucosa; fructus ovoideus, 4 × 2.5 cm.

Tree, 30 m tall. Twigs terete, solid, the tip with brown slender spreading hairs, brown-tomentulose on older parts, the indument wearing off on older parts, diameter of twig 6–8 mm 5 cm below tip. Terminal bud densely brown pubescent. Leaves alternate, coriaceous, elliptic-ovate to elliptic, 15–25 × 6–8 cm, base and apex acute, the upper surface glabrous, lower surface ferruginous-tomentose or tomentulose with some longer hairs along midrib and lateral veins; venation immersed on upper surface, midrib and lateral veins raised on lower surface; lateral veins 18–24, closely spaced, arching toward apex near the margin, but not connected with their superior vein. Petioles ca. 1 cm long, brown-tomentulose, broadly canaliculate, ca. 4 mm diam. Inflorescences in the axils of cataphylls, 5–15 cm long, paniculate, the branchlets 2–3 times cymosely branched, brown-tomentellous, 40–60 flowers per inflorescence, bracts mostly deciduous at anthesis, ca. 3 mm long, elliptic, brown-pubescent outside, glabrous inside. Flowers pale yellow, 11–12 mm diam. Tepals 6, equal, elliptic, 5 mm long, papillose on inside, outer tepals pubescent outside, inner ones minutely puberulous except for the pubescent base. Stamens 9, 4-celled, the outer 6 with one pair of cells extrorse, the other pair introrse; inner stamens with extrorse cells; filaments of outer stamens dorsally pubescent; filaments and anthers of inner 3 stamens poorly differentiated, the stamens forming a tight cylinder around the brown-pubescent style. Glands enlarged, protruding between the outer stamens, but these scarcely enclosing, free. Receptacle pubescent inside. Cupule, when pressed, 4–5 cm diam., ca. 2.5 cm tall, warty fruit ovoid, 4 × 2.5 cm when dry. Flowers and fruits: March. Elevation range: ca. 50 m.

*Collection studied.* COLOMBIA. VALLE: Río Calima, La Trojita, *Cuatrecasas 16656* (F, U, US).

*Pleurothyrium synandrum* is only known from the type collection from near the coast in Depto. Valle, Colombia. This species can immediately be recognized by its ovate-elliptic leaves with the numerous lateral veins close together and its unusual floral structure. In other *Pleurothyrium* species with strongly enlarged glands, not only do the glands grow outward, but also sideways and somewhat inward and the inner three stamens are therefore separated from each other by glandular tissue. Frequently, the glandular mass covers the upper part of the ovary and surrounds the style, while the lower part of the ovary is sunk in the floral tube. In *P. synandrum* the inner three stamens completely surround the style and the glandular tissue does not take part in protecting the pistil. The androecium of this species contains much mucilage, which makes the dried flowers very hard and brittle, whereas after boiling the flowers the parts become soft and slimy; I could therefore not make sure whether the inner stamens were actually (partly) fused or merely tightly pressed together. Another unusual feature of *P. synandrum* is that the basal pair of locelli on the outer stamens has virtually become extrorse. The glandular mass in this species shrinks strongly upon drying, and the outer stamens are raised much higher above the glands in dried flowers than in boiled flowers.

**Pleurothyrium tomentellum** van der Werff, sp. nov. TYPE: Ecuador. Pastaza: Pozo petrolero "Golondrina" de Petro-Canada, 30 km NW of Curaray, elev. 400 m, tree, 15 m, 10

July 1989, *Gudiño 12* (holotype, MO; isotypes, AAU, COL, G, HBG, K, LE, MEXU, NY, QCNE, QRS, US). Figure 41.

Arbor, ad 30 m alta. Ramuli teretes, tomentelli. Gemma terminalis tomentella. Folia alterna, coriacea, 13–35 × 6.5–13 cm, (late) elliptica vel oblonga, apice et basi acuta vel obtusa, supra glabra, subtus ferrugineo-tomentella; nervis lateralibus 9–14 utroque costae latere, costa nervisque supra immersis, subtus elevatis; reticulatione subtus paullo elevata, supra non evidente. Petioli 1.7–3.6 cm longi, canaliculati. Inflorescentiae in axillis bractearum (raro foliorum) ortae, 7–15 cm longae, tomentellae. Flores albi, 6–8 mm diametro. Tepala 6, intus papillosa, oblonga, 2.5–3 mm longa, statura et forma aequalia. Stamina 9, 4-locellata, locellis lateralibus, filamentis ca. 0.8 mm lon-

FIGURE 41. Distribution of *P. tomentellum* (★), *P. tomiwahlii* (●), *P. undulatum* (○), and *P. westphalii* (■).

gis, glandulis incrassatis, stamina cingentibus, contiguis, non connatis. Ovarium glabrum, in stylo attenuatum; tubo florale intus tomentello. Fructus ellipsoideus, 3 × 1.5 cm, cupula verrucata, 2 cm lata, 1 cm profunda.

Tree, to 30 m tall. Twigs terete, smooth or finely ridged, brown-tomentellous, solid, 4–7 mm diam. ca. 5 cm below tip. Terminal bud brown-tomentellous. Leaves alternate, coriaceous, 13–35 × 6.5–13 cm, elliptic, broadly elliptic or oblong, the tip and base acute or obtuse, upper surface glabrous, opaque, lower surface densely rufous-tomentellous or coarsely papillose, the surface completely covered by the indument; lateral veins 9–14 on each side, arching upward near the margin, but not loop-connected; midrib and lateral veins immersed on upper surface, raised on lower surface; tertiary venation (very) weakly raised on lower surface, not visible on upper surface. Petioles 1.7–3.6 cm long, canaliculate to deeply canaliculate, with similar indument as twigs. Inflorescences in axils of deciduous bracts, rarely in axils of leaves, to 7–15 cm long, the branchlets to 4 times dichotomously branched, rufous-tomentellous, bracts mostly deciduous at anthesis, if present tomentellous outside and subglabrous or tomentellous inside. Pedicels 2–6 mm long, rufous-tomentellous. Flowers 6–8 mm diam. Tepals 6, white, papillose-puberulous on inside, oblong, 2.5–3 mm long, equal in size and shape. Stamens 9, 4-celled, the cells lateral, the filaments ventrally pubescent, filaments ca. 0.8 mm long. Glands strongly enlarged, completely surrounding the stamens, but not fused. Pistil glabrous, 1.5 mm long, ovary gradually narrowed into the style, style and ovary of the same length; floral tube densely tomentellous within. Fruit ellipsoid, 3 × 1.5 cm, cupule cup-shaped, warty, 2 cm wide, 1 cm tall. Flowers: January–July. Fruits: January.

Common name (Huaorani): Ontumo.

*Collections studied.* ECUADOR. MORONA-SANTIAGO: 35 km NE from Montalvo, *Zak 4459* (MO, QCNE). PASTAZA:

30 km NWE of Curaray, *Gudiño 12* (AAU, COL, G, HBG, LE, K, MEXU, MO, NY, QCNE, QRS, US); 30 km NE from Curaray, *Gudiño 17* (MO, QCNE); 115 km S of Coca, near Río Tiguino, *Hurtado 1464* (MO, QCNE); Via Auca, 115 km S of Coca, *Neill 8741* (MO, QCNE); 115 km S of Coca, near Río Tiguino, *Neill & Hurtado 8783* (MO, QCNE), *Rubio 56* (MO, QCNE); 110 km S of Coca, 10 km from Río Tiguino, *Palacios 3416* (MO, QCNE). PERU. HUANUCO: Pachitea, Pucallpa region, 24 km SE of Puerto Inca, *Wallnoefer 18-29788* (MO).

*Pleurothyrium tomentellum* is a species with a limited distribution, known only from the Amazonian lowlands of Ecuador, from areas that recently became accessible due to oil exploration, and one collection from Amazonian Peru. According to the label data of *Neill & Hurtado 8783*, the species is locally very common. *Pleurothyrium tomentellum* can be readily identified by the combination of its tomentellous leaves and small (6–8-mm-diam.) flowers. Noteworthy are also the glabrous pistil, pubescent receptacle, and rather small cupule. In leaf characters (texture, indument, lack of marginal vein) and its short inflorescence it resembles *P. palmanum* from Costa Rica, but that species has larger flowers, broader, more or less obovate leaves, and a glabrous receptacle. Most collections have tomentellous lower leaf surfaces and inflorescence bracts that are tomentellous on both surfaces. The type collection has a shorter indument on the leaves, approaching the papillose condition, and the inner surface of the inflorescence bracts is subglabrous. In floral characters the collections are identical (only the sole Peruvian collection has a sparser indument on inner surface of tepals), and the differences mentioned are too weak for recognition of two taxa. Moreover, the type was collected together with a specimen with the slightly longer indument (*Gudiño 12, 17*).

**Pleurothyrium tomiwahlii** van der Werff, sp. nov. TYPE: Ecuador. Los Ríos: Centinela Ridge, elev. 600 m, 16 July 1991, *van der Werff et al. 12365* (holotype, MO; isotypes, AAU, B, BR, C, COL, E, F, G, GH, HBG, K, KUN, LE, MEXU, MY, QCNE, QRS, S, SEL, U, US). Figures 41, 42.

Arbor, 20 m. Ramuli crassi, teretes, juvenales ferrugineo-tomentosi, vetustiores glabrescentes. Gemma terminalis tomentosa. Folia ad apices ramulorum aggregata, chartacea, laminis 11–40 × 6–17 cm, basi obtusis vel acutis, apice rotundatis, obtusis vel breviter acuminatis, (late) obovatis vel (late) ellipticis, utrinque glabris vel paucis pilis erectis praeditis; nervis lateralibus 8–10 utroque costae latere. Petioli 2.5–6 cm longi, base incrassati, canaliculati. Inflorescentiae ex axillis bractearum ortae, tomentosae, paniculatae ramulis semel (raro bis) cymose ramosis, 7–12 cm longae, bracteis sub anthesi deciduis. Tepala 6, aequalia, extus pubescentia, 3 interiora intus pubescentia, 3 exteriora intus praeter partem triangularem basalem glabra vel papillosa, sub anthesi reflexa, ca. 4 mm longa, elliptica. Stamina 9, 4-locellata, locellis lateralibus, filamentis pubescentibus, parte basale in tubo coalitis; glandulis magnis inter stamina exteriora protrudentibus. Ovarium gracile, glabrum, sensim in stylum attenuatum; receptaculo et tubo filamentorum intus pubescente. Frutus ignotus.

Tree, to 20 m tall. Twigs ± terete, solid, with pale bark, the young growth ferruginous-tomentose, soon glabrescent, ca. 8 mm diam. 5 cm below tip. Terminal bud brown tomentose. Leaves clustered near tips of branches, alternate, chartaceous, laminae 11–40 × 6–17 cm, the base obtuse or acute, the tip rounded, obtuse or shortly acuminate, (broadly) obovate, or (broadly) elliptic; glabrous on both surfaces or with scattered erect hairs, these mostly along the major veins or near base of the lamina; lateral veins 8–10 on each side; venation immersed on upper surface or weakly raised, midrib and lateral veins raised on lower surface. Petioles 2.5–6 cm long, strongly canaliculate, the base swollen, with similar indument as on the twig. Inflorescences in the axils of cataphylls near the tips of branches, tomentose, paniculate, the lateral branchlets once cymosely branched, 7–12 cm long, bracts deciduous at anthesis. Flowers cream-colored, fragrant. Tepals 6, equal in shape, densely pubescent outside, the inner three densely pubescent inside, outer three with a basal, triangular, pubescent patch, otherwise glabrous or finely papillose; at anthesis reflexed, ca. 4 mm long, elliptic. Stamens 9, all 4-celled, the cells lateral, filaments of the outer 6 stamens dorsally pubescent; glands at base of inner stamens strongly enlarged and separating the outer stamens from each other; bases of filaments fused into a pubescent column, ca. 1 mm long. Ovary slender, glabrous, gradually narrowed into the style; inside of the floral tube and column formed by the stamens densely pubescent. Fruit unknown. Flowers: July and December. Elevation range: 600–1,400 m.

*Collections studied.* COLOMBIA. ANTIOQUIA: Amalfi, Salazary Marengo, *Callejas 9143* (MO). ECUADOR. LOS RIOS: Centinela Ridge, *van der Werff et al. 12365* (AAU, B, BR, C, COL, E, F, G, GH, HBG, K, KUN, LE, MEXU, MO, NY, QCNE, QRS, S, SEL, U, US), *van der Werff et al. 12367* (AAU, QRS, MO, QCNE). PICHINCHA: Cima de las Montañas de Ila, *Dodson 14531* (MO).

*Pleurothyrium tomiwahlii* is readily identified by its clustered, obovate leaves, long petioles with swollen base, its flowers with reflexed tepals, and the base of the filaments united in a column, giving the flower the appearance of a gonoloboid Asclepiadaceae species. Its closest relatives are the Costa Rican *P. golfodulcense*, in which the androecium

FIGURE 42. *P. tomiwahlii.* — A. Habit. — B, C. Flower sideways and seen from above. — D. Part of inflorescence. — E. Leaf base. — F. Shade leaf, showing less obovate shape and more acute leaf base.

forms a dome (without a column) and in which the glands separate the outer stamens just as in *P. tomiwahlii*; and the Panamanian species *P. racemosum* and *P. pilosum*, with similar floral structure as in *P. golfodulcense*, and with relatively long petioles, obtuse leaf bases and apices, and clustered leaves as in *P. tomiwahlii*. Details of indument, leaf shape and size as mentioned in the species descriptions, as well as the reflexed tepals, characterize *P. tomiwahlii*.

There is considerable variation in leaf size among the few available collections, probably a result of exposure to sunlight. The type tree, with rather small leaves, was free-standing in a pasture, while *van der Werff et al. 12367* was an understory tree in a forest patch. The Dodson collection has the largest leaves and was growing in forest. *Pleurothyrium tomiwahlii* is a rare species; during a day-long search at Centinela only three individuals were seen. Although the single Colombian collection represents a great range extension, *P. tomiwahlii* is such a distinctive species that I have no doubt about its identification.

The specific epithet honors the Wahl family, in recognition of their keen interest in conservation of tropical forests.

**Pleurothyrium trianae** (Mez) Rohwer, Mitt. Inst. Allg. Bot. Hamburg 20: 43. 1986. *Nectandra trianae* Mez, Jahrb. Bot. Gart. Berlin 5: 439. 1889. TYPE: Colombia. *Triana 1037* (holotype, P not seen; isotypes, BM, NY). Figure 43.

*Pleurothyrium zulianense* Lasser, Bol. Tecn. Minist. Agric. 3: 18. 1942. *Octoea zulianense* (Lasser) Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. TYPE: Venezuela. Zulia: en selvas claras del Río Lora, *Pittier 10947* (holotype, VEN not seen; isotypes, G, GH, US).

*Pleurothyrium reflexum* Lasser, Bol. Tecn. Minist. Agric. 3: 18. 1942. *Ocotea reflexa* (Lasser) Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. TYPE: Venezuela. Lara: entre San Isidro y Guarico, *Tamayo 1094* (holotype, VEN not seen; isotypes, F, US).

Large trees, becoming more than 20 m tall. Twigs roundly angular or terete, solid (rarely fistulose), glabrous, but the tips minutely brown-tomentellous, ca. 3 mm diam. 5 cm below the apex. Terminal buds minutely brown-tomentellous. Leaves alternate, chartaceous, elliptic, 9–25 × 3–10 cm, the upper surface glabrous, the lower surface minutely papillose to glabrous, the base acute, the tip shortly acuminate. Lateral veins 8–12 on each side, arching upward near the margin, not loop-connected, venation immersed on upper surface, midrib and lateral veins raised on lower surface. Petioles 10–20 mm long, shallowly canaliculate. Inflorescences in axils of cataphylls, minutely brown-tomentellous, paniculate, the branchlets once or twice cymosely branched, bracts deciduous at anthesis. Pedicels 2.5–4.5 mm long, minutely brown-tomentellous. Flowers white, ca. 4 mm diam., the tepals at anthesis erect or halfway spreading. Tepals 6, equal, ca. 2 mm long, the margin reflexed, minutely tomentellous outside, papillose inside. Stamens 9, glabrous, 4-celled, the cells mostly lateral and opening upward; filaments about as long as the anther, glands enlarged, visible as large lobes between the outer stamens, free. Ovary ellipsoid, glabrous or slightly papillose near the tip, style papillose, pistil 1.5–2.0 mm long. Receptacle glabrous inside. Cupule warty, to 15 mm wide, 10 mm tall, the pedicel not thickened; fruit ellipsoid, to 22 × 16 mm. Fruits: February–June. Flowers: collected in every month except June–July. Elevation range: 10–1,400 m.

*Pleurothyrium trianae* is, as treated here, a wide-ranging and variable species. It has been recorded from Honduras to Ecuador and Venezuela, but the records are not evenly distributed over this area. Only two collections are known from Central America. Nearly all South American collections come from the following three areas = (a) Pacific lowlands of Colombia (type locality of *P. trianae*), (b) Andean foothills in Venezuela (type localities of *P. zulianense* and *P. reflexum*), and (c) the Oriente of Ecuador, while almost no collections are known from the intervening areas. It is therefore not surprising to find local differentiation. The Colombian collections tend to have almost glabrous leaves, a rather sparse indument on twigs, and pedicels that are 3.5–4.5 mm long. The Venezuelan plants have more indument on twigs and leaves and have pedicels 2–2.5 mm long. The Ecuadorian plants agree with the Colombian specimens in their indument, have variable length of pedicels (2–4 mm), and have smaller leaves (9–14 × 3–5 cm) than the other populations (*Palacios 2094* has larger leaves). These differences are nearly all quantitative and form an insufficient basis for the recognition of separate taxa. The length of pedicels cannot be relied on for the separation of taxa because the lateral flowers of a cyme nearly always have shorter pedicels than the central flower and young flowers tend to have slightly shorter pedicels than old flow-

ers. I expect that once collections of *P. trianae* become available from other areas, the differences between populations as described above will disappear. For example, a collection from Antioquia at 1,050 m elevation (*McPherson 12999*) has the denser indument and shorter pedicels commonly found in Venezuelan collections; it also has stiffer leaves than usual for *P. trianae*.

The relationships of *P. trianae* are with a small group of poorly defined species that is characterized by small flowers with erect, more or less inrolled tepals, solid twigs, and chartaceous leaves. This group consists of *P. acuminatum*, *P. amapaense*, *P. amplifolium*, *P. intermedium*, and *P. undulatum*. *Pleurothyrium acuminatum* differs in its relatively long pedicels ((4–)5(–8) mm), and long tepals (3 mm long); *P. amplifolium* has broad leaves, while *P. intermedium*, *P. undulatum*, and *P. amapaense* have a different indument. It is possible that, once more material is available, some of these species will be placed in synonymy.

More distantly related are *P. parviflorum* and *P. poeppigii*, which both have fistulose twigs. Additionally, *P. parviflorum* differs in its glabrous flowers and *P. poeppigii* in its coriaceous leaves. A few collections of *P. trianae* have fistulose stems, and the differences cited above help separate these specimens from *P. parviflorum* and *P. poeppigii*. Differences between *P. trianae* and *P. cuneifolium* are discussed under the latter species.

**Pleurothyrium undulatum** (Meissner) Rohwer, Mitt. Inst. Allg. Bot. Hamburg 20: 44. 1986. *Oreodaphne undulata* Meissner, DC. Prodr. 15(1): 115. 1864. *Ocotea undulata* (Meissner) Mez, Jahrb. Bot. Gart. Berlin 5: 278. 1889. TYPE: Brazil. Amazonas: Prov. Rio Negro, *Riedel 1412* (holotype, LE not seen; isotypes, B, G, K, L, NY). Figure 41.

Tree of unknown size. Twigs terete, solid, minutely brown-tomentellous, glabrescent with age. Terminal bud brown-tomentellous. Leaves alternate, chartaceous, elliptic to narrowly elliptic, 10–17 × 2–5 cm, base and tip acute, glabrous on upper surface, glabrous or minutely papillose on lower surface, venation immersed on upper surface, midrib raised on lower surface, the lateral veins (12–15 on each side) poorly visible and less elevated; marginal vein poorly developed or lacking. Petioles ca. 1.5 cm long, with similar pubescence as twigs. Inflorescences in axils of cataphylls or leaves, brown-tomentellous, especially the ultimate branches, 8–12 cm long, paniculate, the branchlets 2–3 times cymosely branched, the flowers close together; bracts present, ovate, to 2 mm long, tomentellous outside, minutely so inside. Pedicels to 1 mm long, tomentellous. Flowers ca. 3 mm diam., the tepals ± erect at anthesis. Tepals 6, equal, ca. 2 mm long, tomentellous outside, papillose inside, the margin reflexed. Stamens 9, 4-celled, the cells lateral, glands enlarged and protruding between the outer stamens, but not enclosing them and not fused. Ovary globose, glabrous, enclosed by the glabrous receptacle; style papillose. Fruits unknown.

*Collection studied.* BRAZIL. *Riedel 1412* (B, G, K, L, NY).

*Pleurothyrium undulatum* is only known from the type collection made by Riedel in 1824–1825. Meissner (1864) gave as locality only Amazonas, Prov. Rio Negro; the isotype in NY gives as locality Barra, an old name for Manaus. *Pleurothyrium undulatum* was placed by Mez (1889) in *Ocotea*; he considered that the presence of glands at the base of all stamens was typical for *Pleurothyrium*, and although he noted that in respect of anther shape this species resembled *Pleurothyrium*, he treated it in *Ocotea* because of the presence of only six glands. *Pleurothyrium undulatum* belongs to a small group of species characterized by tepals with reflexed margins, often erect tepals at anthesis, marginal vein lacking or weakly developed, small flowers (less than 5 mm diam.) and inflorescences sometimes present in axils of leaves and not restricted to axils of cataphylls. Within this group, the narrow, almost glabrous leaves and the tomentellous pubescence of the inflorescences characterize this species.

**Pleurothyrium vasquezii** van der Werff, sp. nov. TYPE: Peru. Loreto: Maynas, km 32 along carretera Iquitos-Nauta, elev. 150 m, primary forest, *Vasquez & Jaramillo 7889* (holotype, MO; isotypes, AAU, AMAZ, F, G, NY). Figures 44, 45.

Arbor, 20 m alta. Ramuli teretes, solidi, fusco-tomentosi. Folia alterna, firme chartacea vel coriacea, elliptica vel late elliptica, 15–30 × 5–10 cm, basi acuta vel obtusa (rotundata), apice acuminata, supra glabra, subtus pilis erectis praedita, venatione supra immersa, subtus elevata, in dimidio distali brochydodroma, venis lateralibus 9–13 utroque costae latere. Petioli 1.5–3 cm longi, canaliculati. Inflorescentiae ex bractearum axillis ortae (raro ex foliorum axillis), fusco-tomentosae, 10–17 cm longae, paniculatae. Pedicelli 3 4 mm longi. Flores 5–6 mm diametro, rotati. Tepala 6, aequalia, oblonga, ca. 2 mm longa, margine plano, extus tomentella, intus papillosa. Tubus floralis ad ostium constrictus. Stamina 9, 4-locellata, locellis lateralibus vel extrorso-lateralibus, minute papillosa; glandulis magnis, staminibus exterioribus cingentibus, libe-

FIGURE 44. Distribution of *P. vasquezii* (★).

ris. Ovarium ellipticum, papillosum, ca. 1 mm longum, in receptaculo profundo, papilloso inclusum. Cupula verrucosa, 1 cm alta, 1.3 cm lata.

Tree, to 20 m tall. Twigs solid, terete, fuscous-tomentose, glabrescent, 3–4 mm diam. 5 cm below the tip. Terminal bud fuscous-tomentose. Leaves alternate, stiffly chartaceous to coriaceous, elliptic to broadly elliptic, 15–30 × 5–10 cm, the base acute to obtuse, rarely rounded, the tip shortly acuminate, the upper surface glabrous and with immersed midrib and lateral veins, the lower surface with erect hairs, the surface well visible, the elevated midrib and, to a lesser degree, lateral veins tomentose, tertiary venation also raised, lateral veins 9–13 on each side, curving upward near the margin, a marginal vein quite well developed in the distal half. Petioles 1.5–3 cm long, canaliculate, with same kind of tomentum as twig. Inflorescences in axils of cataphylls, rarely in axils of leaves, fuscous-tomentose, 10–17 cm long, paniculate, the branchlets 2–3 times cymosely branched, many-flowered, bracts lacking at anthesis. Pedicels 3–4 mm long, tomentose. Flowers yellow or green, 5–6 mm diam., the tepals spreading at anthesis. Tepals 6, equal, oblong, ca. 2 mm long, the margin plane, tomentellous outside, papillose inside. Floral tube constricted just below tepals. Stamens 9, 4-celled, the cells lateral or one pair lateral-extrorse, opening back-to-back, filaments and anthers minutely papillose; glands enlarged, almost completely enclosing the outer stamens, but not fused. Ovary elliptic, papillose, ca. 1 mm long, enclosed in the papillose, deep receptacle, the upper part covered by the enlarged glands, style ca. 0.5 mm long, papillose; stigma not enlarged, partly hidden by the longer stamens. Cupule cup-shaped, warty, ca. 1 cm tall, 1.3 cm wide (but probably not fully mature). Fruits: February. Flowers: August–October. Elevation range: 100–600 m.

*Collections studied.* BRAZIL. ACRE: Rio Jurua, 1 km upstream from Colonia Rodrigues Alvez, *Campbell 10852* (MO, NY); Reserva INCRA Santa Luzia, km 40 BR-364,

*Pleurothyrium vasquezii* is known from several collections in Amazonian Peru and adjacent Brazil, as far downstream as Manaus. It is the only *Pleurothyrium* species in this area with a sparse, erect pubescence on the lower leaf surface and alternate leaves. *Pleurothyrium brochidodromum* has a very similar indument on the lower leaf surface, but differs in having larger flowers (9–10 vs. 5–6 mm diam.) and in its clustered leaves. A few collections placed in *P. vasquezii* were earlier identified as *P. panurense* (Allen, 1964), but this species has clustered leaves, a very short, appressed indument on the lower leaf surface that completely covers the surface, and flowers ca. 8 mm in diameter.

Two Froes collections (*20526, 21235*) from Brazil have somewhat more coriaceous leaves and roundish leaf bases. However, these collections are fruiting, which may explain their stiffer leaf texture. Because *Ramirez 61* from Peru also has roundish leaf bases and agrees in floral characters with *P. vasquezii*, I placed the Brazilian collections here. Spichiger et al. (1989) reported this species as *Nectandra amplifolia* Mez (= *P. amplifolium* (Mez) Rohwer) from the Arboretum at Jenaro Herrera, Peru (tree 159 in parcela 1). This latter species differs in its puberulous indument on the lower leaf surface, and in its more or less erect tepals with reflexed margins. The same tree is also cited under *Ocotea undulata* (Meissner) Mez (= *P. undulatum* (Meissner) Rohwer), which also has a different indument on the lower leaf surface, and more or less erect tepals with reflexed margins at anthesis.

*Pleurothyrium vasquezii* is named after Rodolfo Vasquez, whose fine collections have added much to our knowledge of the trees in Amazonian Peru.

**Pleurothyrium westphalii** van der Werff, Ann. Missouri Bot. Gard. 74: 410. 1987. TYPE: Guatemala. Alta Verapaz: Sacté, *Kunkel 9* (holotype, BR). Figures 41, 46.

Tree, to 20 m tall. Twigs solid, terete, young ones with brown, dense appressed pubescence, older ones glabrous. Terminal bud densely brown-pubescent. Leaves alternate, membraneous, 15–20 × 4–7 cm, elliptic or narrowly elliptic, the base acute, the margin somewhat decurrent, apex acute, glabrous and gland dotted on the upper surface (except for some appressed hairs near the base of the midrib), lower surface with few appressed hairs, more so near the base; lateral veins 5–9 on each side, arching upward near the margin, but not loop-connected; venation immersed on upper surface, midrib, lateral veins and tertiary venation weakly raised on lower surface. Petioles to 1 cm long, with similar pubescence as twigs. Inflorescences in axils of deciduous bracts, attached below the leaves, ca. 8 cm long, densely gray-brown pubescent, the lowest branches once cymosely branched, otherwise inflorescence racemose. Flowers ca. 8 mm diam. Pedicels ca. 4 mm long. Tepals 6, equal, ovate, 3–4 mm long, densely pubescent on both surfaces. Stamens 9, 4-celled, the cells lateral, anthers glabrous, filaments brown-pubescent; glands strongly enlarged, completely enclosing outer stamens; ovary ellipsoid, glabrous, ca. 1 mm long, enclosed by the glabrous receptacle; stigma platelike. Fruits unknown. Flowers: April. Elevation range: 900–1,100 m.

*Collections studied.* GUATEMALA. ALTA VERAPAZ: Sacte, *Kunkel 9* (BR), *Kunkel 17* (MO).

*Pleurothyrium westphalii*, known only from two collections in Guatemala, is the northernmost representative of the genus. The species can be readily identified by its appressed, gray-brown pubescence, the pubescent tepals (also inner surface is pubescent), pubescent filaments, the few-flowered inflorescences, the membraneous leaves, and the absence of a marginal vein.

**Pleurothyrium williamsii** O. C. Schmidt, Repert, Spec. Nov. Regni Veg. 31: 189. 1933. *Ocotea williamsii* (O. C. Schmidt) Kostermans, J. Sci. Res. (Jakarta) 1: 122. 1952. TYPE: Peru. Loreto: Pebas on the Amazon River, *Llewelyn Williams 1766* (holotype, F probably lost; isotype, B, fragment G). Figure 43.

Shrub or small tree, to 8 m tall. Twigs angular, solid, becoming terete in age, brown-tomentellous to glabrous, 4–5 mm diam. 5 cm below apex.

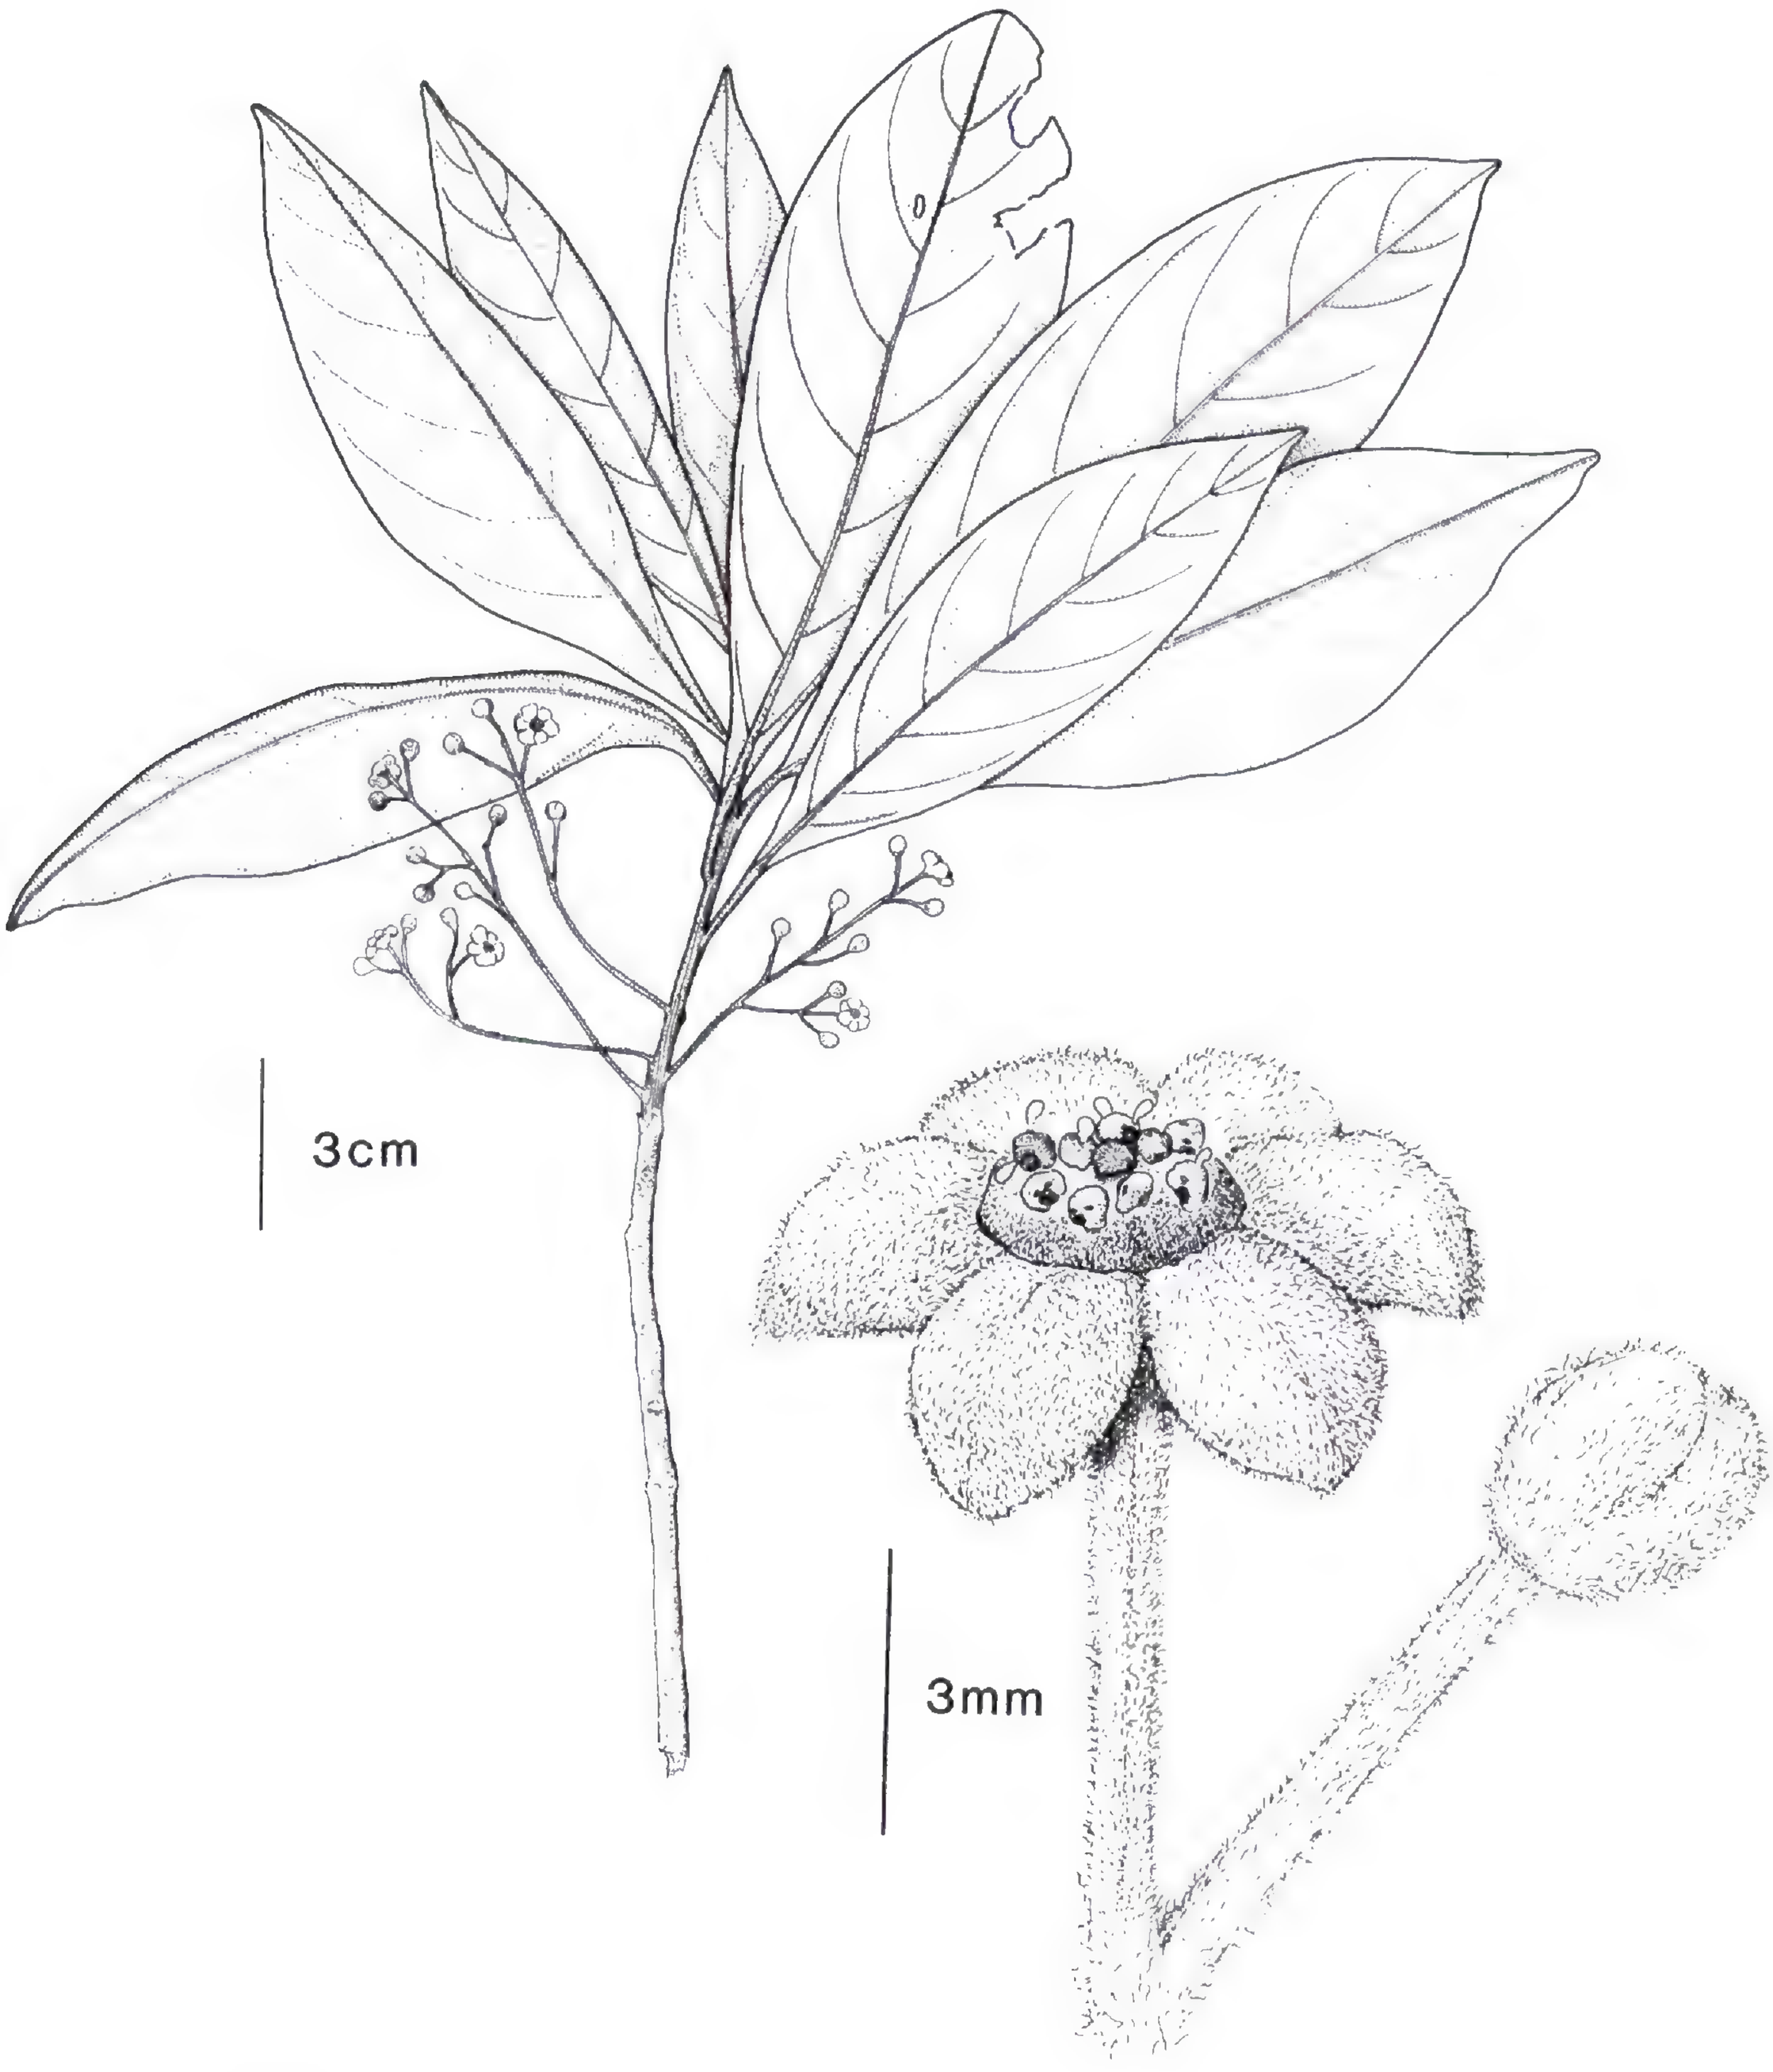

FIGURE 46. *P. westphalii*. Habit and flower.

Leaves clustered, rarely alternate, chartaceous, 30–40 × 6–11 cm, oblanceolate or narrowly obovate, the base cordate, the tip acuminate, acumen to 3 cm long, both surfaces glabrous, but with varying amounts of minute hairs on midrib and lateral veins; venation immersed on upper surface, midrib and lateral veins raised on lower surface, the tertiary venation weakly raised; lateral veins 20 25 on each side, curving upward near the margin and prominently loop-connected in the upper ⅔ of the lamina. Petioles to 8 mm long, with similar indument as twig. Inflorescences in axils of deciduous bracts, pendent, to 20 cm long, rufous-tomentellous, the branchlets 2–3 times cymosely branched, bracts present at anthesis, ovate, tomentellous, to 4 mm long. Flowers white, 8–9 mm diam. Pedicels 3 mm long. Tepals 6, subequal, the outer three slightly wider than the inner three, the outer three tomentellous outside, inner three with a basal triangular tomentellous patch, otherwise papillose, inside of all tepals papillose. Stamens 9, 4-celled, the cells lateral, anthers minutely papillose, glands

of stamens greatly enlarged, surrounding the stamens, fused. Ovary and style densely brown-papillose, floral tube brown-papillose inside; ovary globose, ca. 0.7 mm long, the style distinct, ca. 0.5 mm long. Cupule of young fruit cup-shaped, ca. 2 cm wide and 1 cm tall; young fruit ellipsoid, ca. 1.5 cm long. Fruits: July–October. Flowers: June–July.

*Collections studied.* ECUADOR. NAPO: Aguarico, Reserva Faunistica Cuyabeno, *Palacios 7667* (MO). PERU. LORETO: Quebrada Sucursari, tributary of Río Napo, *Gentry 54300* (MO); Pebas on the Amazon River, *Williams 1766* (B); Maynas, Iquitos, Asociación Agraria Paujil, *Vásquez 10877* (MO); Maynas, Explornapo Camp, Río Sucursari, *Vásquez 8119* (MO), *Vásquez 13078* (MO).

*Pleurothyrium williamsii* is only known from the type collection, four collections, all from Peru in the area north of the Río Napo–Río Amazonas, and one collection from Ecuador. Unfortunately, the holotype, which was requested from the Field Museum, disappeared, together with other *Pleurothyrium* types, while being sent to St. Louis. Of the type collection, only a duplicate in B (with buds) and some inflorescence fragments in G (with a few flowers) exist. The recent collections are a good match as far as floral characters and leaf shape are concerned, but there are some differences. The B specimen has alternate leaves, while the recent specimens and the photo of the holotype (in NY and F) show clustered leaves. The phototypes have the inflorescences alternate along a leafless twig, the recent specimens have the inflorescences near the tip of the stem, while the B specimen has a detached inflorescence. The B specimen is also more tomentulose. However, the similarities in leaf shape and flowers outweigh these differences, and I do not hesitate to assign the two recent collections to *P. williamsii*.

A close relative of this species is *Pleurothyrium panurense* (Meissner) Mez, a species with elliptic-obovate leaves, an obtuse leaf base and similar flowers. It differs, however, in its smaller leaves, the whitish indument on the lower leaf surface, its glabrous ovary, and longer petioles. *Pleurothyrium insigne* differs from *P. williamsii* in its larger leaves, the leaves not so gradually narrowed toward the base, erect indument on lower leaf surface, and its larger flowers. All three species occur in Amazonian Peru and/or adjacent Brazil. Another close relative is *P. maximum*, which see for further discussion.

## IMPERFECTLY KNOWN SPECIES

Among the collections were found a number of specimens that do not belong to any of the treated species and which very likely represent undescribed species. Because these specimens are incomplete (sterile or fruiting), they are not formally described, but only listed below so as to call attention to their existence. I hope that in the near future material adequate for their description will become available.

*G. Proctor Cooper 539*, Panama, Bocas del Toro, region of Almirante (F, NY, US).

A fruiting collection with large (to 35 cm), elliptic to elliptic-oblong, acuminate leaves. Leaves are glabrous below and have a strongly developed marginal vein; the twigs are solid, glabrous or nearly so. A distinct species, included in Burger & van der Werff (1990) as *Pleurothyrium* sp. A.

*Gentry 57004*, Colombia, Valle, Bajo Calima (MO).

A sterile specimen with gigantic leaves, according to the label ca. 1 m long. The specimen has leaves 60–70 cm long and 30–35 cm wide, densely rusty-tomentose below.

*Monsalve 1651*, Colombia, Valle, Bajo Calima (MO).

A species with clustered leaves, dark ferruginous-tomentose below, ca. 15 × 6 cm. Young inflorescences and infructescences are very short, ca. 1 cm long, and carry only one bud or fruit. There are five collections of this species, but none with flowers.

*López & H. Triana 24*, Colombia, Antioquia, Parque Nacional de las Orquideas (MO).

Characterized by its obovate to obovate-elliptic leaves, glabrous below, with 15–20 pairs of lateral veins and an obtuse to rounded leaf base. The young cupules are covered with many small lenticels.

*Vasquez 3220*, Peru, Loreto, Requena (MO).

Leaves glabrous, whorled, narrowly oblong with abruptly rounded base. Related to *P. williamsii*, but with narrower, oblong leaves and much smaller inflorescences.

## EXCLUDED SPECIES

*Pleurothyrium bahiense* (Meissner) Barroso = *Urbanodendron bahiense* (Meissner) Rohwer

*Pleurothyrium chrysothyrsus* Meissner = *Rhodostemonodaphne*

*Pleurothyrium cowanianum* C. K. Allen = *Rhodostemonodaphne kunthiana* (Nees) Rohwer

*Pleurothyrium ferrugineum* Meissner = *Ocotea arnottiana* (Nees) van der Werff
*Pleurothyrium glandulosum* (Lundell) Lundell = *Nectandra*
*Pleurothyrium velutinum* Meissner = *Ocotea calophylla* Mez

List of species recognized. New species are in boldface.

1. **Pleurothyrium acuminatum** van der Werff
2. *Pleurothyrium amapaense* Allen
3. *Pleurothyrium amplifolium* (Mez) Rohwer
4. *Pleurothyrium bifidum* Nees
5. **Pleurothyrium bracteatum** van der Werff
6. **Pleurothyrium brochidodromum** van der Werff
7. **Pleurothyrium cinereum** van der Werff
8. *Pleurothyrium costanense* van der Werff
9. **Pleurothyrium crassitepalum** van der Werff
10. *Pleurothyrium cuneifolium* Nees
11. **Pleurothyrium giganthum** van der Werff
12. **Pleurothyrium glabrifolium** van der Werff
13. **Pleurothyrium glabritepalum** van der Werff
14. *Pleurothyrium golfodulcense* Burger & Zamora
15. *Pleurothyrium grandiflorum* van der Werff
16. *Pleurothyrium hexaglandulosum* van der Werff
17. **Pleurothyrium insigne** van der Werff
18. *Pleurothyrium intermedium* (Mez) Rohwer
19. **Pleurothyrium marginale** van der Werff
20. *Pleurothyrium maximum* O. C. Schmidt
21. *Pleurothyrium nobile* A. C. Smith
22. **Pleurothyrium obovatum** van der Werff
23. *Pleurothyrium palmanum* (Mez & J. D. Smith) Rohwer
24. *Pleurothyrium panurense* (Meissner) Mez
25. *Pleurothyrium parviflorum* Ducke
26. **Pleurothyrium pauciflorum** van der Werff & Hammel

27. **Pleurothyrium pilosum** van der Werff
28. *Pleurothyrium poeppigii* Nees
29. **Pleurothyrium prancei** van der Werff
30. **Pleurothyrium racemosum** van der Werff
31. *Pleurothyrium steyermarkianum* Allen
32. **Pleurothyrium synandrum** van der Werff
33. **Pleurothyrium tomentellum** van der Werff
34. **Pleurothyrium tomiwahlii** van der Werff
35. *Pleurothyrium trianae* (Mez) Rohwer
36. *Pleurothyrium undulatum* (Meissner) Rohwer
37. **Pleurothyrium vasquezii** van der Werff
38. *Pleurothyrium westphalii* van der Werff
39. *Pleurothyrium williamsii* O. C. Schmidt

*Specimens studied.* If collected by a team, only last name of the first collector on the label is listed. Thus, Berg & Akkermans becomes Berg.

Note added in proof.

At the very last moment, the collection *Herrera & Fallas 4638* was received for identification. This collection represents an undescribed species, which could not be incorporated in the manuscript. The description of this species and a discussion of its affinities are presented in this note.

**Pleurothyrium immersum** van der Werff, sp. nov. TYPE: Costa Rica. Punarenas: Cantón de Golfito, Dos Brazos de Río Tigre, Fila Puriscal Rico (fls), *Herrera & Fallas 4638* (holotype, MO; isotypes, BM, CR, HBG, INB, MEXU, QRS, US, USJ).

Haec species *P. golfodulcense* proxima, sed foliis floribusque minoribus, reticulatione immersa, tepalis intus pubescentibus et inflorescentia paniculato-cymosa differt.

Tree, 20 m tall. Twigs terete, solid, finely gray appressed-pubescent, 1–2 mm diam. ca. 5 cm below the tip. Terminal bud densely appressed-pubescent. Leaves alternate, firmly chartaceous, 5–9 × 1.5–2.5 cm, elliptic, base acute, tip acuminate or acute, upper surface glabrous, gland dotted, lower surface with scattered appressed hairs, these more dense along midrib, or glabrous; midrib slightly raised on both surfaces, otherwise venation immersed and scarcely visible; lateral veins 5 6, not loop-connected. Petioles 4 9 mm long, finely appressed-pubescent. Inflorescences in axils of normal leaves or cataphylls, paniculate-cymose, the lateral branchlets once or twice cymosely branched, densely gray-pubescent, bracts often present at anthesis, narrowly elliptic, to 1.5 mm long, pubescent on both surfaces. Flowers yellow-green, the tepals spreading to bent downward, ca. 5 mm diam. Pedicels 2–4 mm long. Tepals 6, equal or nearly so, pubescent on both surfaces, the margin plane, elliptic, ca. 2 mm long, the inner 3 ca. 1.5 mm wide, outer 3 ca. 1 mm wide. Stamens 9, all 4-celled, fully immersed in the glandular mass, with only the cells and valves recognizable; glands strongly enlarged, fused, and forming a pillowlike mass; stamens, especially those of whorl II, separated from each other by the glandular tissue and not restricted to the center of the glandular mass. Pistil ca. 1.2 mm long, the moderately pubescent ovary gradually narrowed into the glabrous style. Receptacle pubescent inside. Cupule and fruit unknown. Flowers: November. Elevation range: ca. 700 m.

*Pleurothyrium immersum* is only known from the type collection made on the Osa Peninsula, collected in the same general area as *P. golfodulcense*; these two species are closely related. Characters shared by both are the position of the stamens in the glandular mass (not crowded together in the center, but stamens of whorl II separated from the others by the glandular tissue), position of inflorescences (not infrequently in axils of normal leaves), the reflexed tepals in older flowers, and the acute-acuminate leaf tips. However, the two species differ in the following characters: *P. immersum* has much smaller leaves (5 9 vs. 10–20 cm), the lateral veins are immersed and not raised on lower leaf surface, flowers are much smaller (4–5 vs. 9–12 mm diam.), tepals are pubescent (not papillose) on inner surface, and the inflorescences are paniculate-cymose, not racemose.

In the key, *Pleurothyrium immersum* would run to couplet 37, where the combination in *P. immersum* of pubescent inner surface of tepals and a pubescent pistil will cause a problem. However, *P. immersum* differs from all other *Pleurothyrium* species with glabrous or appressed-pubescent lower leaf surfaces in its small leaves with immersed venation. The glandular dots on the upper leaf surface are also a good indicator for this species.

# A REVISION OF *PANICUM* SUBG. *DICHANTHELIUM* SECT. *DICHANTHELIUM* (POACEAE: PANICOIDEAE: PANICEAE) IN MESOAMERICA, THE WEST INDIES, AND SOUTH AMERICA[1]

## Abstract

A revision of *Panicum* subg. *Dichanthelium* sect. *Dichanthelium* (Poaceae: Panicoideae: Paniceae) for Mesoamerica, the West Indies, and South America is presented, considering exomorphological, anatomical data and caryological characters. Thirty-seven species and seven varieties of section *Dichanthelium* of *Panicum* are recognized from this area. *Panicum caparaoense* is described as a new species, and *Panicum dichotomum* var. *tenue* as a new combination. An anatomical description of section *Dichanthelium*, with photomicrographs of representative species, is given, together with a key, morphological descriptions, and distribution maps. It is concluded that section *Dichanthelium* is not sufficiently distinct to be regarded as a separate genus. The taxonomic position of *Dichanthelium* within *Panicum* is discussed.

*Dichanthelium* was established by Hitchcock & Chase (1910) as a subgenus of *Panicum* in their treatment of North American species of the genus. *Dichanthelium* was delimited due to the presence of an overwintering rosette of short, broad leaves, which produce simple culms with terminal, chasmogamous inflorescences in the spring. Later in the season, branch culms arise at the nodes of the vernal culms, forming loose to rather dense fascicles of reduced leaves and branches together with cleistogamous inflorescences.

Hitchcock & Chase (1910) recognized 17 informal groups in *Dichanthelium*, 110 species and 5 subspecies. The taxa were distinguished principally by characters of the spikelet and leaf blade. Gould (1974) raised *Dichanthelium* to generic rank. This decision was followed by Clark & Gould (1975), Brown & Smith (1975), Gould & Clark (1978), Clark (1977), Gould (1980), Freckmann (1981a, b), and Hansen & Wunderlin (1988) based on the foliar and floral dimorphism, ploidy level, Kranz syndrome, and ornamentation of the upper anthecium as diagnostic characters for the genus. Pohl (1980), Lelong (1984), Zuloaga (1987), Webster (1988), and Morrone & Zuloaga (1991), however, retained *Dichanthelium* as a subgenus of *Panicum*, due to a lack of adequate characters to support the segregation of these two taxa. Variation in several characters, such as the presence or absence of the basal rosette, and foliar and floral dimorphism in tropical species were not considered by Hitchcock & Chase (1910), Gould (1974), and subsequent authors in their decision to separate *Dichanthelium* from *Panicum*.

The present treatment includes a comprehensive taxonomic and anatomical analysis of the 37 species of section *Dichanthelium* occurring in Mesoamerica, the West Indies, and South America, which comprise all tropical species of the section.

## Materials and Methods

Scanning electron micrographs (SEMs) were prepared of the upper anthecia of most of the species, utilizing the procedures described by Soderstrom & Zuloaga (1989). The vouchers for this

[1] We thank Vladimiro Dudás for the illustrations. Zuloaga acknowledges support of a fellowship from the John Simon Guggenheim Memorial Foundation, to which he expresses appreciation. Zuloaga's fieldwork in Colombia and Venezuela was carried out under grant #3964-88 from the National Geographic Society, to whom Zuloaga is also grateful.

[2] Instituto de Botánica Darwinion, Casilla de Correo 22, San Isidro, 1642, Argentina.

[3] Grassland Research Center, Private Bag X05, Lynn East, 0039, South Africa.

study are marked with an asterisk in the specimens examined section of the taxonomic treatment. Field procedures included collection and drying of herbarium specimens, and immediately fixing leaves, spikelets, and other structures in FAA (formalin-ethanol-acetic acid) (Johansen, 1940) and thereafter transferring this material to 70% ethanol in the laboratory for storage. Transverse sections of leaf blade material 10 μm thick were prepared after desilicification in 30% hydrofluoric acid (Breakwell, 1914), dehydration in a methyl cellosolve series (Feder & O'Brien, 1968), and embedding in Tissue Prep (Fisher Scientific); the sections were stained in safranin and fast green.

Abaxial epidermal scrapes of leaf blades were prepared by removing the mesophyll and vascular tissue with a scalpel and camel hair brush following the method of Metcalfe (1960). The epidermis was stained in safranin.

The standardized terminology of Ellis (1976, 1979) was used to describe the anatomical structure of the leaf blades. The following abbreviations are used in the anatomical description:

vb/s—vascular bundle/s
1′vb/s—first-order vascular bundle/s
2′vb/s—second-order vascular bundle/s
3′vb/s—third-order vascular bundle/s
ibs—inner bundle sheath; i.e., mestome sheath
obs—outer bundle sheath; i.e., parenchyma sheath

## Morphology

*Basal rosette.* The rosette is typical of North American species of section *Dichanthelium* and is also sometimes present in some West Indian species, *P. scoparium* Lam., *P. aciculare* Desv., and *P. acuminatum* Sw. However, this feature is absent from species from Mesoamerica and South America, as well as from some species that are widespread in both North and South America, such as *P. aciculare*, *P. acuminatum*, and *P. sphaerocarpon* Elliott.

*Foliar dimorphism.* Leaf size is variable in representatives of section *Dichanthelium*. Leaf blades are usually broad and long on the main culms and smaller on the axillary culms in species from North America. However, this dimorphism is absent in species from Mesoamerica and South America. Main and axillary culms are persistent in Mesoamerican and South American species (Morrone & Zuloaga, 1991), while in North American species only the rosette usually persists.

*Inflorescences.* The inflorescence in section *Dichanthelium* is typically a lax, diffuse panicle borne on the uppermost node of the culm; it is short-exserted to exserted. The axes of the branches are pilose or glabrous; when glabrous they usually have multicellular glands. Each axis ends in a developed spikelet; these spikelets are solitary on the branches, or occasionally geminate in specimens of *P. hebotes* Trin. The panicle, although usually open, is contracted in *P. superatum* Hackel and *P. aciculare*.

*Glands.* Multicellular glands are a characteristic feature of several species of section *Dichanthelium*. These glands are present in *P. acuminatum*, *P. sabulorum* var. *polycladum* (E. Ekman) Palacios, *P. sabulorum* var. *cordatum* Zuloaga & Morrone, *P. stigmosum* Trin., *P. adenorachis* Zuloaga & Morrone, *P. sphaerocarpon*, *P. strigosum* Muhlenb., *P. surrectum* Chase ex Zuloaga & Morrone, *P. ensifolium* Elliott, *P. scoparium*, *P. cucaense* Zuloaga & Morrone, *P. divergens* HBK, and *P. laxiflorum* Lam. These glands occur on the axes of the inflorescence branches, peduncles, pedicels, culms, sheaths, and blades.

*Spikelets.* The spikelets are ellipsoid to obovoid, with two glumes, two florets, and two flowers. They disarticulate at the base of the lower glume. Lower glume length varies from ¼ to ⅘ the length of the spikelet. The upper glume and lower lemma are isomorphic and 7–11(–15)-nerved, or occasionally 5-nerved in *P. sciurotis* Trin. and *P. ensifolium*. The lower floret is either staminate or neuter; the lower palea may be as long as the lemma or reduced to absent in *P. aciculare* and *P. penicillatum* Nees ex Trin. The upper anthecium is almost as long as the spikelet; the upper lemma and palea are indurate, smooth and shining, and pale (but dark in *P. hebotes*) with simple papillae regularly distributed over the surface. The upper lemma is shortly apiculate or crested and pilose or glabrous, with the margins involute and covering ⅔ of the upper palea. The upper palea is 2-nerved. The upper floret is bisexual, with two conduplicately truncate lodicules that embrace the lower margins of the palea, three stamens, and a gynoecium with two free styles and a plumose stigma.

*Floral dimorphism.* Hitchcock & Chase (1910) and Gould & Clark (1978) described the presence of both chasmogamous and cleistogamous flowers in the species of *Dichanthelium* from North America. Study of herbarium specimens and native and cultivated Mesoamerican and South American plants, including widespread species from both North America and South America, demonstrated that the production of chasmogamous and cleistogamous flowers is extremely variable. Climatic fac-

tors, such as humidity and temperature, appear to determine the proportion of cleistogamous flowers produced.

Cleistogamous flowers also occasionally occur on species of section *Dichanthelium* from Mesoamerica and South America.

## Chromosome Numbers

Section *Dichanthelium* is characterized by a basic chromosome number of $x = 9$. Gould & Soderstrom (1967) mentioned one deviation in this character, a count of $2n = 20$, $x = 10$ for *P. missionum* Mez, non Ekman (= *Panicum surrectum* Chase ex Zuloaga & Morrone).

Most of the species are diploid, with $2n = 18$. In addition, six tetraploid counts, one hexaploid count, and one octoploid count are also known.

The following list summarizes chromosome counts determined for species of section *Dichanthelium* treated in the present contribution:

*Panicum aciculare* Desv. var. *aciculare*: $2n = 18$ (Brown, 1948; Dubcovsky & Zuloaga, 1992).

*P. aciculare* Desv. var. *arenicoloides* (Ashe) Beetle: $2n = 18$ (Brown, 1948; Gould, 1958; Burton, 1942, as *P. arenicoloides* Ashe; Brown, 1948, as *P. angustifolium* Elliot).

*P. acuminatum* Sw. var. *acuminatum*: $n = 9$ (Davidse & Pohl, 1972a, 1978, as *P. olivaceum* A. Hitchc. & Chase; Spellenberg, 1970, as *P. olivaceum*); $2n = 18$ (Dubcovsky & Zuloaga, 1992).

*P. acuminatum* Sw. var. *longiligulatum* (Nash) Lelong: $2n = 18$ (Brown, 1948, as *P. longiligulatum* Nash and *P. wrightianum* Scribner).

*P. aequivaginatum* Swallen: $2n = 18$ (Dubcovsky & Zuloaga, 1992).

*P. davidsei* Zuloaga & Morrone: $2n = 72$ (Dubcovsky & Zuloaga, 1992).

*P. dichotomum* L.: $2n = 18$ (Brown, 1948; Clark, 1977; Sherif et al., 1983; Brown, 1948, as *P. barbulatum* Michaux, *P. yadkinense* Ashe, and *P. caerulescens* Hackel ex A. Hitchc.).

*P. dichotomum* L. var. *unciphyllum* (Trin.) Zuloaga & Morrone: $2n = 18$ (Brown, 1948, as *P. albomarginatum* Nash).

*P. divergens* HBK: $2n = 18$ (Burton, 1942; Brown, 1948; Sherif et al., 1983, as *P. commutatum* Schult.).

*P. ensifolium* Baldwin ex Elliott: $2n = 18$ (Brown, 1948; Brown, 1948, as *P. chamaelonche* Trin.).

*P. laxiflorum* Lam.: $2n = 18$ (Brown, 1948; Gould, 1958; Pohl & Davidse, 1971; Bowden, 1960, as *P. xalapense* Kunth).

*P. portoricense* Desv. ex Ham.: $2n = 18$ (Brown, 1946; Brown, 1948, as *P. lancearium* Trin.).

*P. pycnoclados* Tutin: $2n = 18$ (Dubcovsky & Zuloaga, 1992).

*P. sabulorum* Lam. var. *polycladum* (E. Ekman) Palacios: $2n = 36$ (Parodi, 1946; Núñez, 1952, as *P. sabulorum*; Dubcovsky & Zuloaga, 1992).

*P. sabulorum* Lam. var. *sabulorum*: $2n = 54$ (Dubcovsky & Zuloaga, 1992; Parodi, 1946; Núñez, 1952, as *P. fultum* Hackel).

*P. sciurotoides* Zuloaga & Morrone: $2n = 18$ (Dubcovsky & Zuloaga, 1992).

*P. scoparium* Lam.: $n = 9$ (Davidse & Pohl, 1972b); $2n = 18$ (Brown, 1948).

*P. sphaerocarpon* Elliott: $n = 9$ (Spellenberg, 1970; Davidse & Pohl, 1972a, 1978; Reveal & Spellenberg, 1976); $2n = 18$ (Church, 1929; Brown, 1948; Gould, 1958; Pohl & Davidse, 1971; Reveal & Spellenberg, 1976; Dubcovsky & Zuloaga, 1992; Brown, 1948, as *P. sphaerocarpon* Elliott var. *inflatum* (Scribner & Smith) A. Hitchc.).

*P. strigosum* Muhlenb.: $2n = 18$ (Brown, 1946; Brown, 1948, as *P. ciliatum* Elliott).

*P. viscidellum* Scribner: $n = 18$ (Davidse & Pohl, 1972a, 1974); $2n = 36$ (Pohl & Davidse, 1971; Dubcovsky & Zuloaga, 1992).

## Leaf Anatomy

Anatomical data for 14 species of section *Dichanthelium* are presented by means of photomicrographs (Figs. 1–23). The following species were studied: *P. aciculare*, *P. acuminatum*, *P. aequivaginatum*, *P. cumbucana* Renvoize, *P. davidsei*, *P. hebotes*, *P. peristypum* Zuloaga & Morrone, *P. pycnoclados*, *P. sabulorum*, *P. sciurotoides*, *P. sphaerocarpon*, *P. stigmosum*, *P. superatum*, and *P. viscidellum*. For comparative purposes the North American species *P. boscii* Poir., *P. clandestinum* L., and *P. oligosanthes* Schultes are also included in this study. *Panicum acuminatum* is the only species studied anatomically with specimen samples from both American continents. For this species a comparison between the leaf anatomy of the basal rosette leaves and the cauline leaves is also made.

The leaf anatomy of section *Dichanthelium* is variable, with few unifying or diagnostic characters being evident; the vascular bundle sheaths and their extensions are the most consistent and valuable anatomical character for distinguishing the section

C

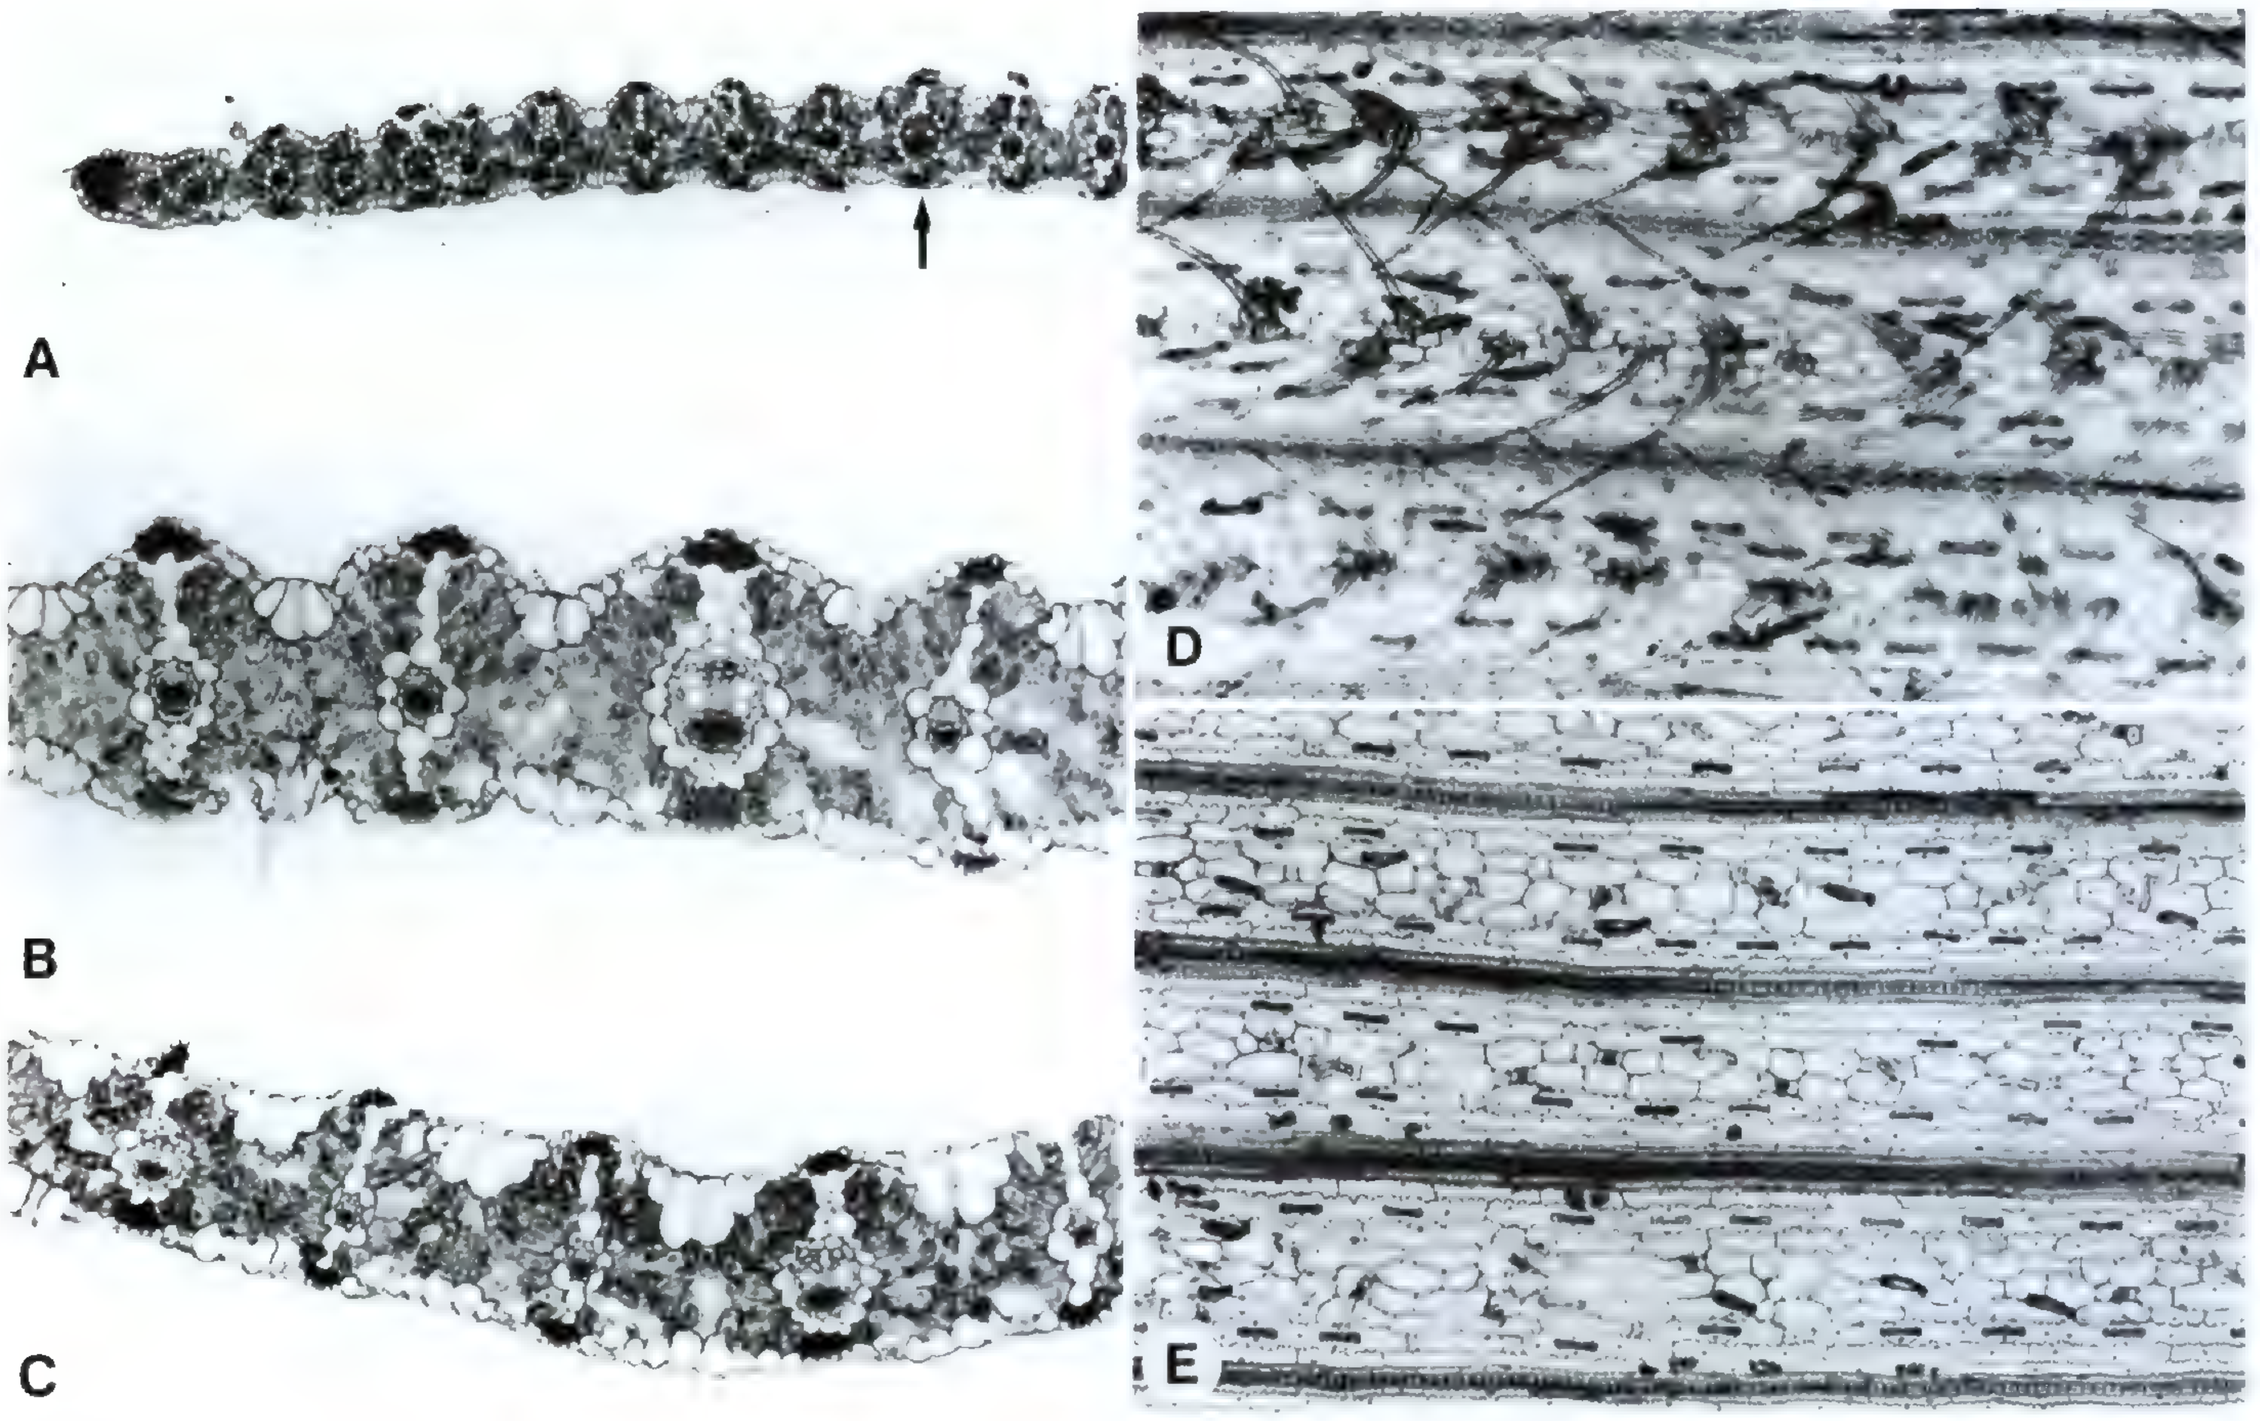

FIGURE 2. Leaf blade anatomy of South American specimens of *Panicum acuminatum*. A–C. Transectional anatomy.—A. Outline of half of lamina showing rounded margin with well-developed sclerenchyma cap and undifferentiated median vascular bundles (arrowed).—B. Detail of semiradiate chlorenchyma, colorless outer bundle sheath and extension cells, uniseriate adaxial and abaxial bundle sheath extensions, and small sclerenchyma strands associated with the third-order vascular bundles and slight adaxial ribs and furrows; note the raised cushion cells associated with the macrohairs, which are very common in the abaxial intercostal zones.—C. Specimen with thinner leaf without ribs and furrows. D, E. Abaxial epidermal structure.—D. Specimen with numerous recurved macrohairs located along the intercostal zones; microhairs also relatively common.—E. Specimen with few macrohairs, these associated with two inflated epidermal cells; the central files of the intercostal zones with bulliformlike long cells (based on *Zuloaga 4202*; A ×100; B–E ×250).

and subgenus *Dichanthelium* from most of the other $C_3$ subgenera of *Panicum*. A detailed description of section *Dichanthelium* based on the studied species is presented below.

## LEAF BLADE IN TRANSVERSE SECTION

*Outline:* expanded, either flat or very broadly V-shaped; arms of lamina either straight or outwardly bowed; two halves of lamina symmetrical about the median vascular bundle; leaf width variable and leaf blade section includes between 17 and 117 vbs; *P. aciculare* (Fig. 1) is an exception with narrow (only 11 vbs), inrolled leaf blades. *Ribs and furrows:* variable, from flat adaxial surfaces without ribs or furrows to medium furrows (about a quarter of the leaf thickness); furrows wide and open, occurring between all vbs; adaxial ribs, when present, located over the vbs, with rounded apices, and all are structurally uniform; abaxial ribs usually absent but slight ribbing may be developed; in *P. aciculare* abaxial ribs are clearly present (Fig. 1B). *Midrib:* variable, from undifferentiated median vb to definite keel; median vbs, structurally indistin-

←

FIGURE 1. Leaf blade anatomy of *Panicum aciculare*. A. Blade outline showing atypical, narrow, slightly inrolled blade containing only three first-order bundles with the central median bundle (arrowed) structurally identical to the lateral first-order bundles.—B. Detail of unusually prominent adaxial ribs and furrows, small, bulliform cells, and thick abaxial cuticle without stomata; translucent parenchymatous sheath and extension cells are present as are adaxial and abaxial sclerenchyma strands; the rather dense mesophyll tissue exhibits no pattern of cellular arrangement.—C. Abaxial epidermis without stomata, the costal zones are five cells wide with cross-shaped silica bodies separated by tall and narrow cork cells, the intercostal long cells are elongated-rectangular with very sinuous walls, and small, narrow microhairs occur in the intercostal zones; macrohairs are absent (based on *Zuloaga & Londoño 4201*; A ×100; B, C ×250).

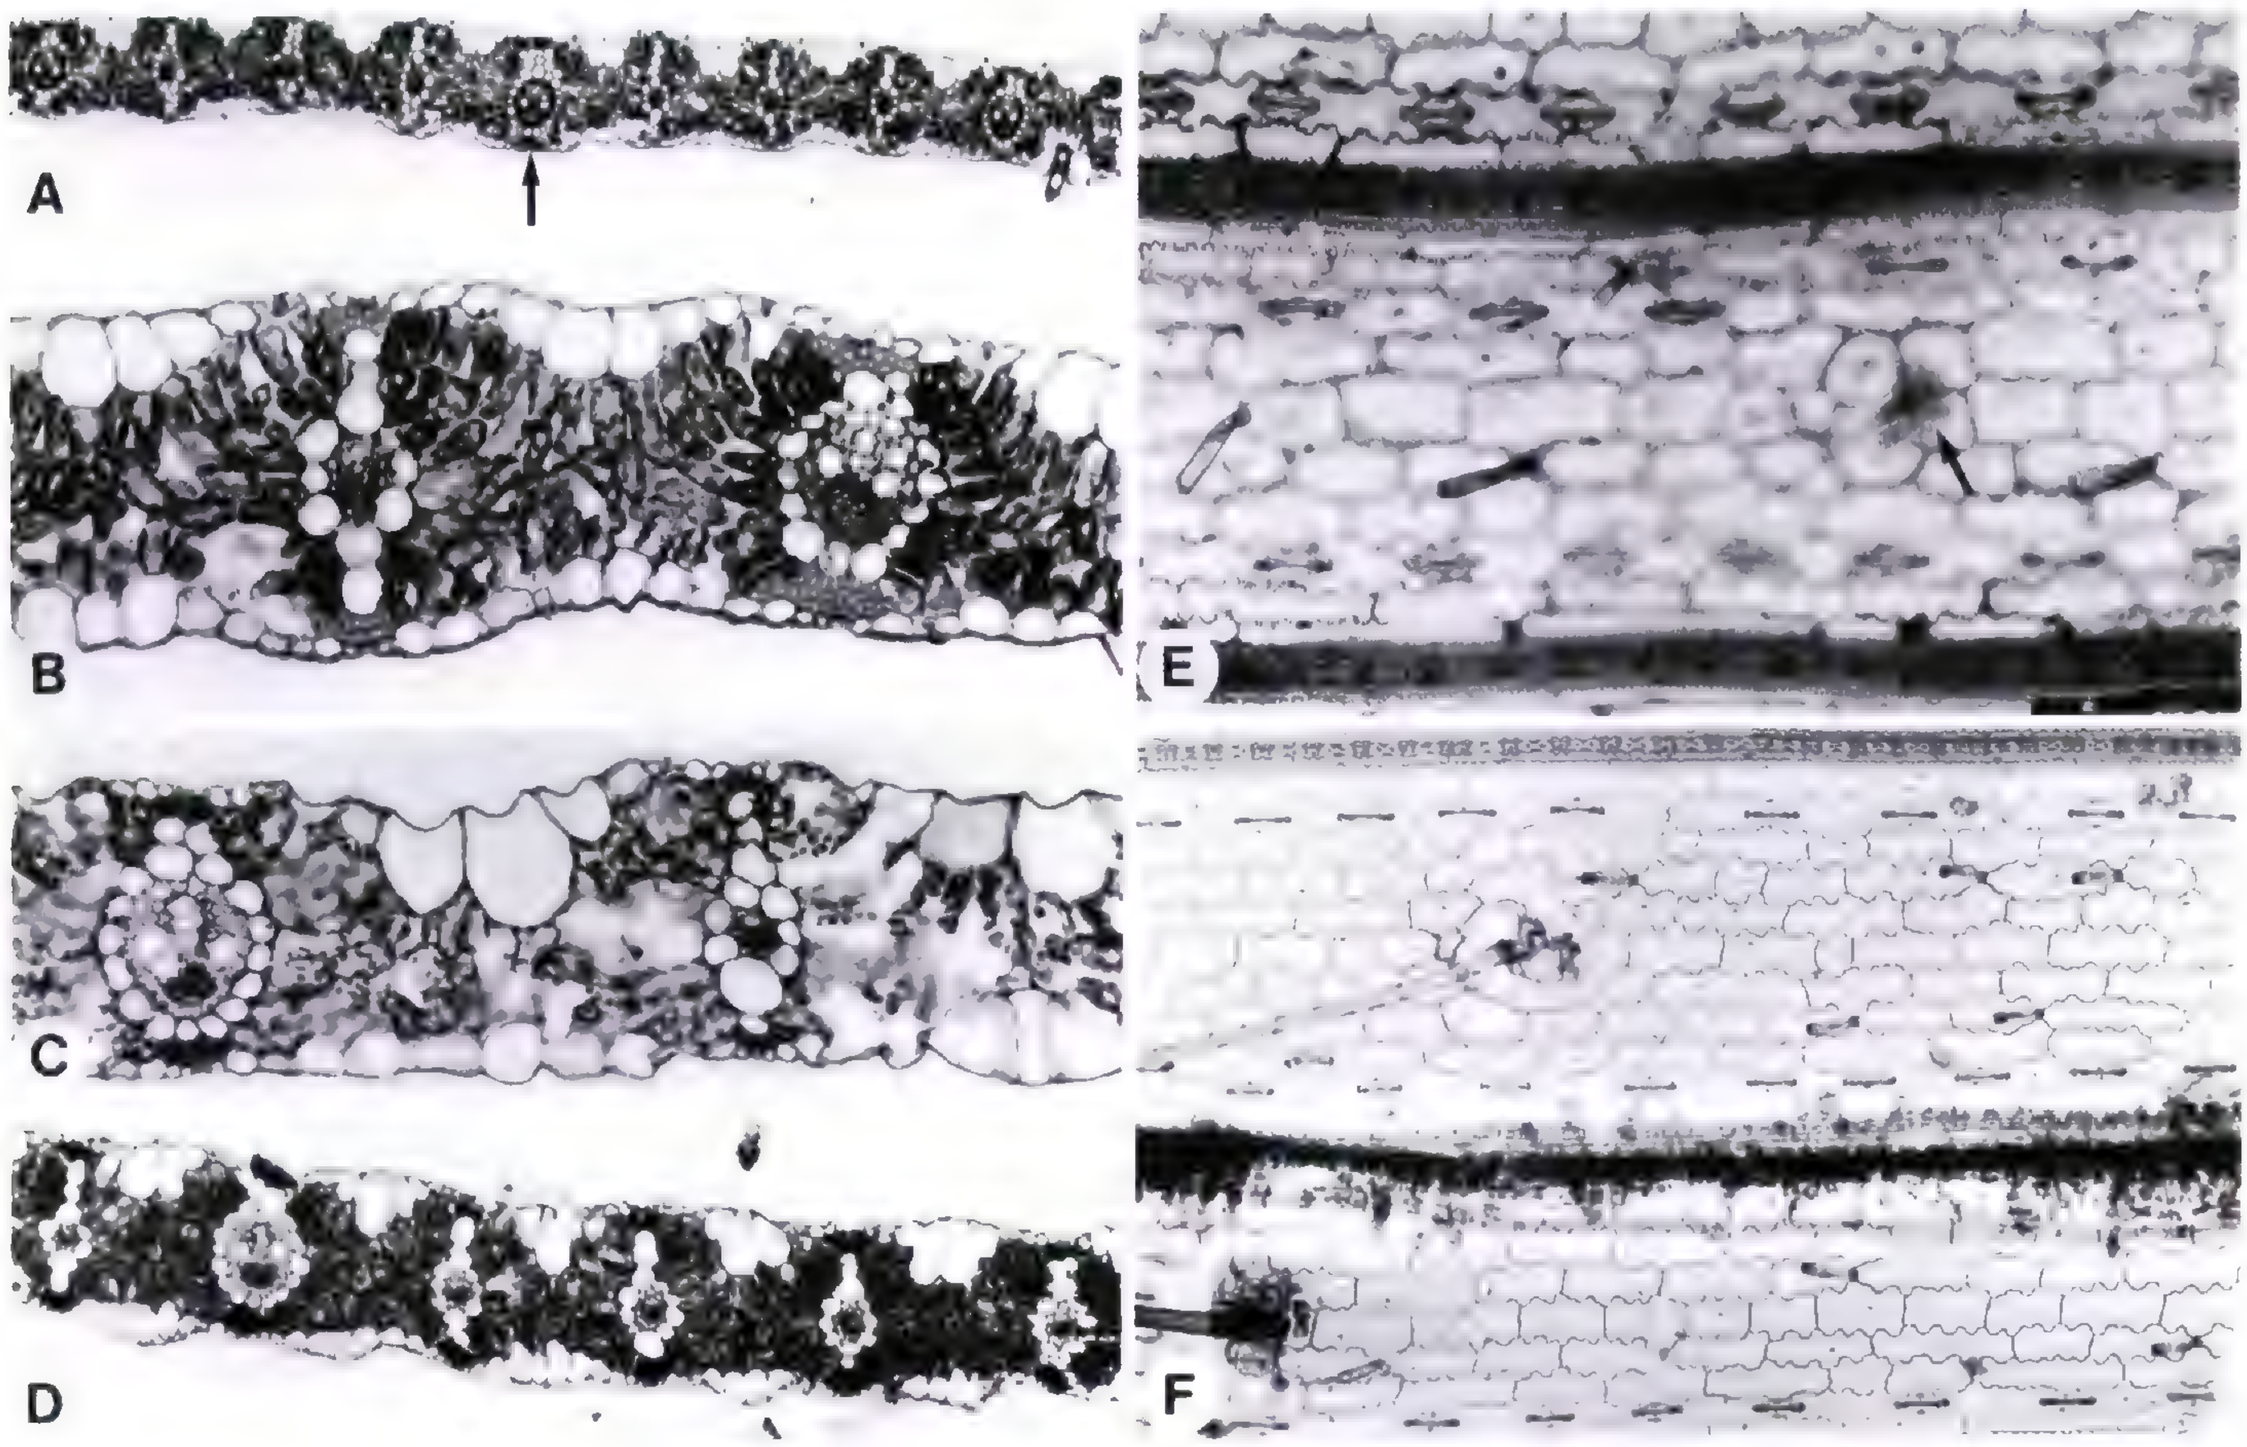

FIGURE 3. Leaf blade anatomy of *Panicum acuminatum* specimens from North America. A–D. Transverse leaf blade sections.—A. Median part of blade with midrib (arrowed) structurally barely distinct from lateral first-order bundles; note cushion-based macrohair; adaxial ribs and furrows not present.—B. Semiradiate chlorenchyma tissue with a tendency to adaxial palisade and abaxial spongy mesophyll tissue; note adaxial and abaxial uniseriate bundle sheath extensions associated with the third-order bundle, the extensions linked to small sclerenchyma strands.—C. Specimen with diffuse chlorenchyma tissue with very large intercellular air spaces and very thin cuticle. —D. Specimen with compact mesophyll tissue; no adaxial ribs or furrows developed. E, F. Abaxial epidermis.—E. Detail of small macrohair with associated cushion base cells (arrowed), elongated fingerlike microhairs (at least twice the length of the stomata), intercostal long cells and numerous stomata in files adjacent to the narrow costal zones.—F. Epidermis of specimen with thin cuticle and diffuse mesophyll; note macrohairs, sinuous walls of long cells, microhairs, stomata, and narrow costal zones, only three cells wide (A, B, E, based on *Davidse & Ellis 30825*; C, F, based on *Davidse & Ellis 30807*; D, based on *Zuloaga 2492*; A ×100; D, F ×250; B, C, E ×400).

guishable from other 1′vbs, most common (Figs. 2A, 5A, 12B, 15C, 16A, 17A, 18A, C, 23A); midribs (Figs. 3A, 11A, 14A, 21A) and keels (Figs. 8A, C, 10A, 22A) much less common; keels include either 1 or 3 abaxially positioned vbs and adaxially located parenchyma ground tissue; no lacunae present.

*Vascular bundle arrangement:* number of vbs very variable with 3, 5, 7, 9, 11, 13, or 15 1′vbs in entire blade; *P. aciculare*, with 3 (Fig. 1), and *P. sabulorum*, which may have only 5, also have the narrowest leaf blades; 2 (*P. aciculare* and *P. sabulorum*, Fig. 12D), 3, 4, 5, 6, 7, and rarely 8, 3′vbs are located between consecutive lateral 1′vbs; the wider the leaf the more 1′vbs and the more minor bundles are present between the 1′vbs; 2′vbs absent. Vbs usually displaced slightly toward the abaxial side of the blade thickness although they may be centrally situated; all vbs positioned at the same level. *Vascular bundle description:* 3′vbs angular with phloem distinguishable. 1′vbs elliptical in outline; phloem adjoins ibs; lysigenous cavities and protoxylem present; circular metaxylem vessels narrow with diameters less than half those of the obs cells. *Vascular bundle sheaths:* obs of 1′ and 3′vbs conspicuous, entire, round to elliptical, consisting of 5–8 (3′vbs) or 12–18 (1′vbs) inflated, rounded cells; chloroplasts absent except in a few specimens (e.g., *P. sphaerocarpon*, Fig. 15A–D, as well as specimens of *P. viscidellum* with silicified macrohair bases, Fig. 20). Adaxial and abaxial bundle sheath extensions in all species; adaxial 3′vb extensions usually uniseriate (but may be biseriate) and consisting of 1–5 cells, whereas abaxial extensions are shorter (usually only 1 cell deep) and wider; the extensions consist of conspicuous, thin-walled, colorless cells very similar to the obs cells; the extensions extend and join small

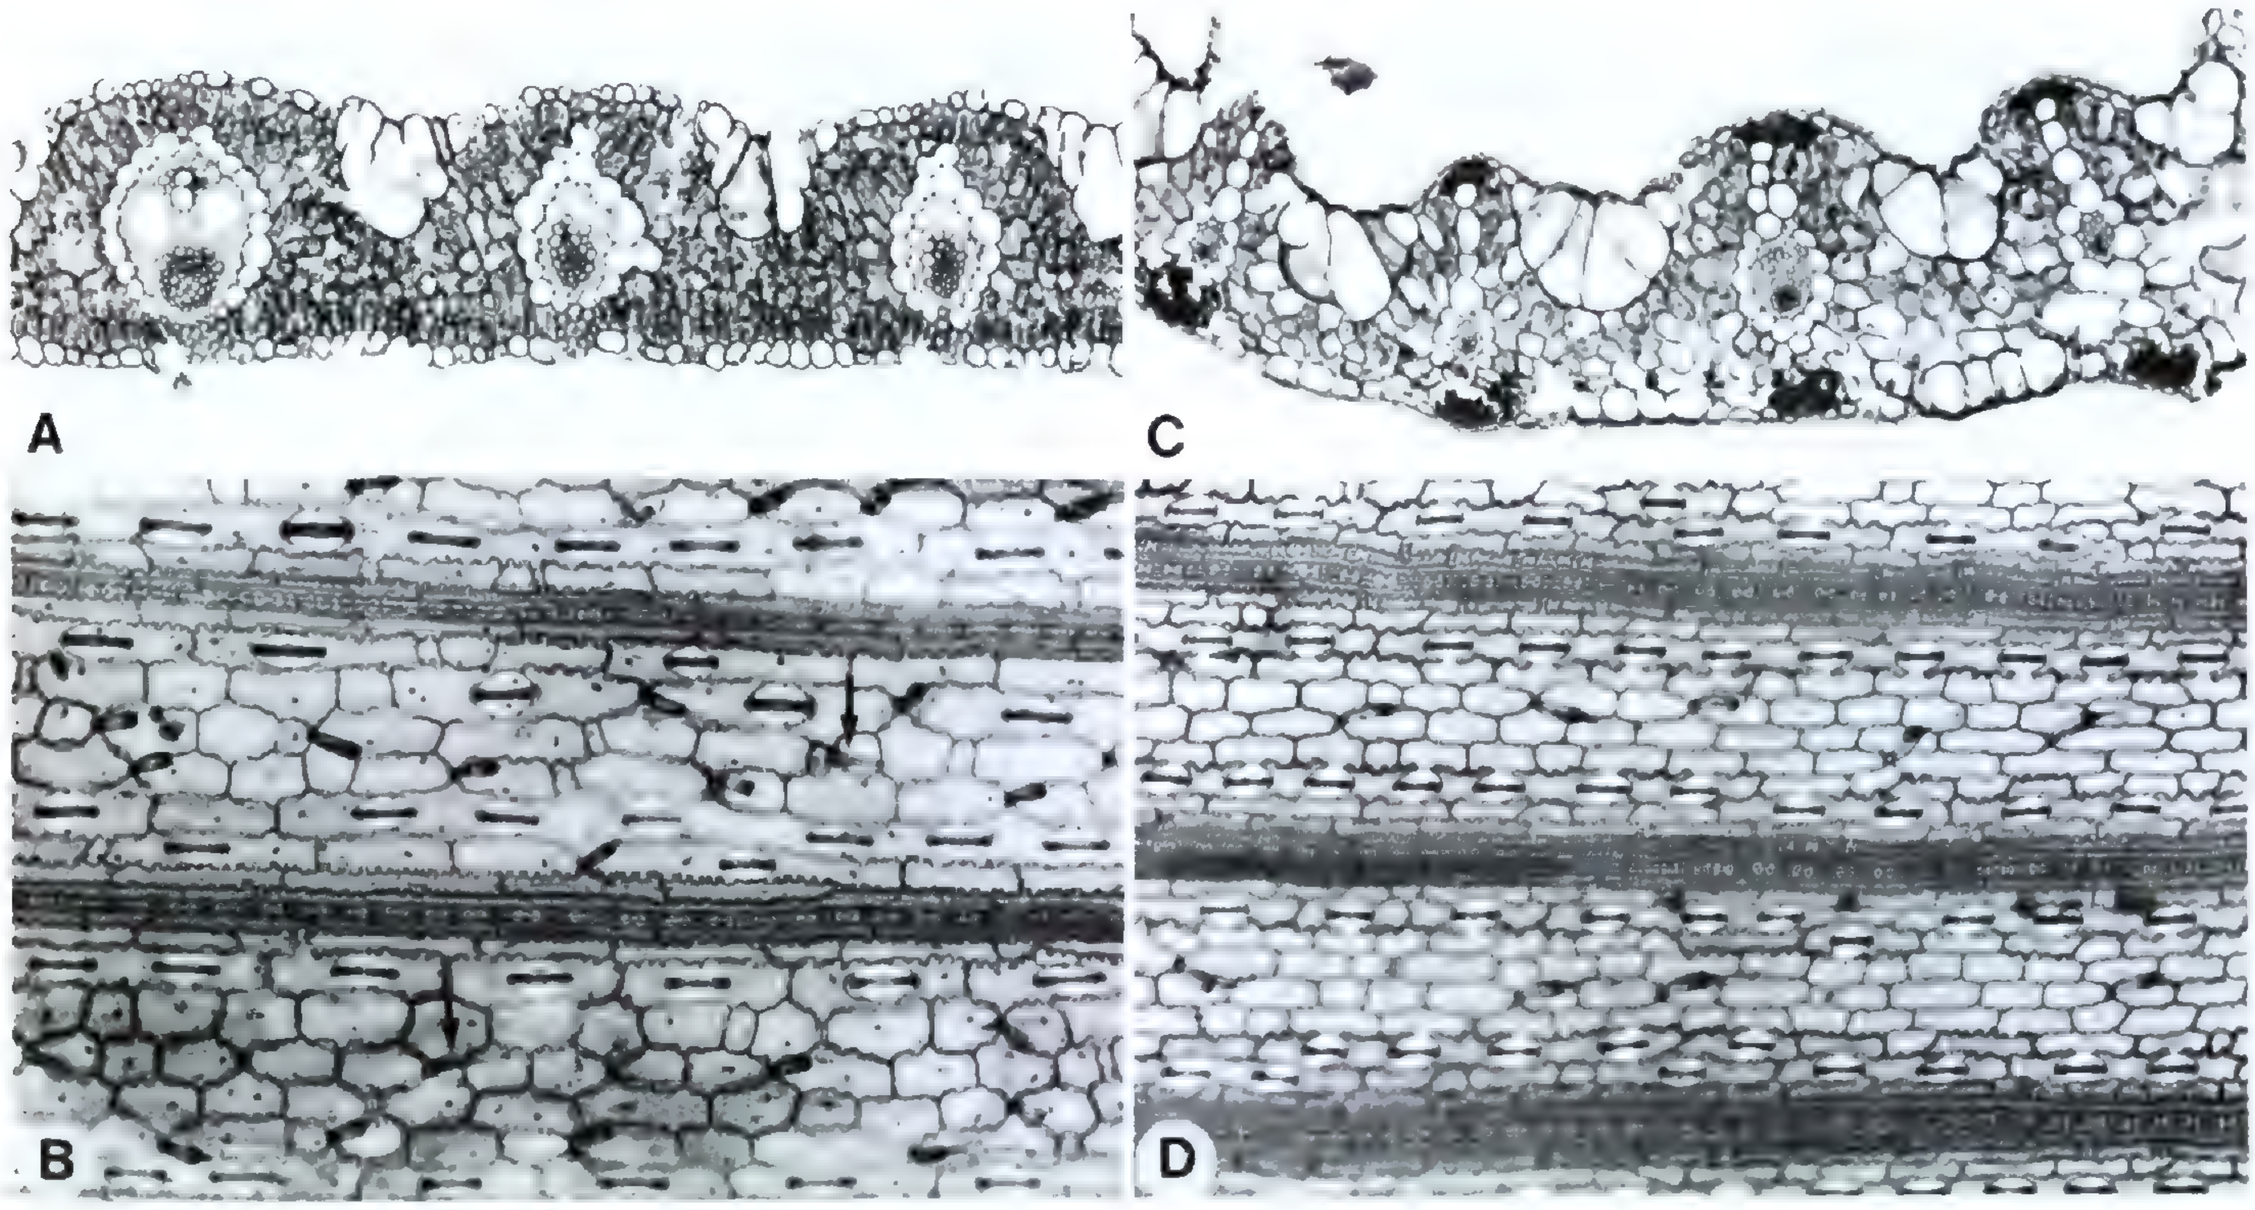

FIGURE 4. A comparison of the leaf blade anatomy of the upper culm leaves and the basal rosette leaves of *Panicum acuminatum*. A, B. Upper culm leaves.—A. Transverse section showing slight adaxial ribs and furrows, distinct bulliform cell groups, and very short bundle sheath extensions; the mesophyll is unusual in that the abaxially located cells are also palisadelike in their arrangement, and the mesophyll tissue is dense, without large intercellular air spaces.—B. Abaxial epidermis with short long cells, short microhairs (less than twice the length of the stomatal complexes) and dumbbell-shaped silica bodies alternating with cross-shaped cork cells on the central files of the costal zones; note the very short macrohairs (arrowed), these barely distinct from hooks except that they are associated with a single inflated epidermal cell. C, D. Basal rosette leaves.—C. Transverse section showing distinct adaxial ribs and furrows, well-developed uniseriate extensions to four cells long and diffuse mesophyll tissue with the abaxial cells resembling spongy mesophyll.—D. Abaxial epidermis with short long cells, microhairs at least twice the length of the stomata, no macrohairs, and with costal zones to five cells wide; the silica bodies are irregular in shape, often resembling the dumbbell type (A–D, based on *Zuloaga 2490*; A–D ×250).

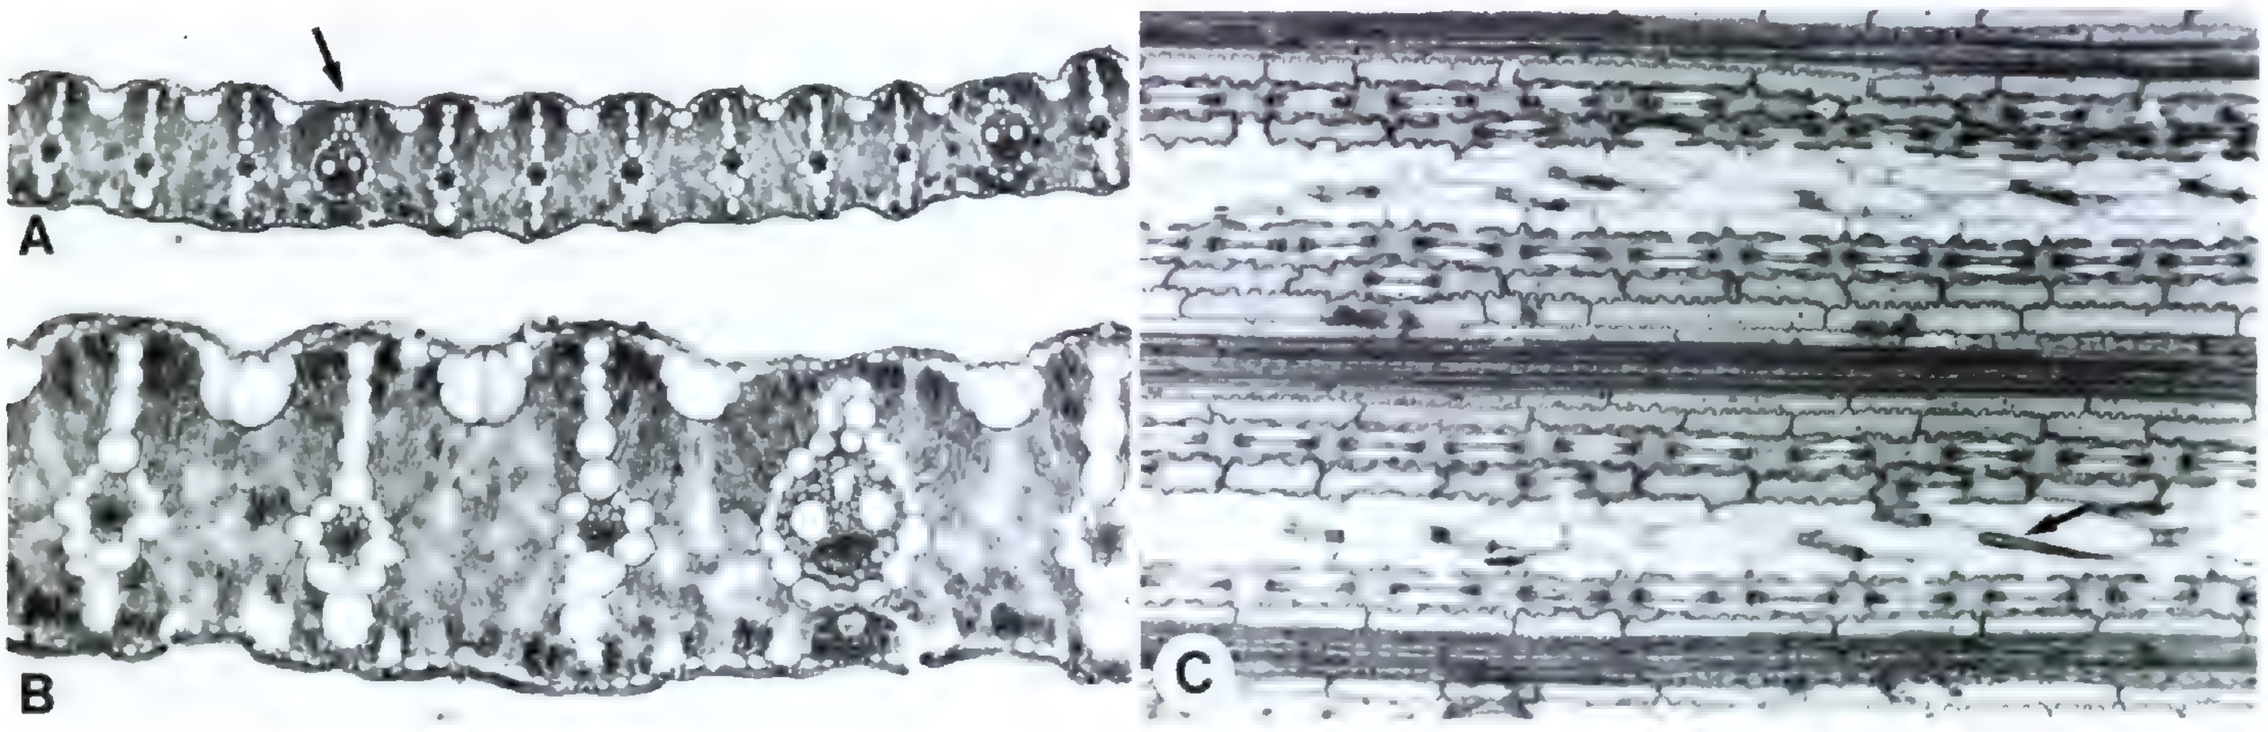

FIGURE 5. Leaf blade anatomy of *Panicum aequivaginatum*. A, B. Transectional anatomy.—A. Center of lamina showing median vascular bundle (arrowed) undifferentiated from other first-order vascular bundles.—B. Detail of conspicuous outer bundle sheath and uniseriate extension cells without chloroplasts; the mesophyll separable into spongy and palisade chlorenchyma tissue and the cells are densely arranged; bulliform cells are small and sclerenchyma strands minute.—C. Abaxial epidermis showing clear differentiation between the narrow costal zones with dumbbell-shaped silica bodies and much wider intercostal zones; the latter are differentially stained, the cell files adjacent to the costal zones as well as the interstomatal files staining darkly, the central files staining only slightly; microhairs and few short macrohairs (arrowed) are located along these central interstomatal files; specimens with thicker cuticles (e.g., B) lack these central intercostal files with microhairs and macrohairs (A, B, based on *Zuloaga et al. 4470*; C, based on *Zuloaga et al. 2469*; A ×100; B ×250; C ×400).

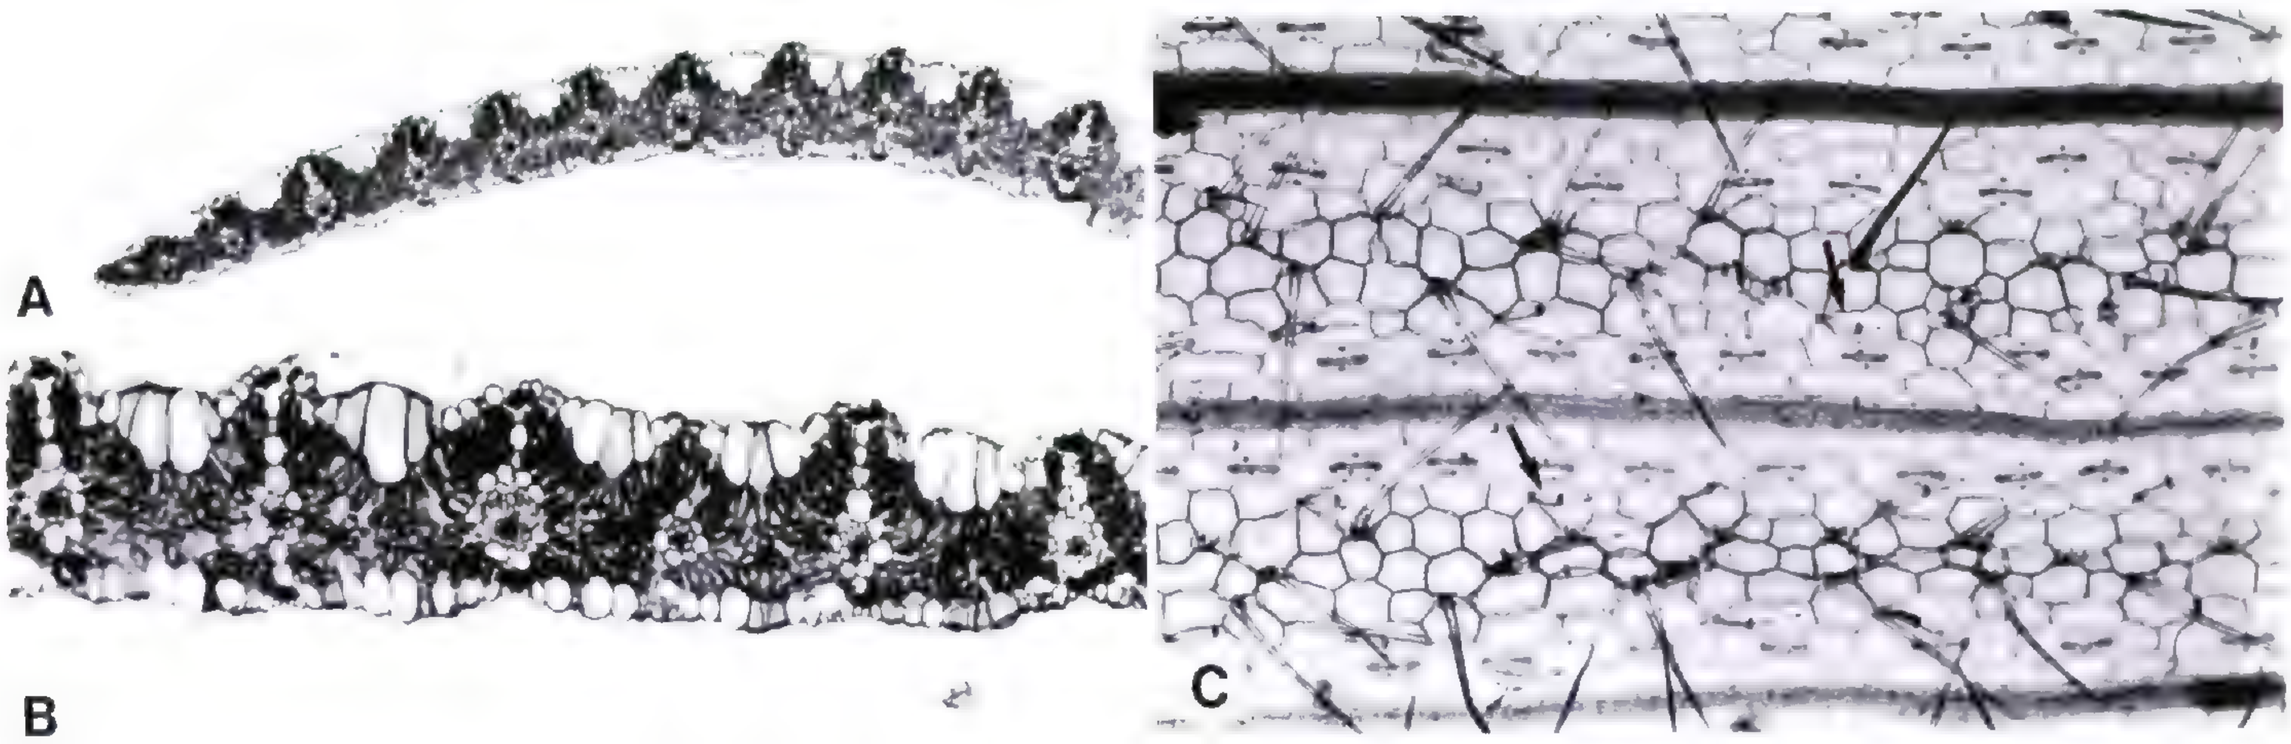

FIGURE 6. Leaf blade anatomy of *Panicum cumbucana*. A, B. Transverse leaf sections.—A. Gently tapering margin with evenly spaced vascular bundles.—B. Detail showing bundle sheath extensions, small adaxial and abaxial sclerenchyma strands and rather dense chlorenchyma tissue with a tendency toward the radiate type of cellular arrangement.—C. Abaxial epidermis structure with narrow costal zones only three to five cells wide; silica bodies are dumbbell-shaped to nodular and very narrow; the wide intercostal zones composed of short, hexagonal long cells and microhairs (arrowed) and macrohairs are common, the latter being rather short and pointed and inserted between only a few (two to three) specialized epidermal cells, one of which appears to be inflated (A–C, based on *Calderón 2425*; A ×100; B, C ×250).

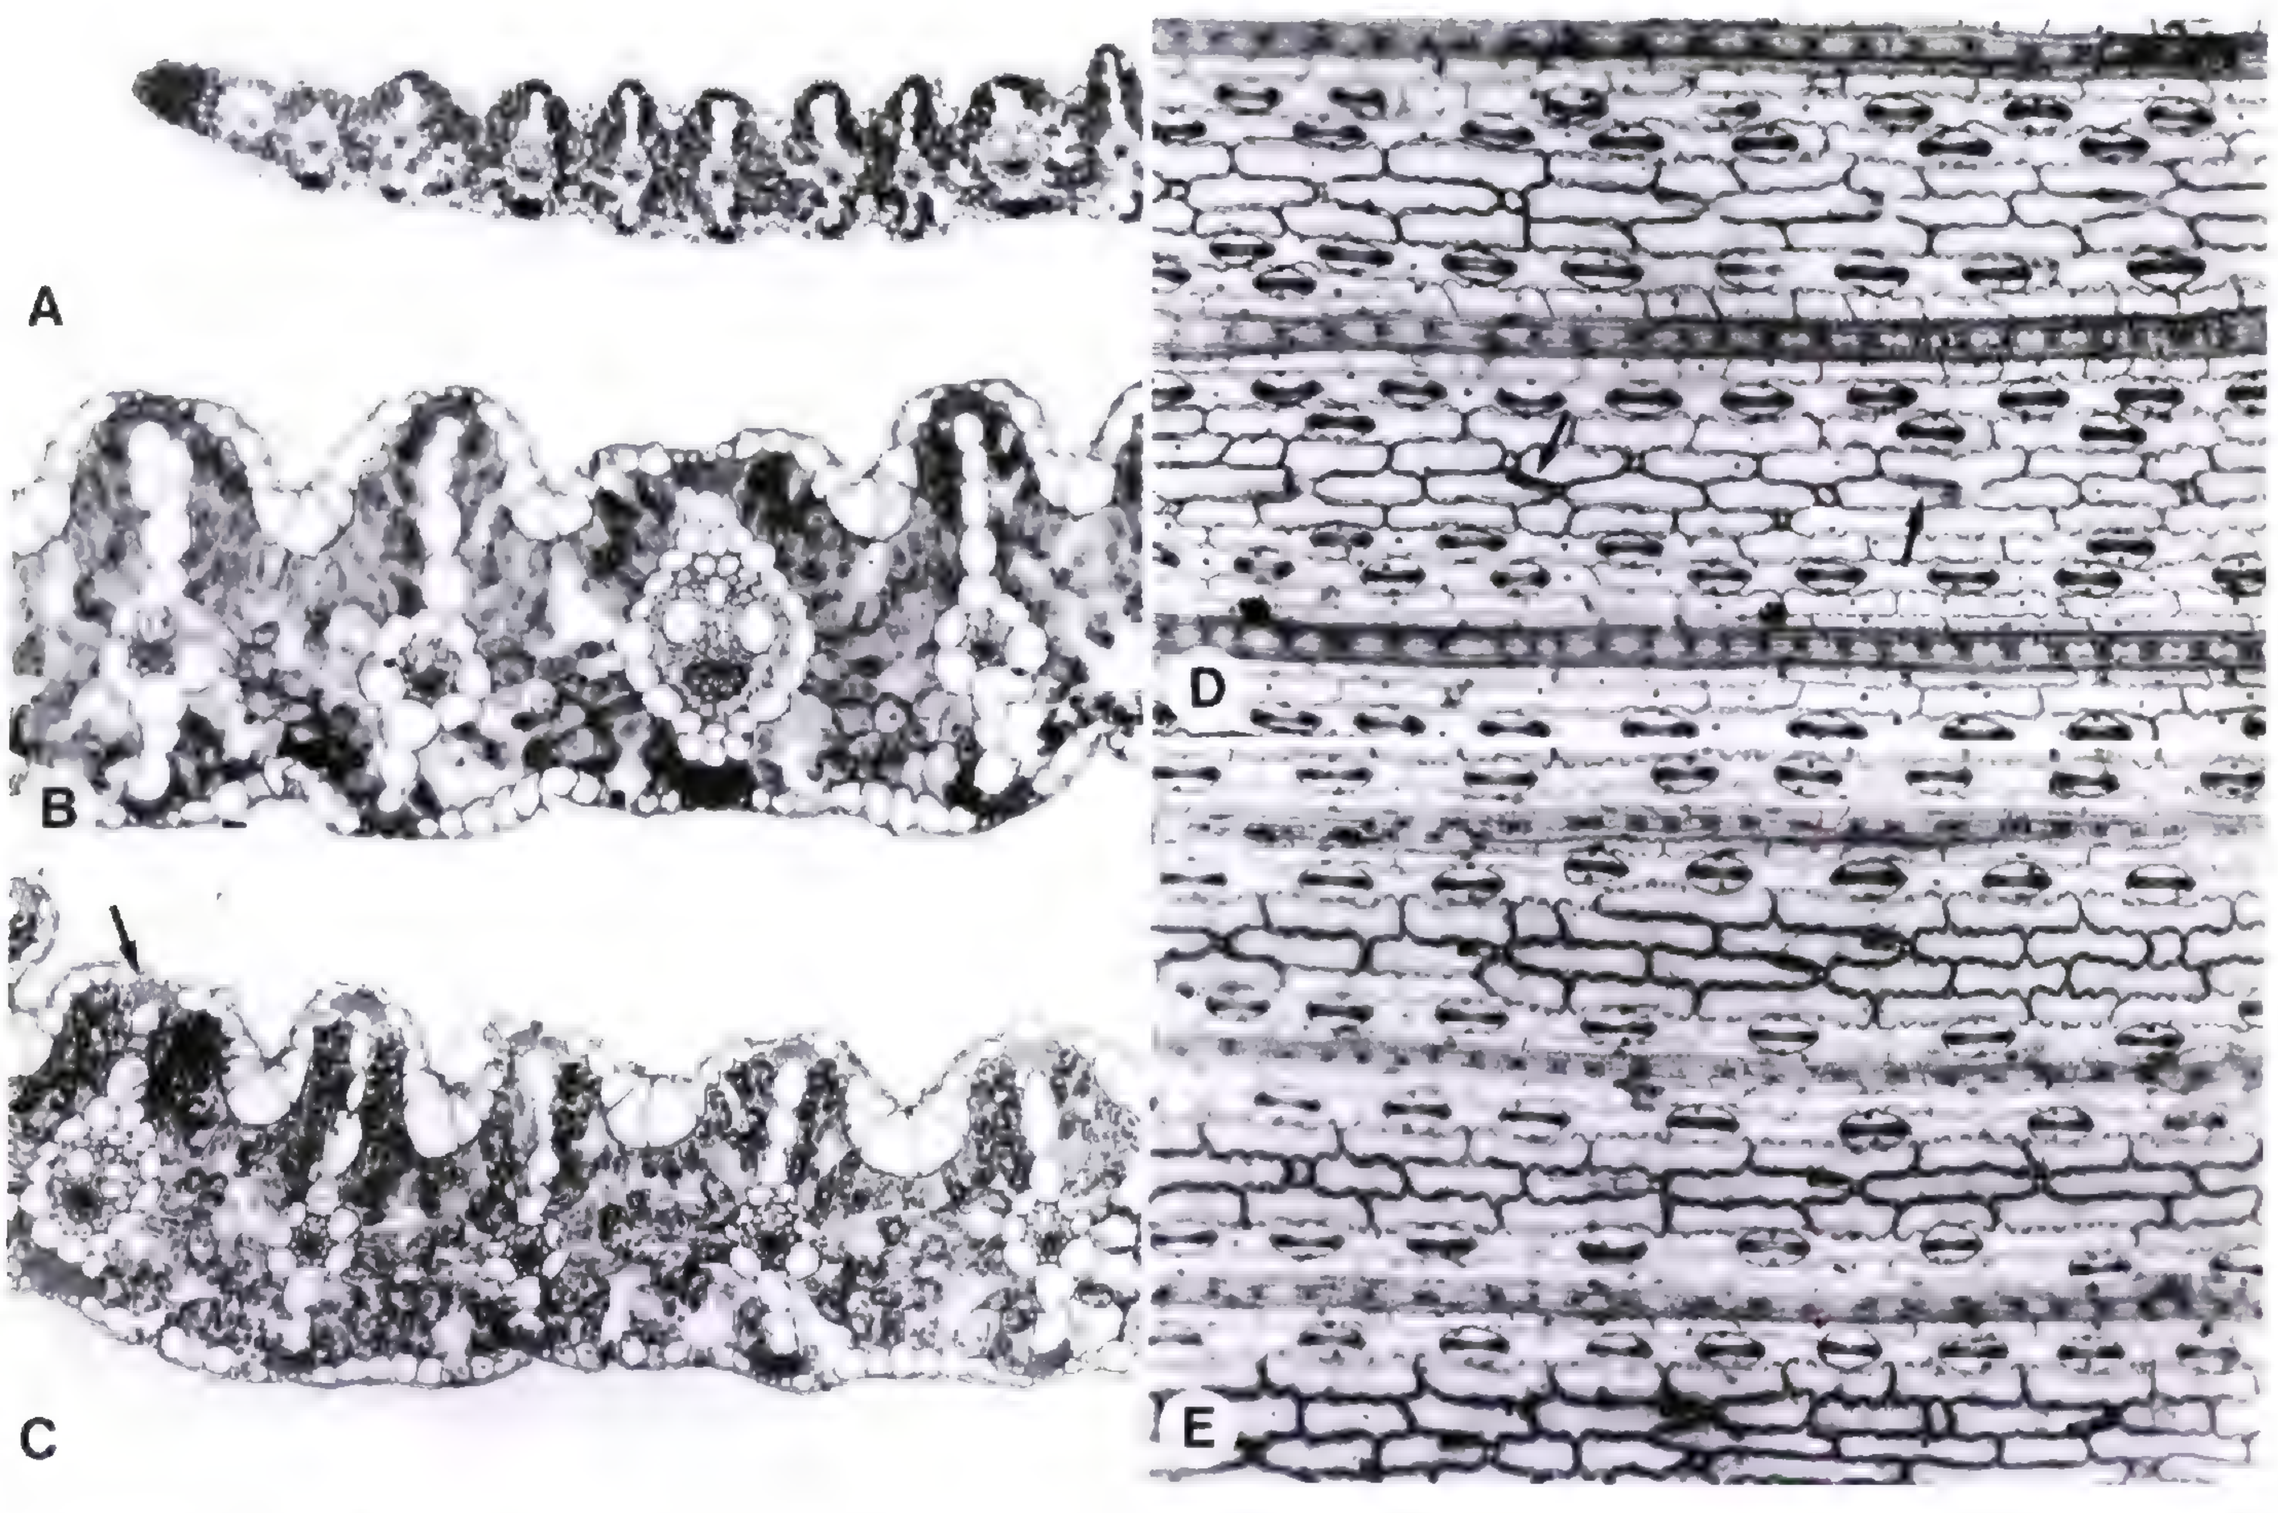

FIGURE 7. Leaf blade anatomy of *Panicum davidsei*. A–C. Transectional anatomy.—A. Gently tapering margin with sclerenchyma cap; adaxial ribs and furrows well developed, slight abaxial furrows present.—B. Long (four or more cells), uniseriate bundle sheath extensions associated with third-order bundles only—first-order bundles with wider extensions (triseriate) but much shorter, consisting of only one cell row; parenchyma sheath and extension cells conspicuous, translucent; the mesophyll approaches the radiate type, particularly the adaxial palisadelike tissue; bulliform cells small; small sclerenchyma strands associated with all bundles, both adaxially and abaxially.—C. Very similar anatomical structure except first-order adaxial bundle sheath extension uniseriate and three cells long (arrowed).—D, E. Abaxial epidermal structure.—D. Interstomatal cells, stomata, and microhairs (arrowed) common but no other epidermal appendages present.—E. No appendages except for microhairs; two stomatal files in each intercostal zone each separated by a short interstomatal cell; costal files of three cell files, the central with alternating dumbbell-like silica bodies and cork cells (A, B, D, based on *Zuloaga et al. 4427*; C, E, based on *Zuloaga et al. 4406*; A ×100; B–E ×250).

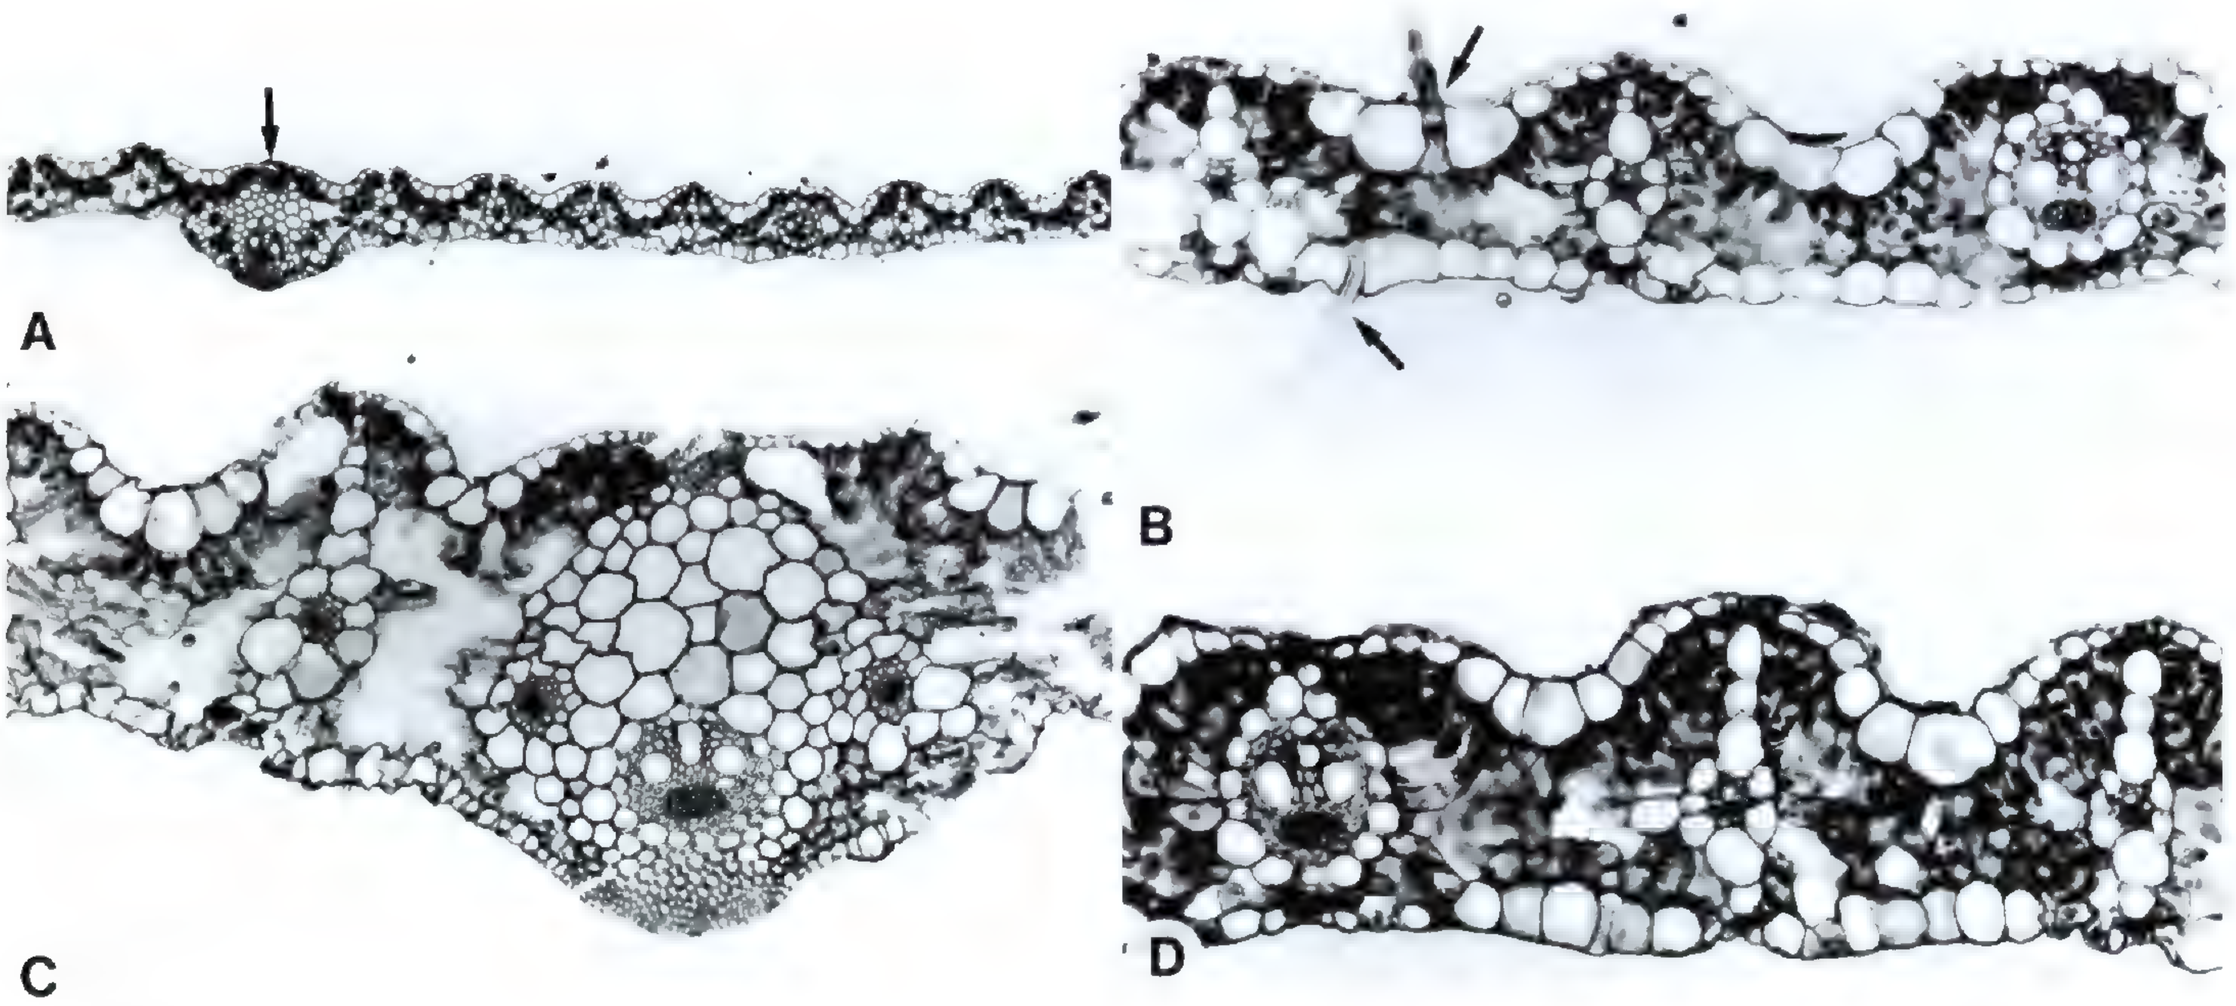

FIGURE 8. Leaf blade anatomy of *Panicum hebotes* as seen in transverse section.—A. Expanded leaf blade with keel (arrowed) incorporating three vascular bundles and adaxial parenchyma.—B. Detail of very short bundle sheath extensions, adaxial ribs, and furrows, and diffuse mesophyll tissue with large intercellular air spaces; note adaxially located chlorenchyma cells with semiradiate arrangement; adaxial and abaxial macrohairs (arrowed) present, these without raised cushion cells but inserted between unmodified epidermal cells.—C. Greater detail of keel structure showing one first-order and two third-order vascular bundles embedded in parenchymatous ground tissue.—D. Thicker leaf with longer adaxial bundle sheath extension; these cells clearly evident in the chlorenchyma cells; abaxial epidermal cells large and inflated (A, B, based on *Zuloaga et al. 2373*; C, based on *Zuloaga et al. 4534*; D, based on *Zuloaga et al. 2390*; A ×100; C ×250; B, D ×400).

sclerenchyma strands on both adaxial and abaxial surfaces. Ibs entire, of small cells with uniformly thickened walls.

*Sclerenchyma:* small, inconspicuous sclerenchyma strands associated with all vbs, both adaxially and abaxially; these strands linked to bundle sheath extensions; fibers lignified; small, rounded sclerenchyma caps located in leaf margins (Figs. 2A, 7A, 15A, 18D).

*Mesophyll:* chlorenchyma semiradiate with adaxial cells tending to a palisade-type of arrangement; abaxially located chlorenchyma cells irregular in shape, diffusely arranged with large intercellular air spaces, resembling spongy mesophyll; walls not invaginated; mesophyll varies from dense to very diffuse, irregular tissue; always more than 5 chlorenchyma cells between consecutive vbs. No colorless tissue apart from the bundle sheath extensions.

*Adaxial epidermal cells:* bulliform cells present in adaxial furrows between all vbs; usually in restricted groups with larger, fan-shaped central cells; size of bulliform cells very variable. Epidermal cells small, regular in size; no papillae or prickles, but macrohairs may be present.

*Abaxial epidermis cells:* very narrow costal zones; wide intercostal zones, often with larger, inflated, bulliformlike cells in the central files (e.g., *P. hebotes*, Fig. 8B, D); cuticle often very thin; no papillae or prickles, but macrohairs either common or absent, either with raised cushion-bases or inserted between unmodified epidermal cells as seen in section.

### Abaxial Epidermis as Seen in Surface View

*Intercostal long cells:* variable, short-rectangular (Figs. 13F, 16E) to hexagonal, resembling bulliform cells (Fig. 10C, D); side walls parallel or angled outward, end walls vertical, and anticlinal walls either unthickened or slightly thickened; rectangular cells with moderately undulating anticlinal walls but hexagonal cells usually with straight walls; intercostal cell shape variable across intercostal zones, with lateral cells being elongate and rectangular and central files being hexagonal and bulliformlike; no short cells between successive long cells except in *P. aciculare* (Fig. 1C). *Stomata:* absent in *P. aciculare* (Fig. 1C) but otherwise always present; low-triangular to low dome-shaped; two rows of stomata in each intercostal zone, these restricted to the edges adjacent to the costal zones; a single short interstomatal cell present between successive stomata in a file.

*Intercostal short cells:* absent except in *P. aciculare* (Fig. 1C), where they are tall and narrow. *Papillae:* absent. *Prickles:* absent throughout sam-

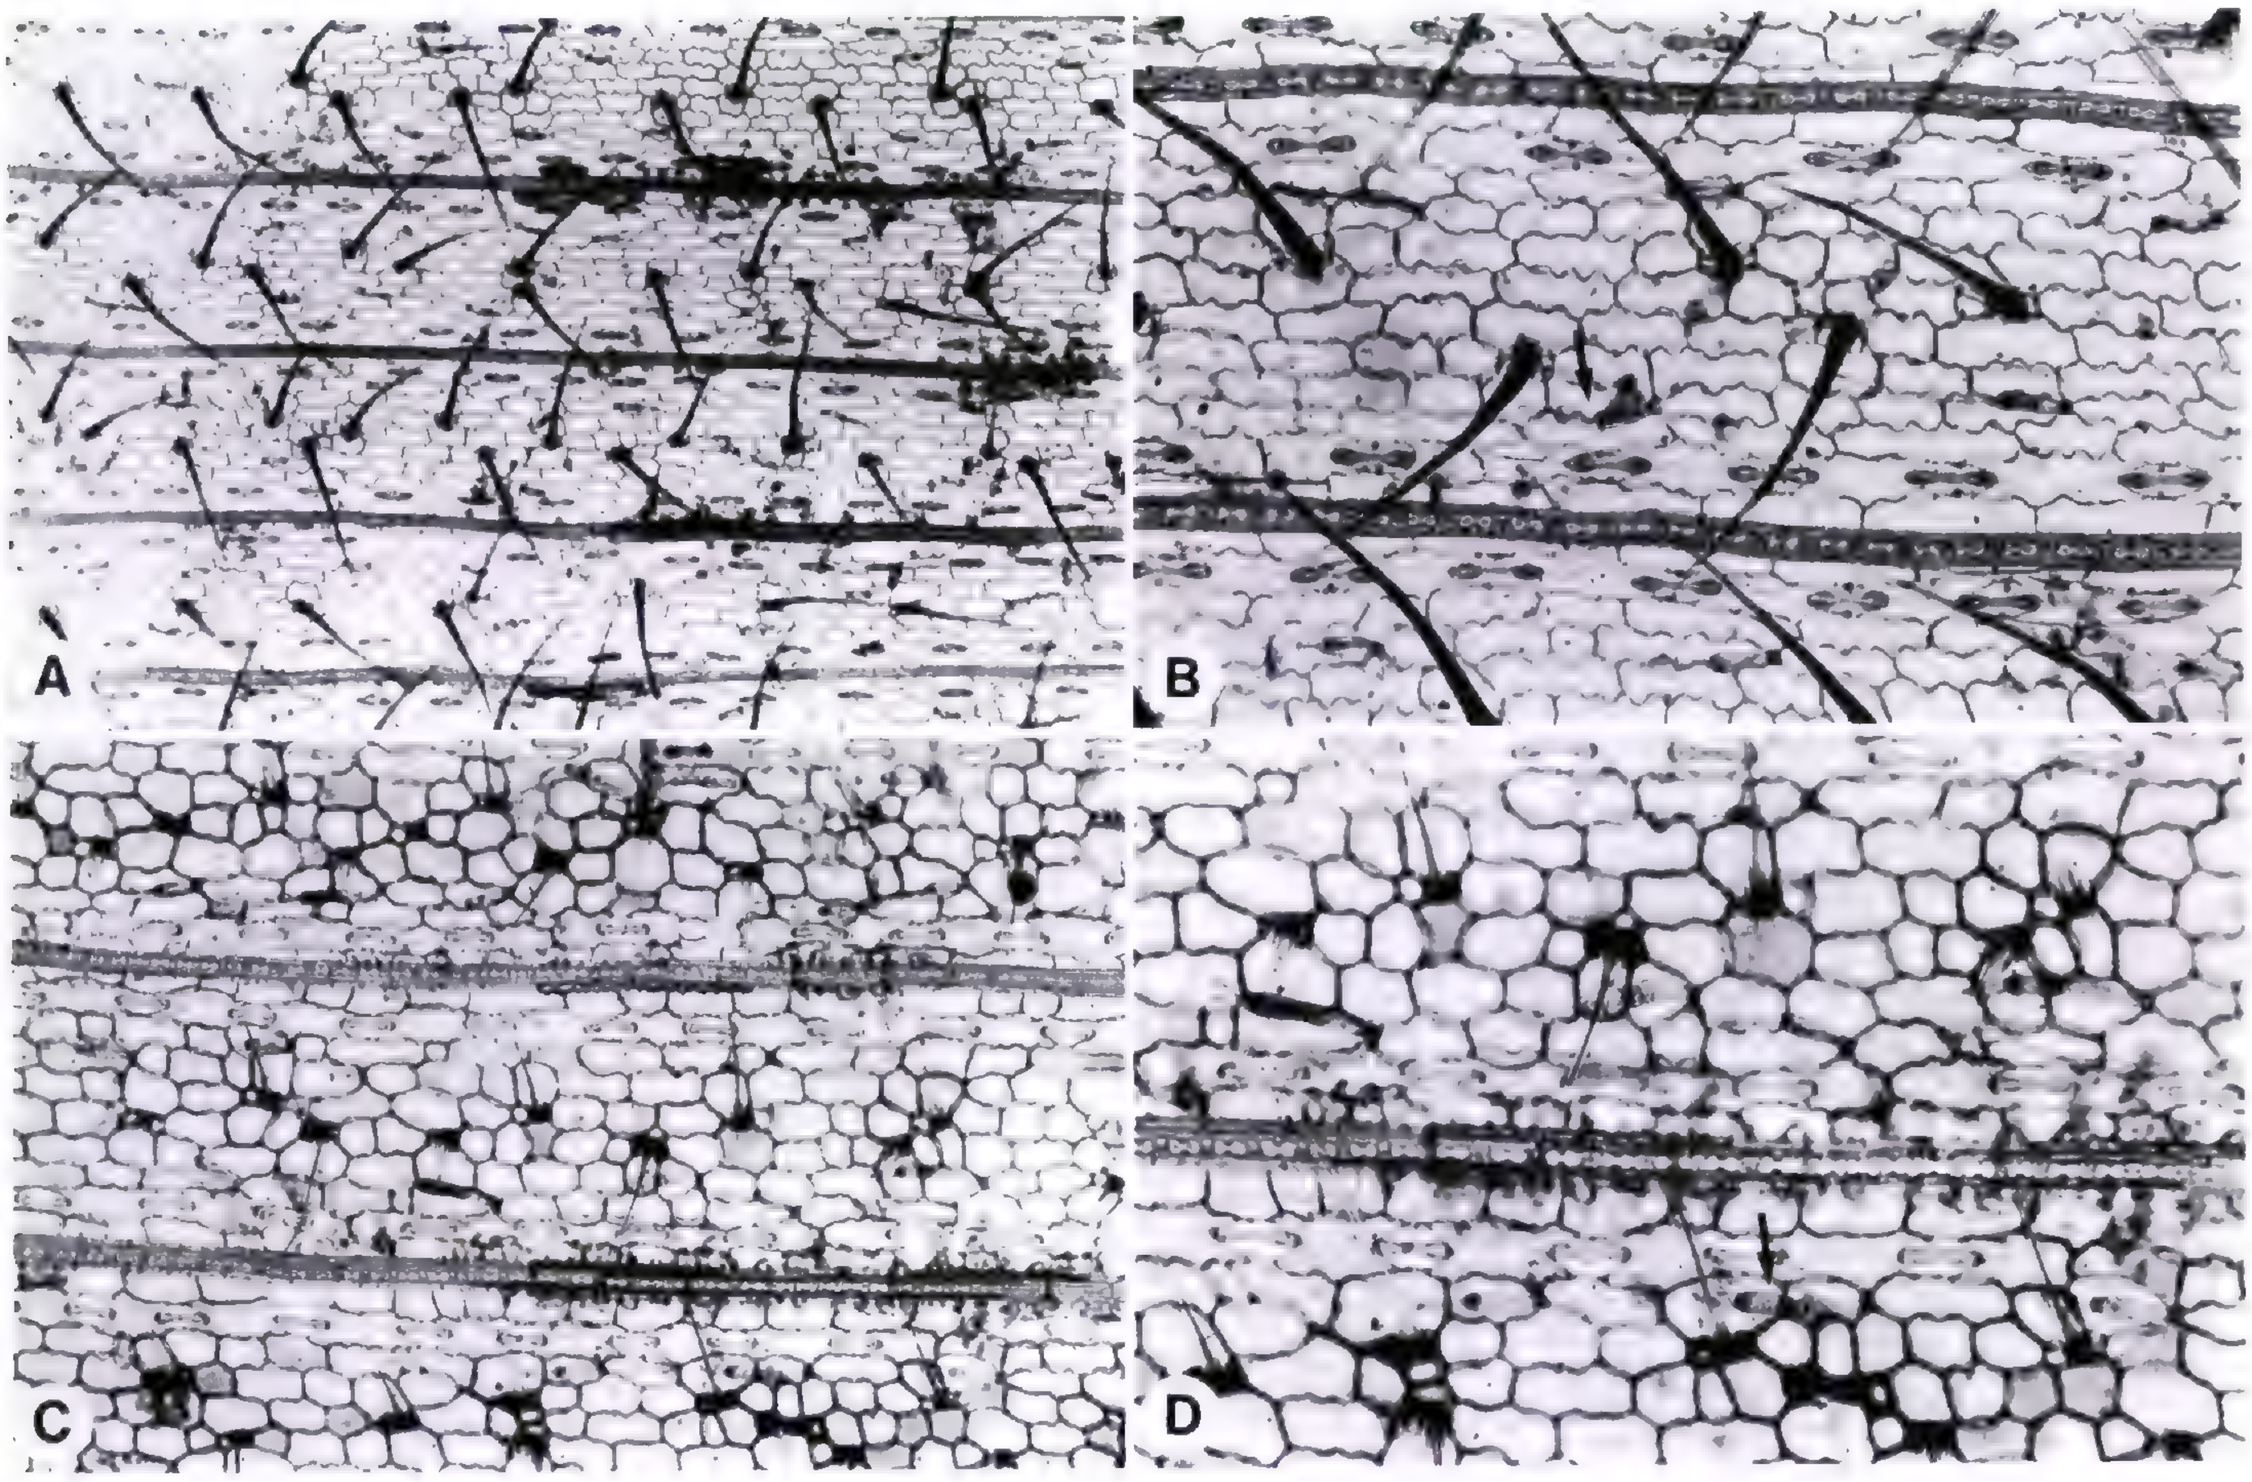

FIGURE 9. Abaxial leaf blade epidermis of *Panicum hebotes*.—A. Epidermal pattern showing marked zonation with very narrow costal zones and wide intercostal zones with numerous macrohairs.—B. Detail of irregular dumbbell-shaped costal silica bodies alternating with short, rectangular cork cells; intercostal long cells short with sinuous walls; macrohair bases associated with two specialized epidermal cells, one of which appears inflated; note that all the microhairs are three-celled (arrowed)—a very unusual configuration.—C. Typical epidermal cellular arrangement of this species; cells associated with the macrohair bases stain darkly.—D. Short intercostal long cells, macrohairs, and stomata; the microhairs (arrowed) all consist of three cells (A, B, based on *Zuloaga et al. 2373*; C, D, based on *Zuloaga et al. 2390*; A ×160; C ×250; B, D ×400).

ple. *Microhairs:* bicellular, fingerlike, with basal cell slightly shorter than distal cell; elongate, equal in length to the stomatal complexes to more than twice their length; distal cell deciduous with very thin walls; common in the central files of the intercostal zones; very rarely absent as in *P. sphaerocarpon* (Fig. 15E, F); *Panicum hebotes* always with unique tricellular microhairs (Fig. 9B, D). *Macrohairs:* either absent or present, variable in structure; two types can be recognized: long, thick hairs inserted into raised cushion-bases (Figs. 11C, 19A–D), and thin, needlelike hairs with only two specialized epidermal cells associated with the base (Figs. 6C, 9A–D, 10C, D); all intermediates occur between these extremes; recurved hairs may occur (Figs. 2D, 14D, E); macrohairs always restricted to intercostal zones; size and frequency very variable. *Silica bodies:* costal bodies irregular in shape, cross-shaped to equidimensional dumbbell-shaped to elongate dumbbell-shaped or even nodular (the latter type only overlying 3′vbs); confined to costal zones where they alternate regularly with similar-shaped or shorter cork cells; only 3 (rarely 5) files of cells per costal zone, with 1 file with silica bodies. No intercostal silica bodies.

## Discussion of Leaf Anatomy of Section *Dichanthelium*

Leaf blades in section *Dichanthelium* are typically flat, open, expanded, and symmetrical about the midrib. Leaf width is variable, including between 11 and 117 vascular bundles. *Panicum acicularе* differs from all other representatives of the section in having narrow, inrolled blades with only 11 bundles (Fig. 1A, B). This species also differs in several other respects, which may be linked to these narrow leaf blades.

The degree of development of adaxial ribs and furrows varies in section *Dichanthelium*, from complete absence to well-developed medium ribs and furrows. The full range of variation found in the section can occur in a single species, as is seen in *P. acuminatum* (Fig. 2B, C). Midrib structure is also variable, ranging from median vascular bundles structurally indistinguishable from the lateral

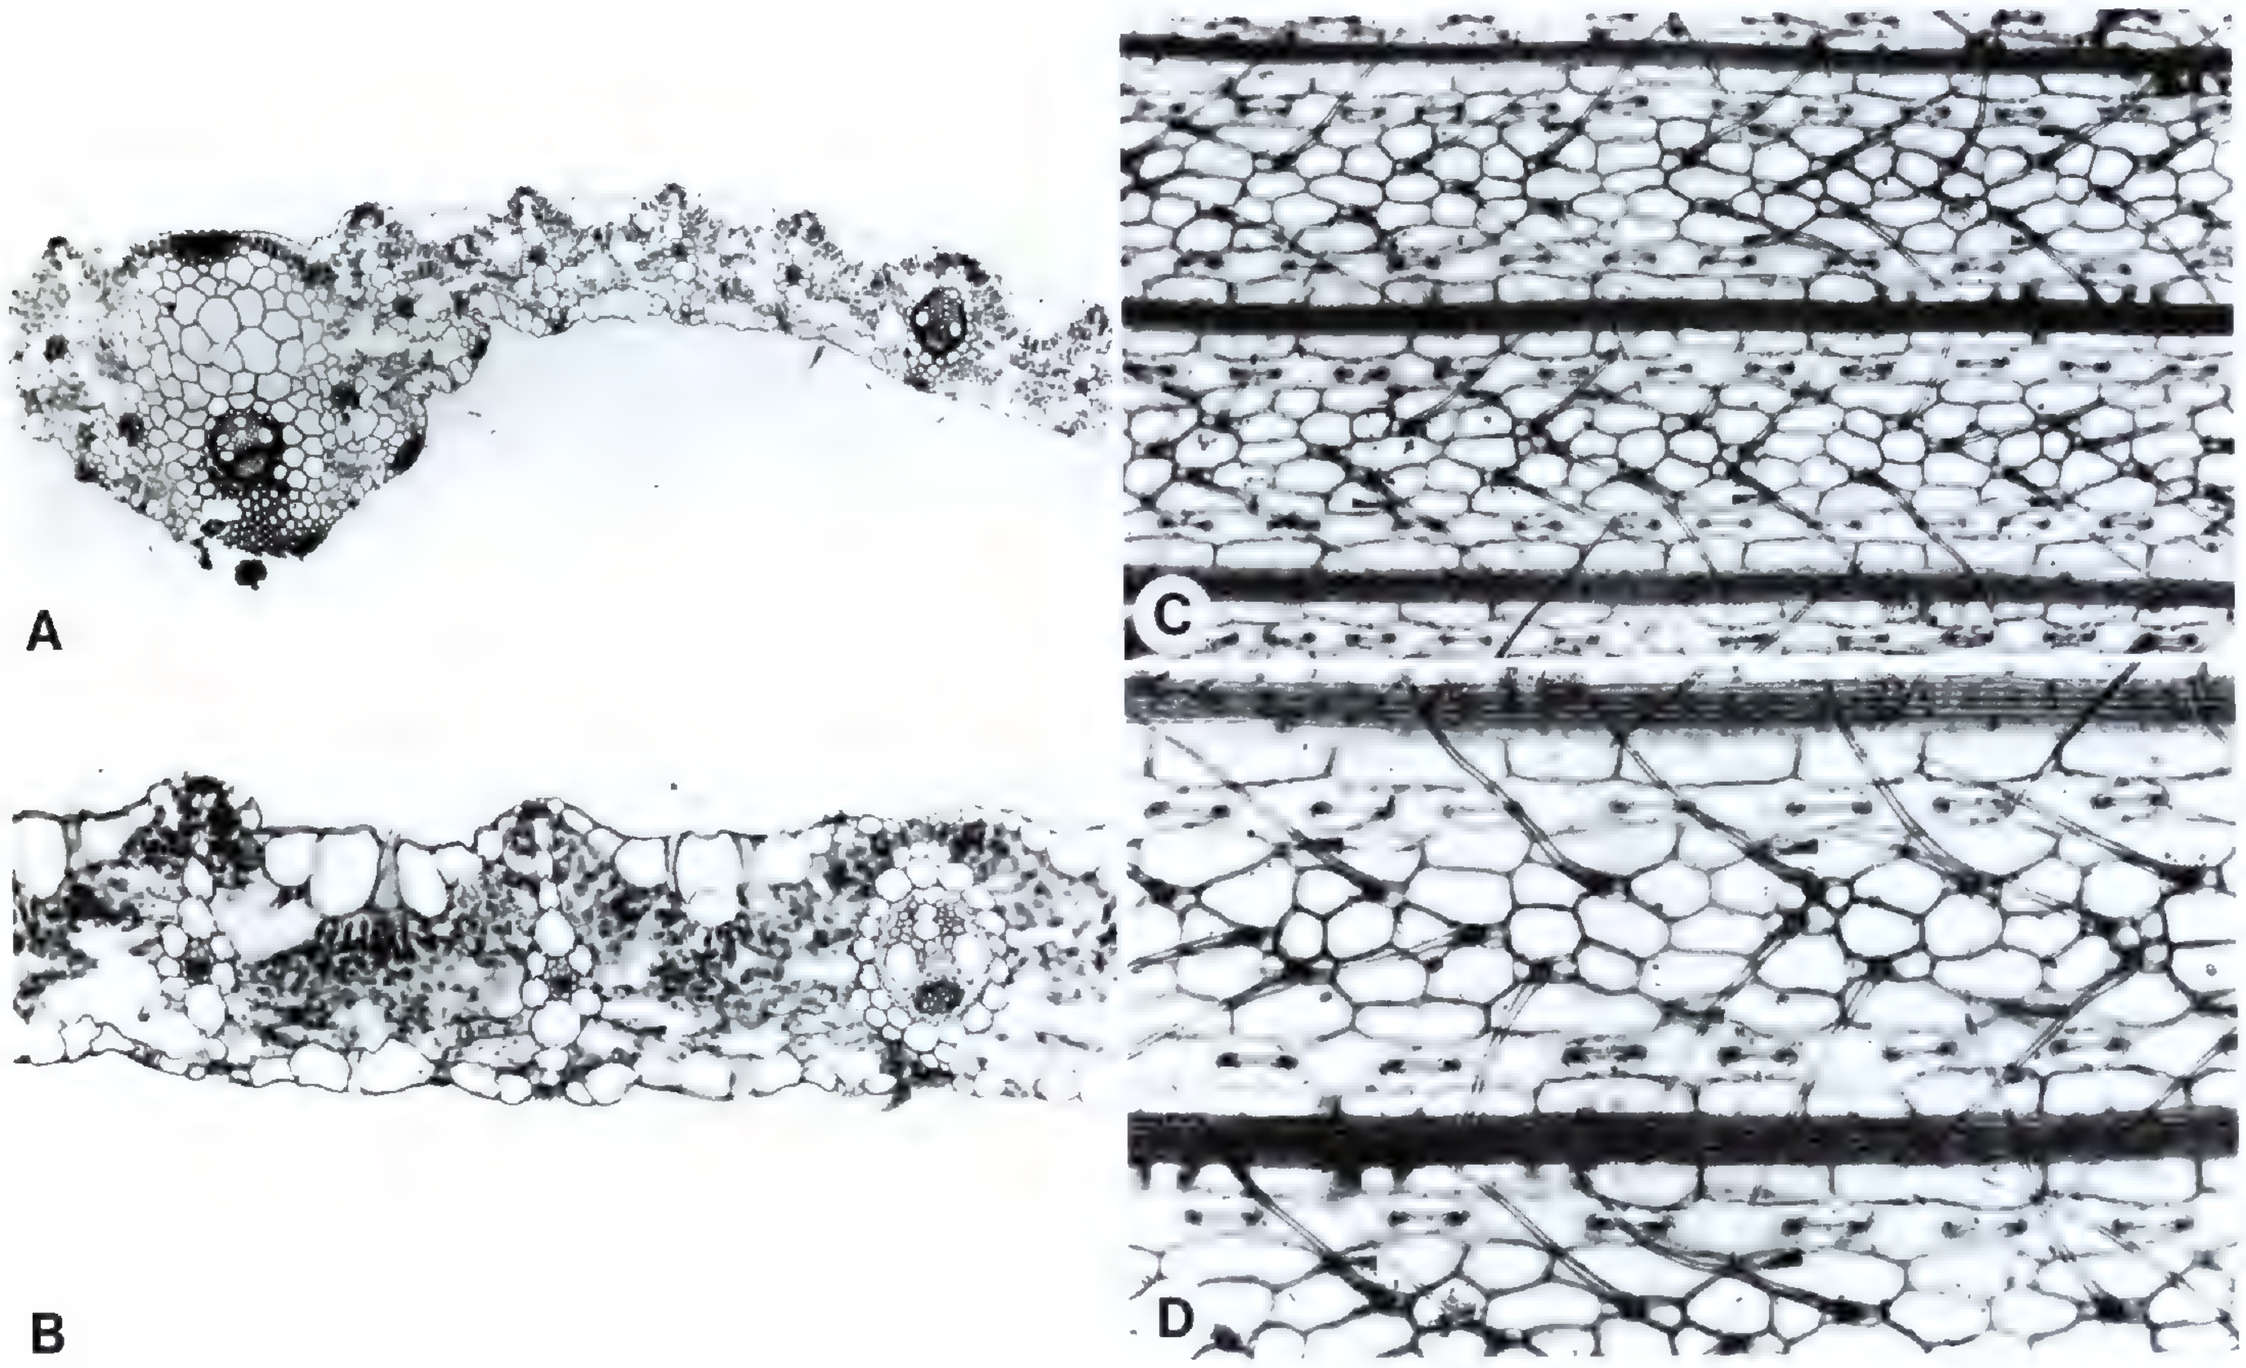

FIGURE 10. Leaf blade anatomy of *Panicum peristypum*. A, B. Anatomy as seen in transverse section.—A. Well-developed keel containing three vascular bundles and adaxial parenchyma ground tissue.—B. Detail of diffuse mesophyll and bundle sheaths and their extensions. C, D. Abaxial epidermis.—C. Epidermal pattern with very narrow costal zones and wide intercostal zones containing numerous macrohairs.—D. Detail of inflated basal cells associated with the macrohairs, bicellular microhairs, stomata, and short, irregularly shaped long cells (A–D, based on *Zuloaga et al. 2398*; A ×100; B, C ×250; D ×400).

first-order bundles to well-developed keels including up to three vascular bundles and extensive parenchyma ground tissue. Generally, each species is consistent in midrib structure, having either a median bundle, a midrib, or a keel. This is not always consistent, however; for example, all midrib types were apparent on different leaves of the same plant of *P. peristypum*.

The vascular bundle sheaths and their extensions are the most consistent and valuable anatomical character distinguishing *Dichanthelium* from the other $C_3$ taxa in *Panicum*. Colorless parenchyma

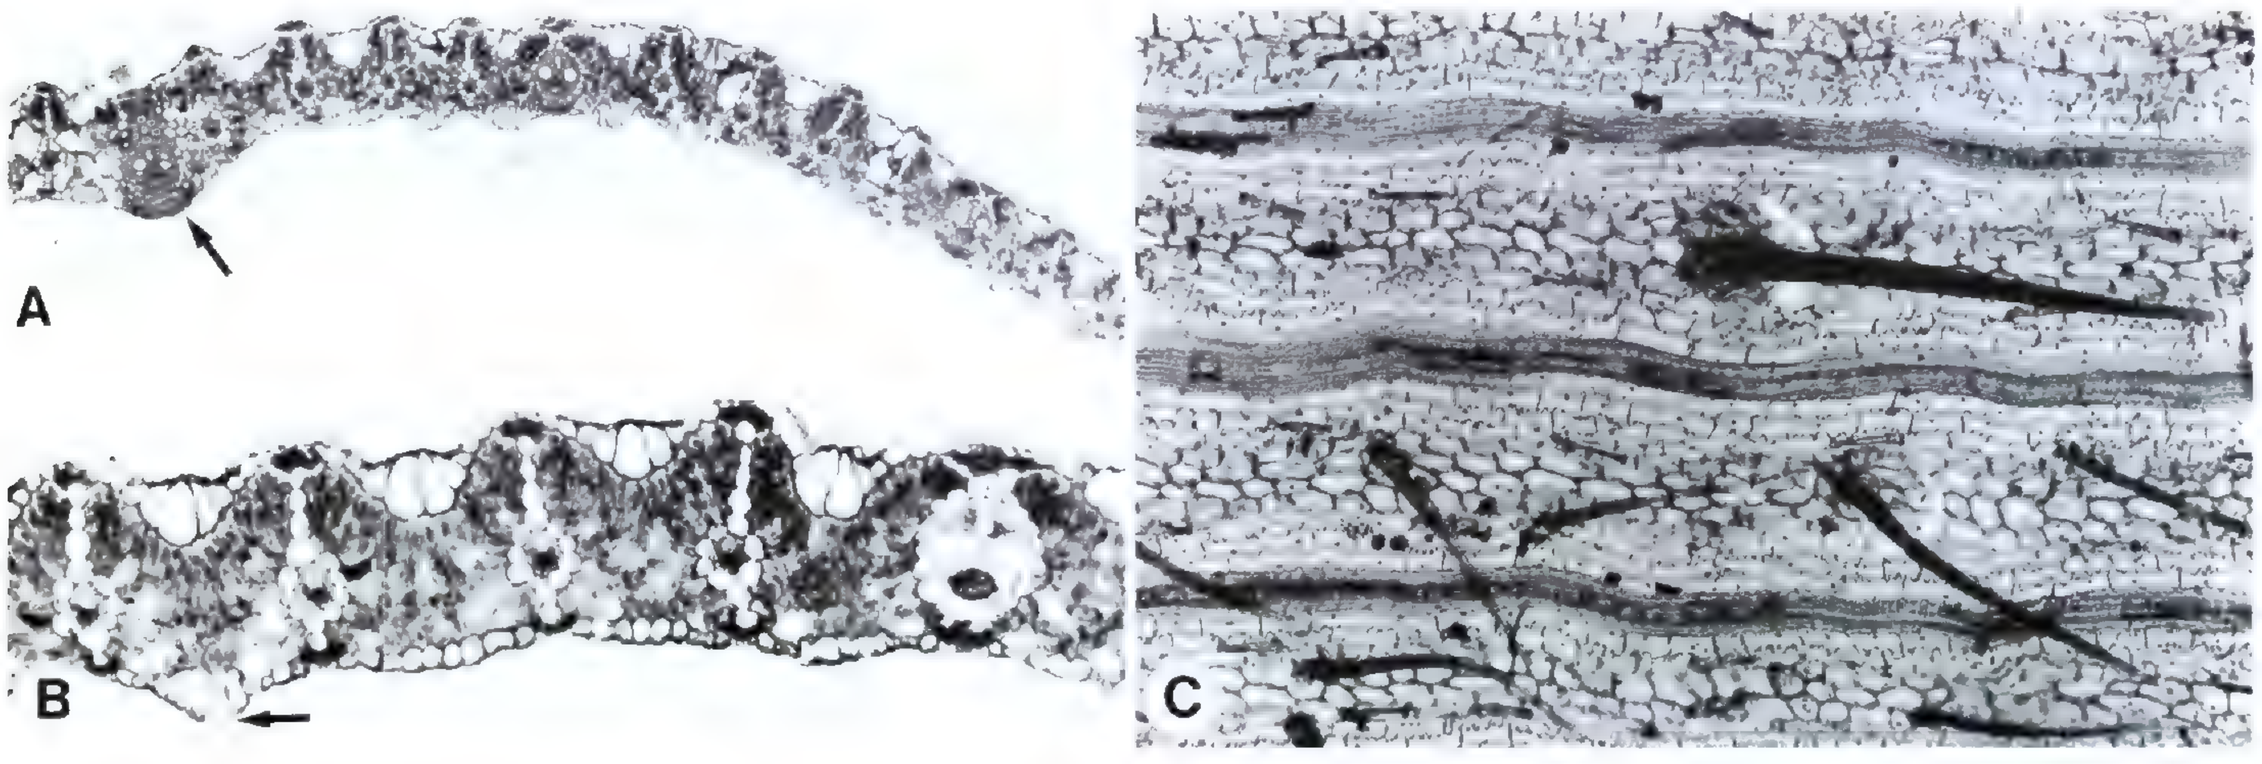

FIGURE 11. Anatomy of *Panicum pycnoclados*. A, B. Transectional anatomy.—A. Midrib (arrowed) comprising a single vascular bundle distinguishable from other first-order bundles by the large adaxial and abaxial sclerenchyma girders.—B. Rather compact mesophyll of the intermediate type with palisade and spongy tissue differentiated; third-order bundles with long uniseriate extensions; note macrohair with base inserted between raised cushion cells (arrowed).—C. Abaxial epidermis with thick macrohairs associated with cushion bases (A–C, based on *Zuloaga et al. 4404*; A ×100; B, C ×250).

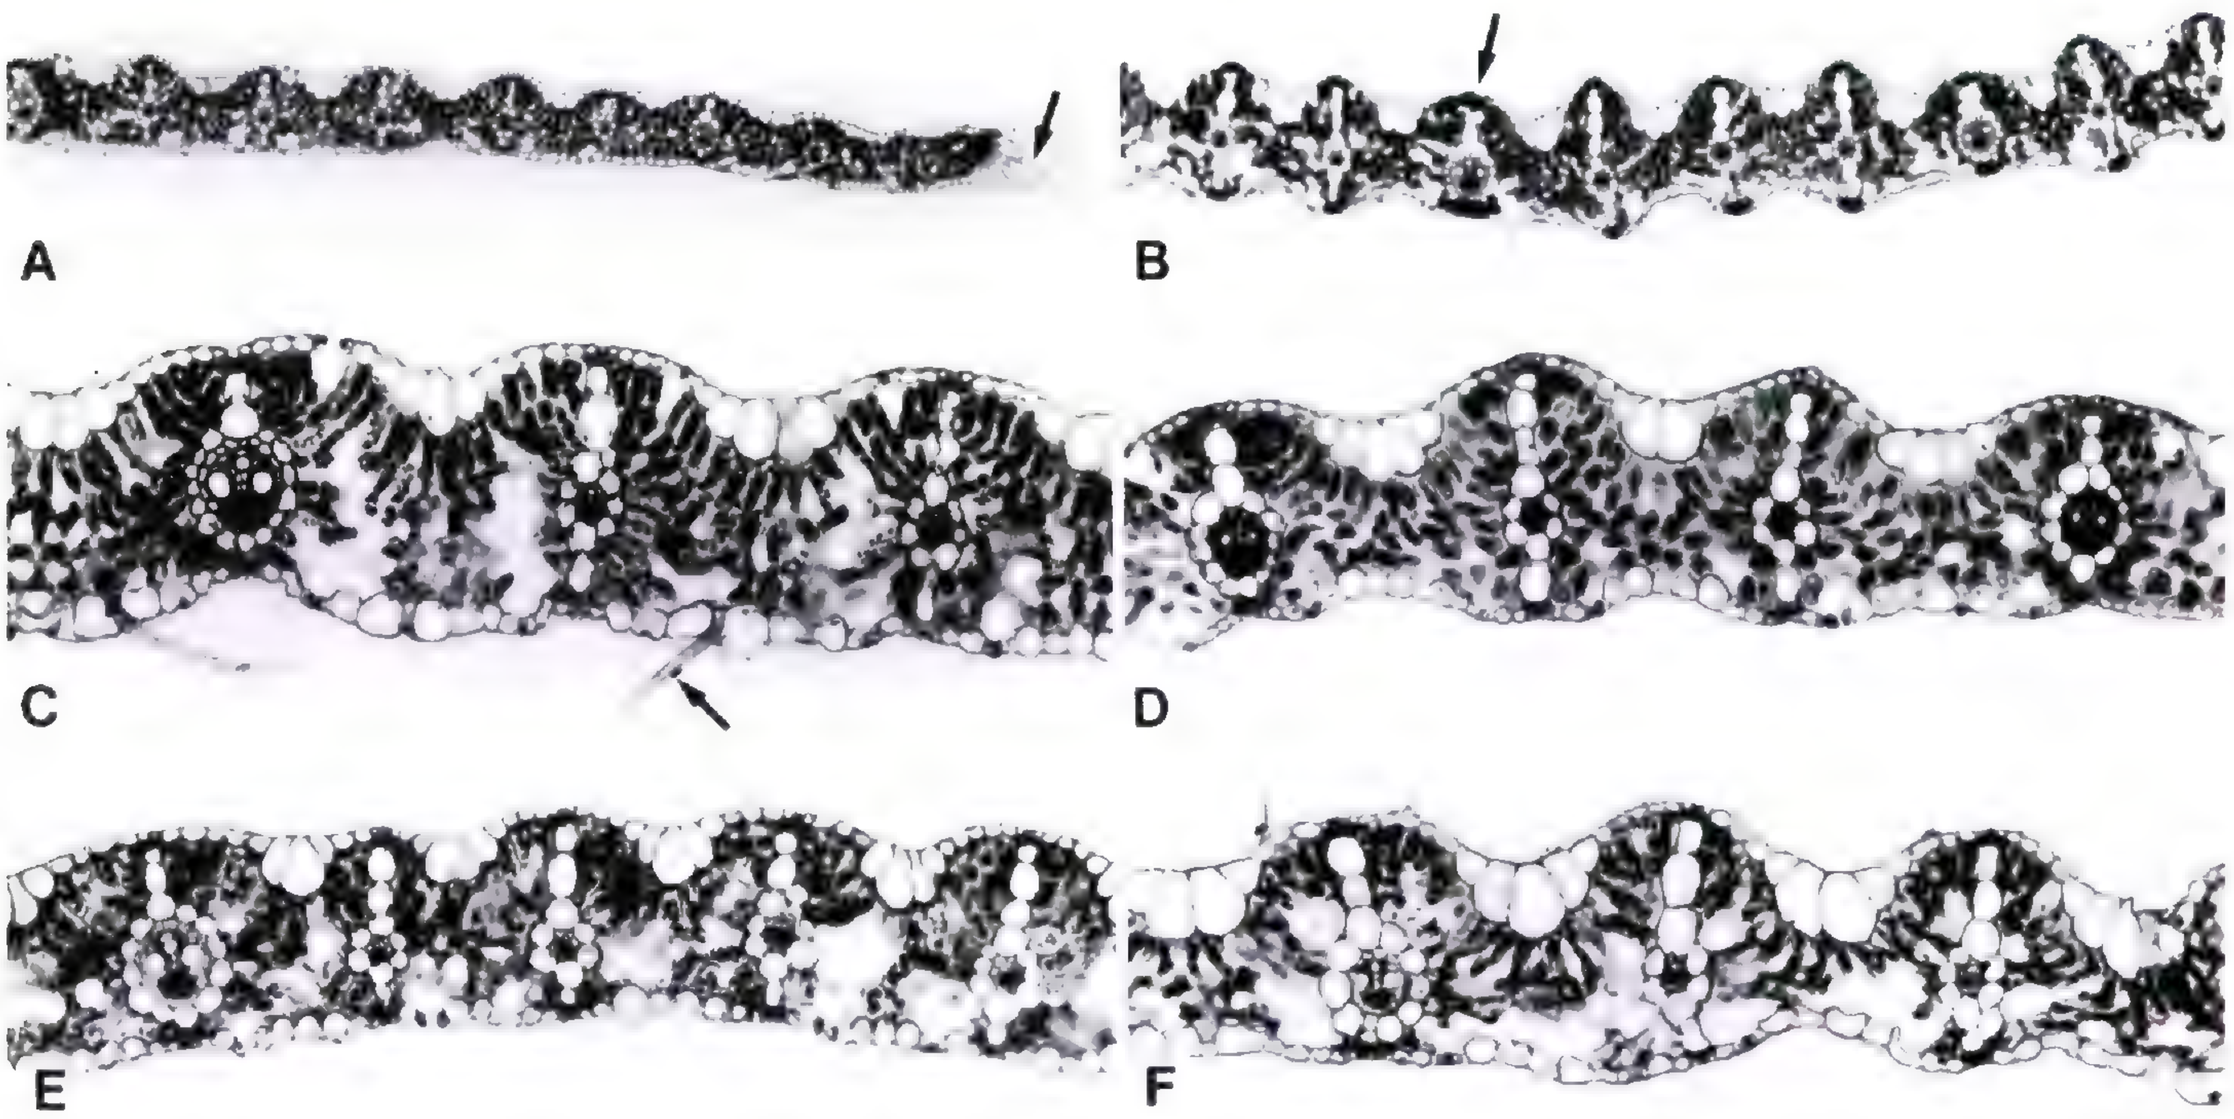

FIGURE 12. Leaf blade anatomy of *Panicum sabulorum* in transverse section.—A. Expanded blade showing margin with base of thick, cushion-based macrohair (arrowed).—B. Center of lamina with median vascular bundle (arrowed) indistinguishable from lateral first-order bundles.—C. Detail of diffuse mesophyll tending to the radiate type of arrangement; note short bundle sheath extensions and macrohairs without cushion bases (arrowed).—D. Denser mesophyll tissue with conspicuous outer bundle sheath and extension cells and small but discrete bulliform fans located in the troughs of the shallow adaxial furrows.—E. Typical anatomy of this species except that no macrohairs are present.—F. Well-developed bundle sheath extensions and very diffuse mesophyll (A, C, based on *Zuloaga 2060*; B, based on *Zuloaga 1972*; D, based on *Zuloaga 2128*; E, based on *Zuloaga 2380*; F, based on *Zuloaga 2352*; A, B ×100; C–F ×250).

sheath and extension cells are present in all taxa studied. *Panicum sphaerocarpon* (Fig. 15A–D) is an exception, as unspecialized chloroplasts appear to occur in the outer sheath and extension cells. In a few specimens of *P. viscidellum* (Fig. 20A–D), plastidlike structures are also evident in these tissues, but these appear to be found primarily in older, senescing leaves. Nevertheless, all specimens of section *Dichanthelium* examined had bundle sheath extensions, the length correlated with the thickness of the leaf blade. Section *Cordovensia* of subgenus *Dichanthelium* also has prominent adaxial bundle sheath extensions. Extensions are thus diagnostic for subgenus *Dichanthelium*, but occur sporadically in the other $C_3$ subgenus of *Panicum*, *Phanopyrum* (Raf.) Pilger, where they are found in section *Lorea* Zuloaga (*P. chnoodes* Trin. and *P. trinii* Kunth), and often in species of sections *Parvifolia* (A. Hitchc. & Chase) Pilger, *Stolonifera* (A. Hitchc. & Chase) Pilger, and *Megista* Pilger. Sections *Laxa* (A. Hitchc. & Chase) Pilger, *Parviglumia* (A. Hitchc. & Chase) Pilger, and *Phanopyrum* of subgenus *Phanopyrum* are without bundle sheath extensions, as is the intermediate $C_3/C_4$ subgenus *Steinchisma* (Raf.) Zuloaga.

The mesophyll tissue, together with the absence of specialized chloroplasts in the bundle sheath cells, indicates that section *Dichanthelium* is non-Kranz throughout. More than five chlorenchymatous mesophyll cells are always found between successive vascular bundles, implying that many chlorenchyma cells are more than two cells removed from the nearest bundle sheath cell. These parameters have been shown to predict reliably the photosynthetic pathway in grasses (Hattersley & Watson, 1975), and section *Dichanthelium* is consequently considered to be entirely $C_3$. This has been confirmed by Brown (1977) for 73 species of *Dichanthelium*.

The mesophyll tissue of section *Dichanthelium* is also of interest in that the chlorenchyma tissue does not display the irregular pattern of cellular arrangement that is normally associated with non-Kranz leaf anatomy. Instead, it is semiradiate, with the adaxially located cells palisadelike and the abaxial cells resembling spongy mesophyll tissue. This anatomy is clearly distinguishable from that of the pooid $C_3$ grasses, but most $C_3$ panicoids also have mesophyll of this type. *Panicum sphaerocarpon* (Fig. 15B) is unusual in that the adaxial chlorenchyma cells are also interspaced with intercellular air spaces, although a semiradiate arrangement is still evident.

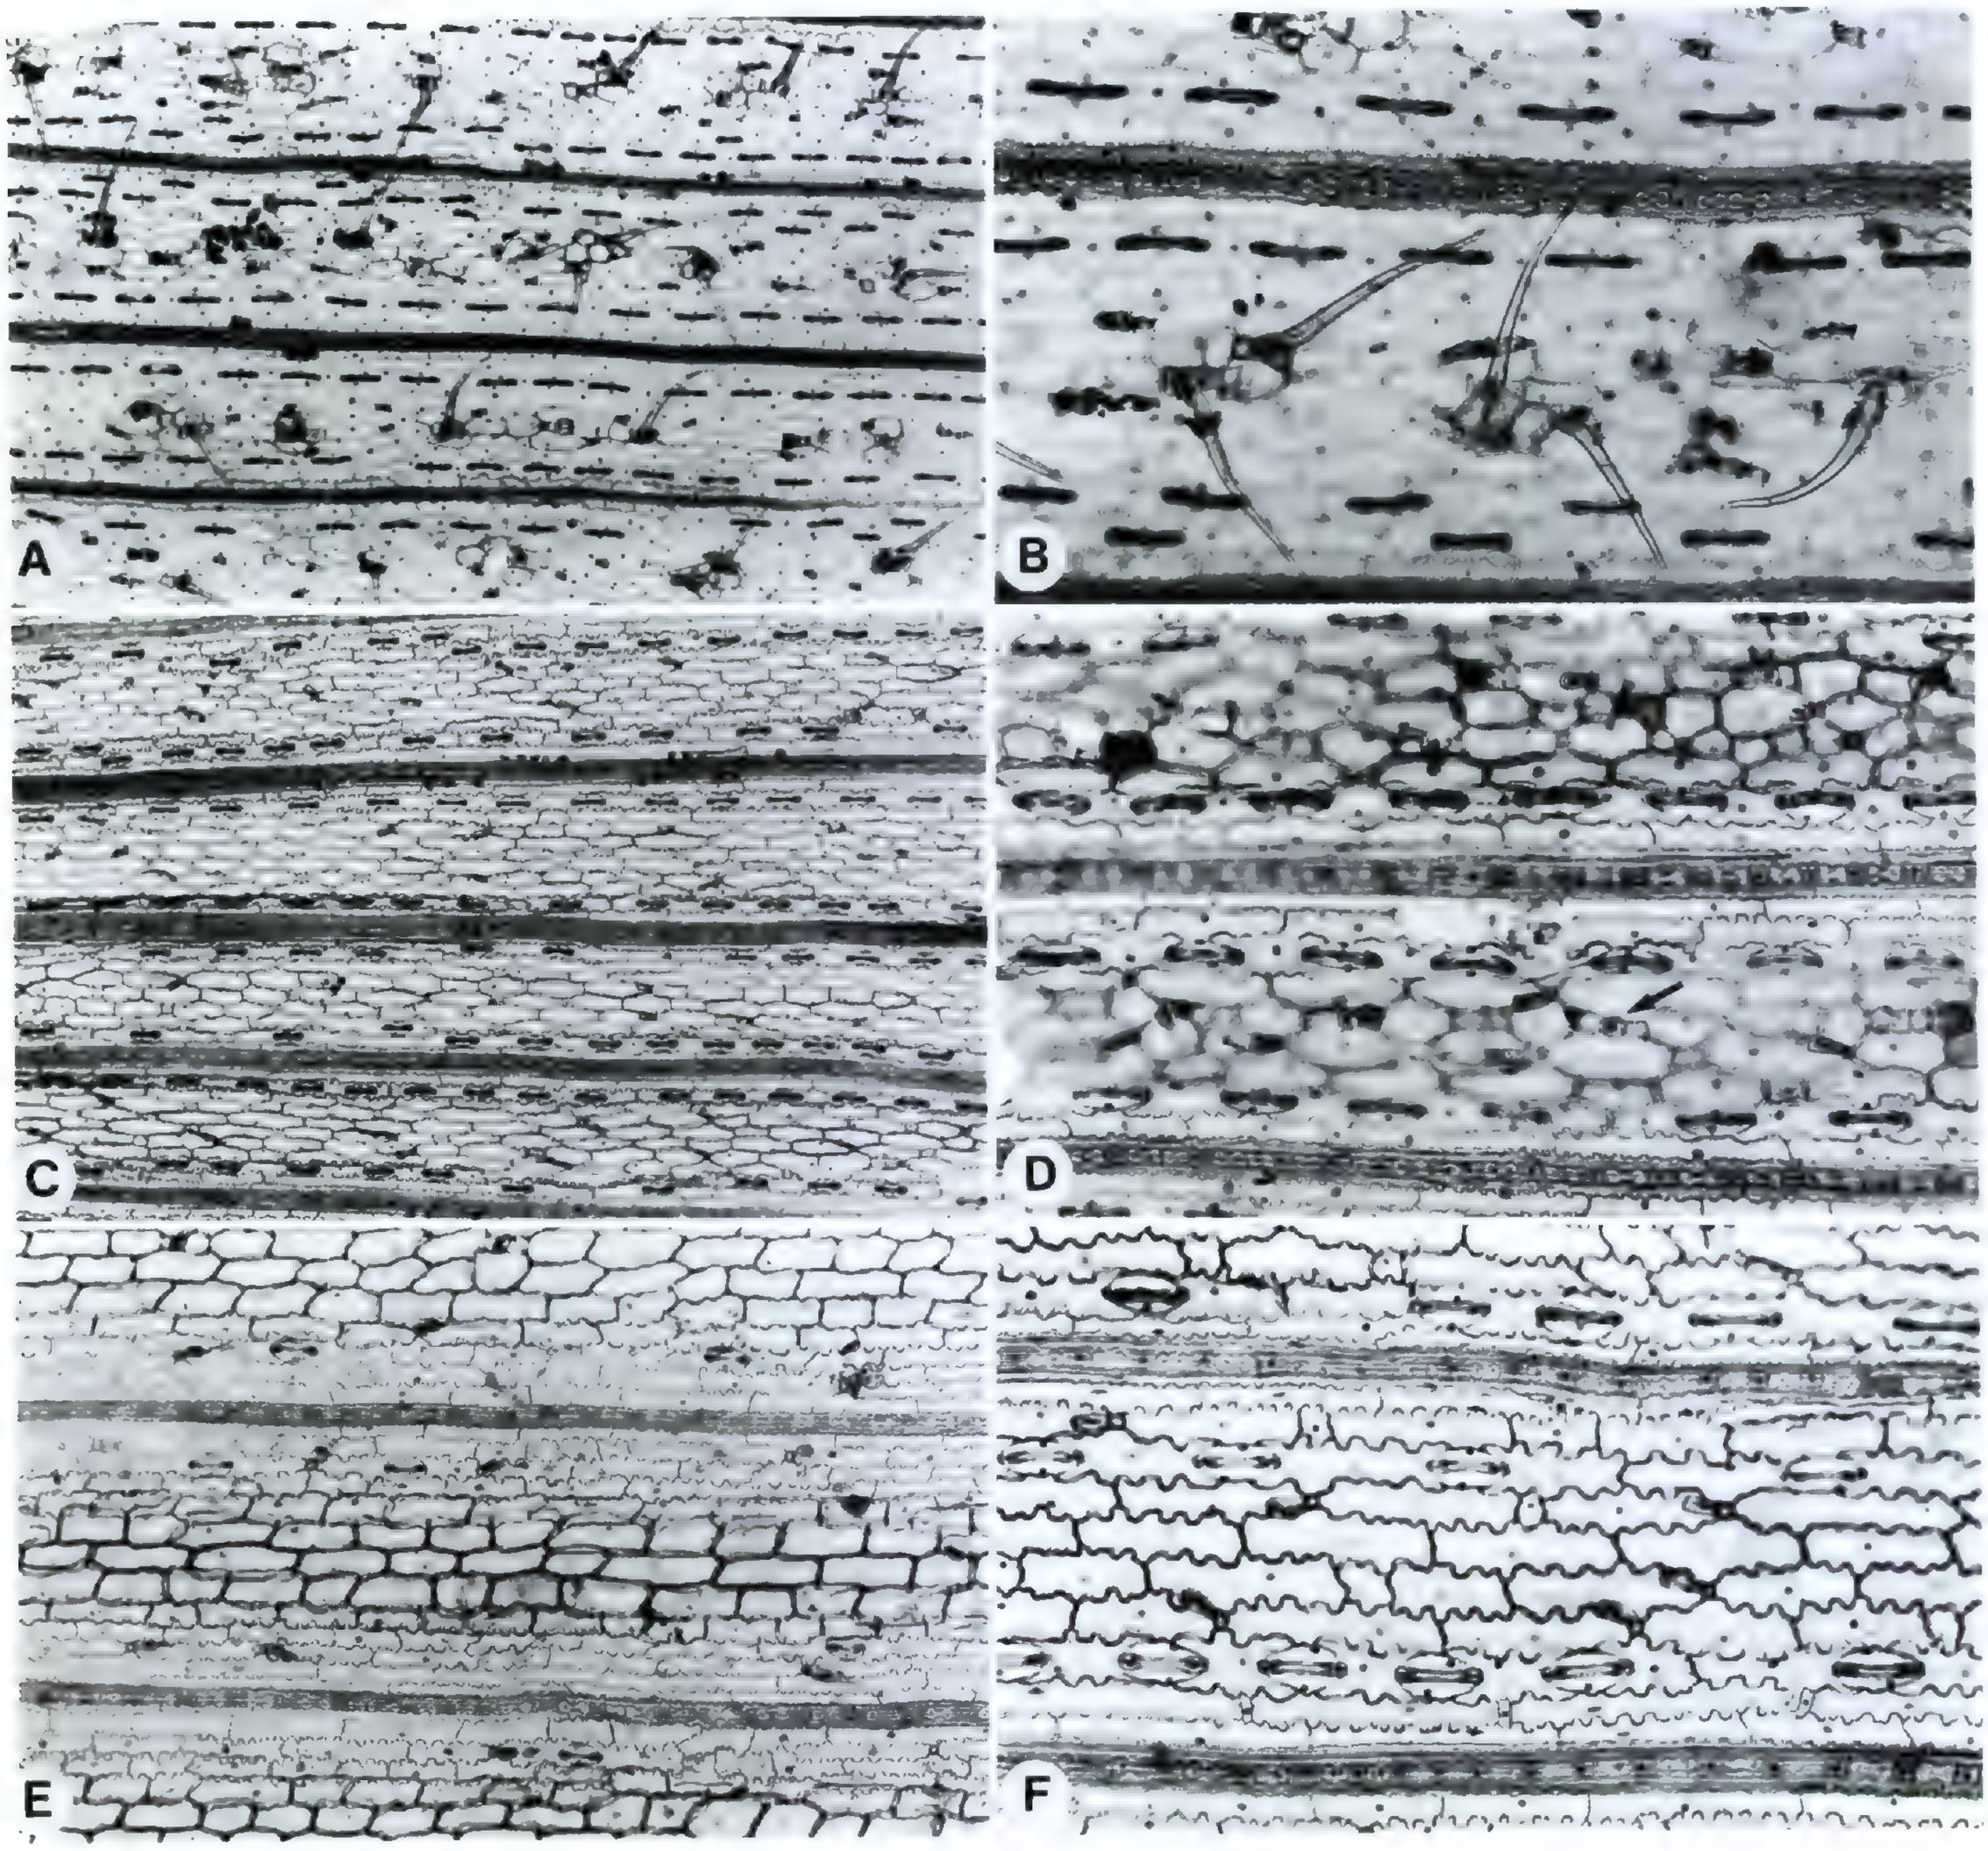

FIGURE 13. Abaxial epidermis of *Panicum sabulorum*. —A. Epidermal pattern with short macrohairs restricted to the center of the intercostal zones; note numerous stomata in two files immediately adjacent to the costal zones. —B. Detail of macrohair bases and few associated epidermal cells, irregular arrangement of dumbbell-like silica bodies in costal zones, and short bicellular microhairs. —C. Specimen without abaxial macrohairs and somewhat wider costal zones (but still consisting of three cell files). —D. Specimen without macrohairs, but note pairs of inflated epidermal cells indicative of deciduous macrohair bases (arrowed); the microhairs are clearly visible, particularly the basal cell. —E. Specimen in which the intercostal zones can be subdivided into two areas: those adjacent to the costal zones with sinuous-walled long cells, few stomata, and few microhairs, and the centrally located files which are bulliformlike; a few small macrohairs were observed in these central files. F. Intercostal zones with rectangular, sinuous-walled long cells throughout, stomata in two separate files near the costal zones and bicellular microhairs common along the central cell files (A, B, based on *Zuloaga 2060*; C, based on *Zuloaga 1972*; D, based on *Zuloaga 2128*; E, based on *Zuloaga 2352*; F, based on *Zuloaga 2380*; A, C ×160; E ×250; B, D, F ×400).

*Panicum hebotes* is unique in section *Dichanthelium* in having three-celled microhairs (Fig. 9B, D). Multicellular microhairs are rare in the Poaceae, where they have only been reported for the Guaduelleae, a primitive bambusoid tribe (Soderstrom & Ellis, 1987), lodicules of *Streptogyna crinita* (Soderstrom & Judziewicz, 1988), a few species of *Pentachistis* from the Arundinoideae (Ellis & Linder, 1991), *Paspalum* L. (Türpe, 1966) and *Panicum validum* Mez (Zuloaga et al., 1989) of the Panicoideae.

Multicellular glands are present in the abaxial intercostal zones of the epidermis of *P. adenorachis* (Morrone & Zuloaga, 1991).

## CONCLUSIONS

This study of species of *Dichanthelium* from Mexico and the West Indies to Argentina dem-

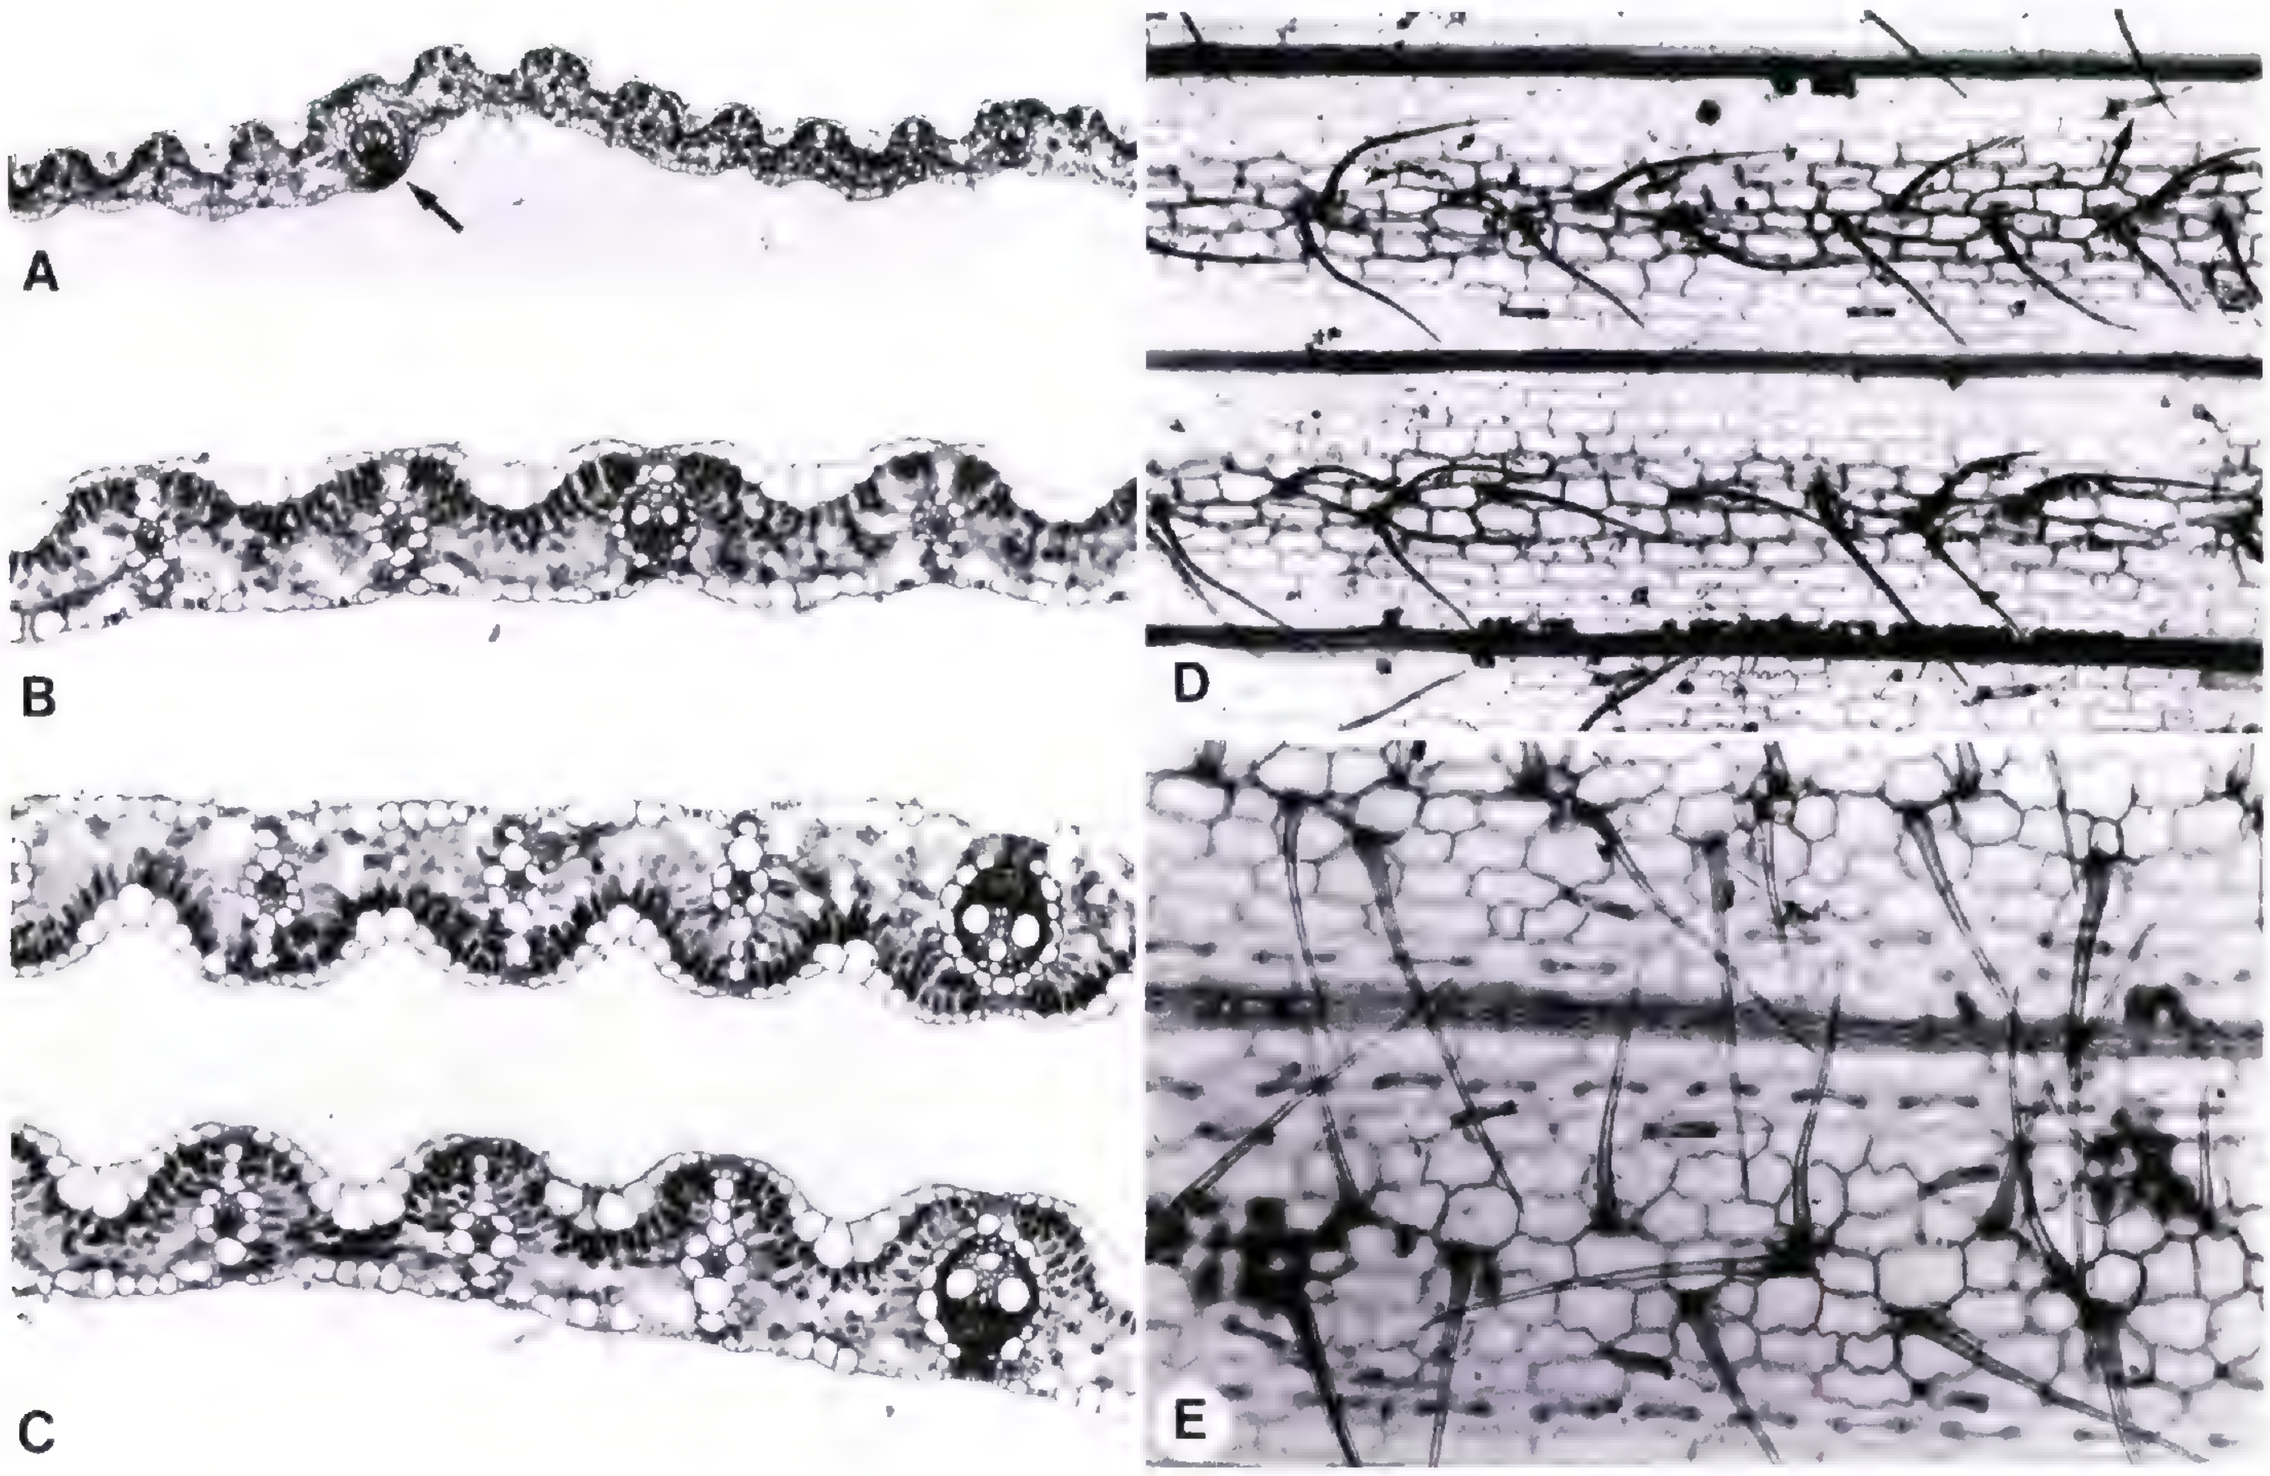

FIGURE 14. Leaf blade anatomy of *Panicum sciurotoides*. A–C. Anatomy in transverse section.—A. Central lamina showing keel with additional sclerenchyma and parenchyma development (arrowed); note macrohairs.—B. Thin blade with palisade and spongy mesophyll tissue distinguishable; bundle sheath extensions very short.—C. Thin lamina with extensive intercellular air spaces in the spongy mesophyll tissue; bundle sheath extensions visible in association with the third-order bundles. D, E. Abaxial epidermis. D. Curved macrohairs without cushion bases common along central files of intercostal zones, these files with bulliformlike cells; lateral files of intercostal zones with rectangular long cells with sinuous walls; elongate, fingerlike microhairs occur along these files (arrowed); stomata absent.—E. Detail of macrohairs and their bases, microhairs, and long cells, which are very short and irregular in shape (A, B, D, based on *Zuloaga et al. 2349*; C, E, based on *Zuloaga et al. 2354*; A ×100; B, C, D ×250; E ×400).

onstrates that there are insufficient differences to justify separation of *Dichanthelium* from *Panicum* as a distinct genus. The data presented also show a significant variation in the characters traditionally used to separate these taxa at the generic level. The rosettes and foliar and floral dimorphism are traditionally used to delimit *Dichanthelium* as a genus, but are only characteristic of species with a boreal distribution, and are absent in the rest of the species of the subgenus (Morrone & Zuloaga, 1991). This even applies to widespread species of *Dichanthelium* distributed from the United States to northern South America. Morrone & Zuloaga (1991) suggested that these characters could represent an evolutionary adaptation to harsh winters.

Gould & Clark (1978) noted that *Dichanthelium* includes mostly diploid species, with only three known polyploids. They contrasted this with *Panicum*, in which polyploid species predominate. Dubcovsky & Zuloaga (1992) confirmed the presence of additional polyploid species, including tetraploids and octoploids, in *Dichanthelium* representatives from South America. Consequently, differences in the ploidy level between *Dichanthelium* and other subgenera of *Panicum* are considered to be taxonomically insignificant.

Brown & Smith (1975) and Gould & Clark (1978) justified the separation of *Dichanthelium* from *Panicum* on the basis of the Kranz syndrome. These authors characterized *Dichanthelium* as $C_3$ or non-Kranz and *Panicum* as $C_4$ or Kranz. However, many non-Kranz species of *Panicum* are placed in subgenus *Phanopyrum* (Zuloaga, 1987), so this distinction does not seem useful in separating *Dichanthelium*. There are also no consistent differences in the ornamentation of the upper anthecium between *Dichanthelium* and other groups of *Panicum* (Zuloaga, 1987). This difference was used by Gould & Clark (1978) to distinguish *Dichanthelium* from *Panicum*.

Within *Panicum*, *Dichanthelium* can be distinguished at the subgeneric level by the following set

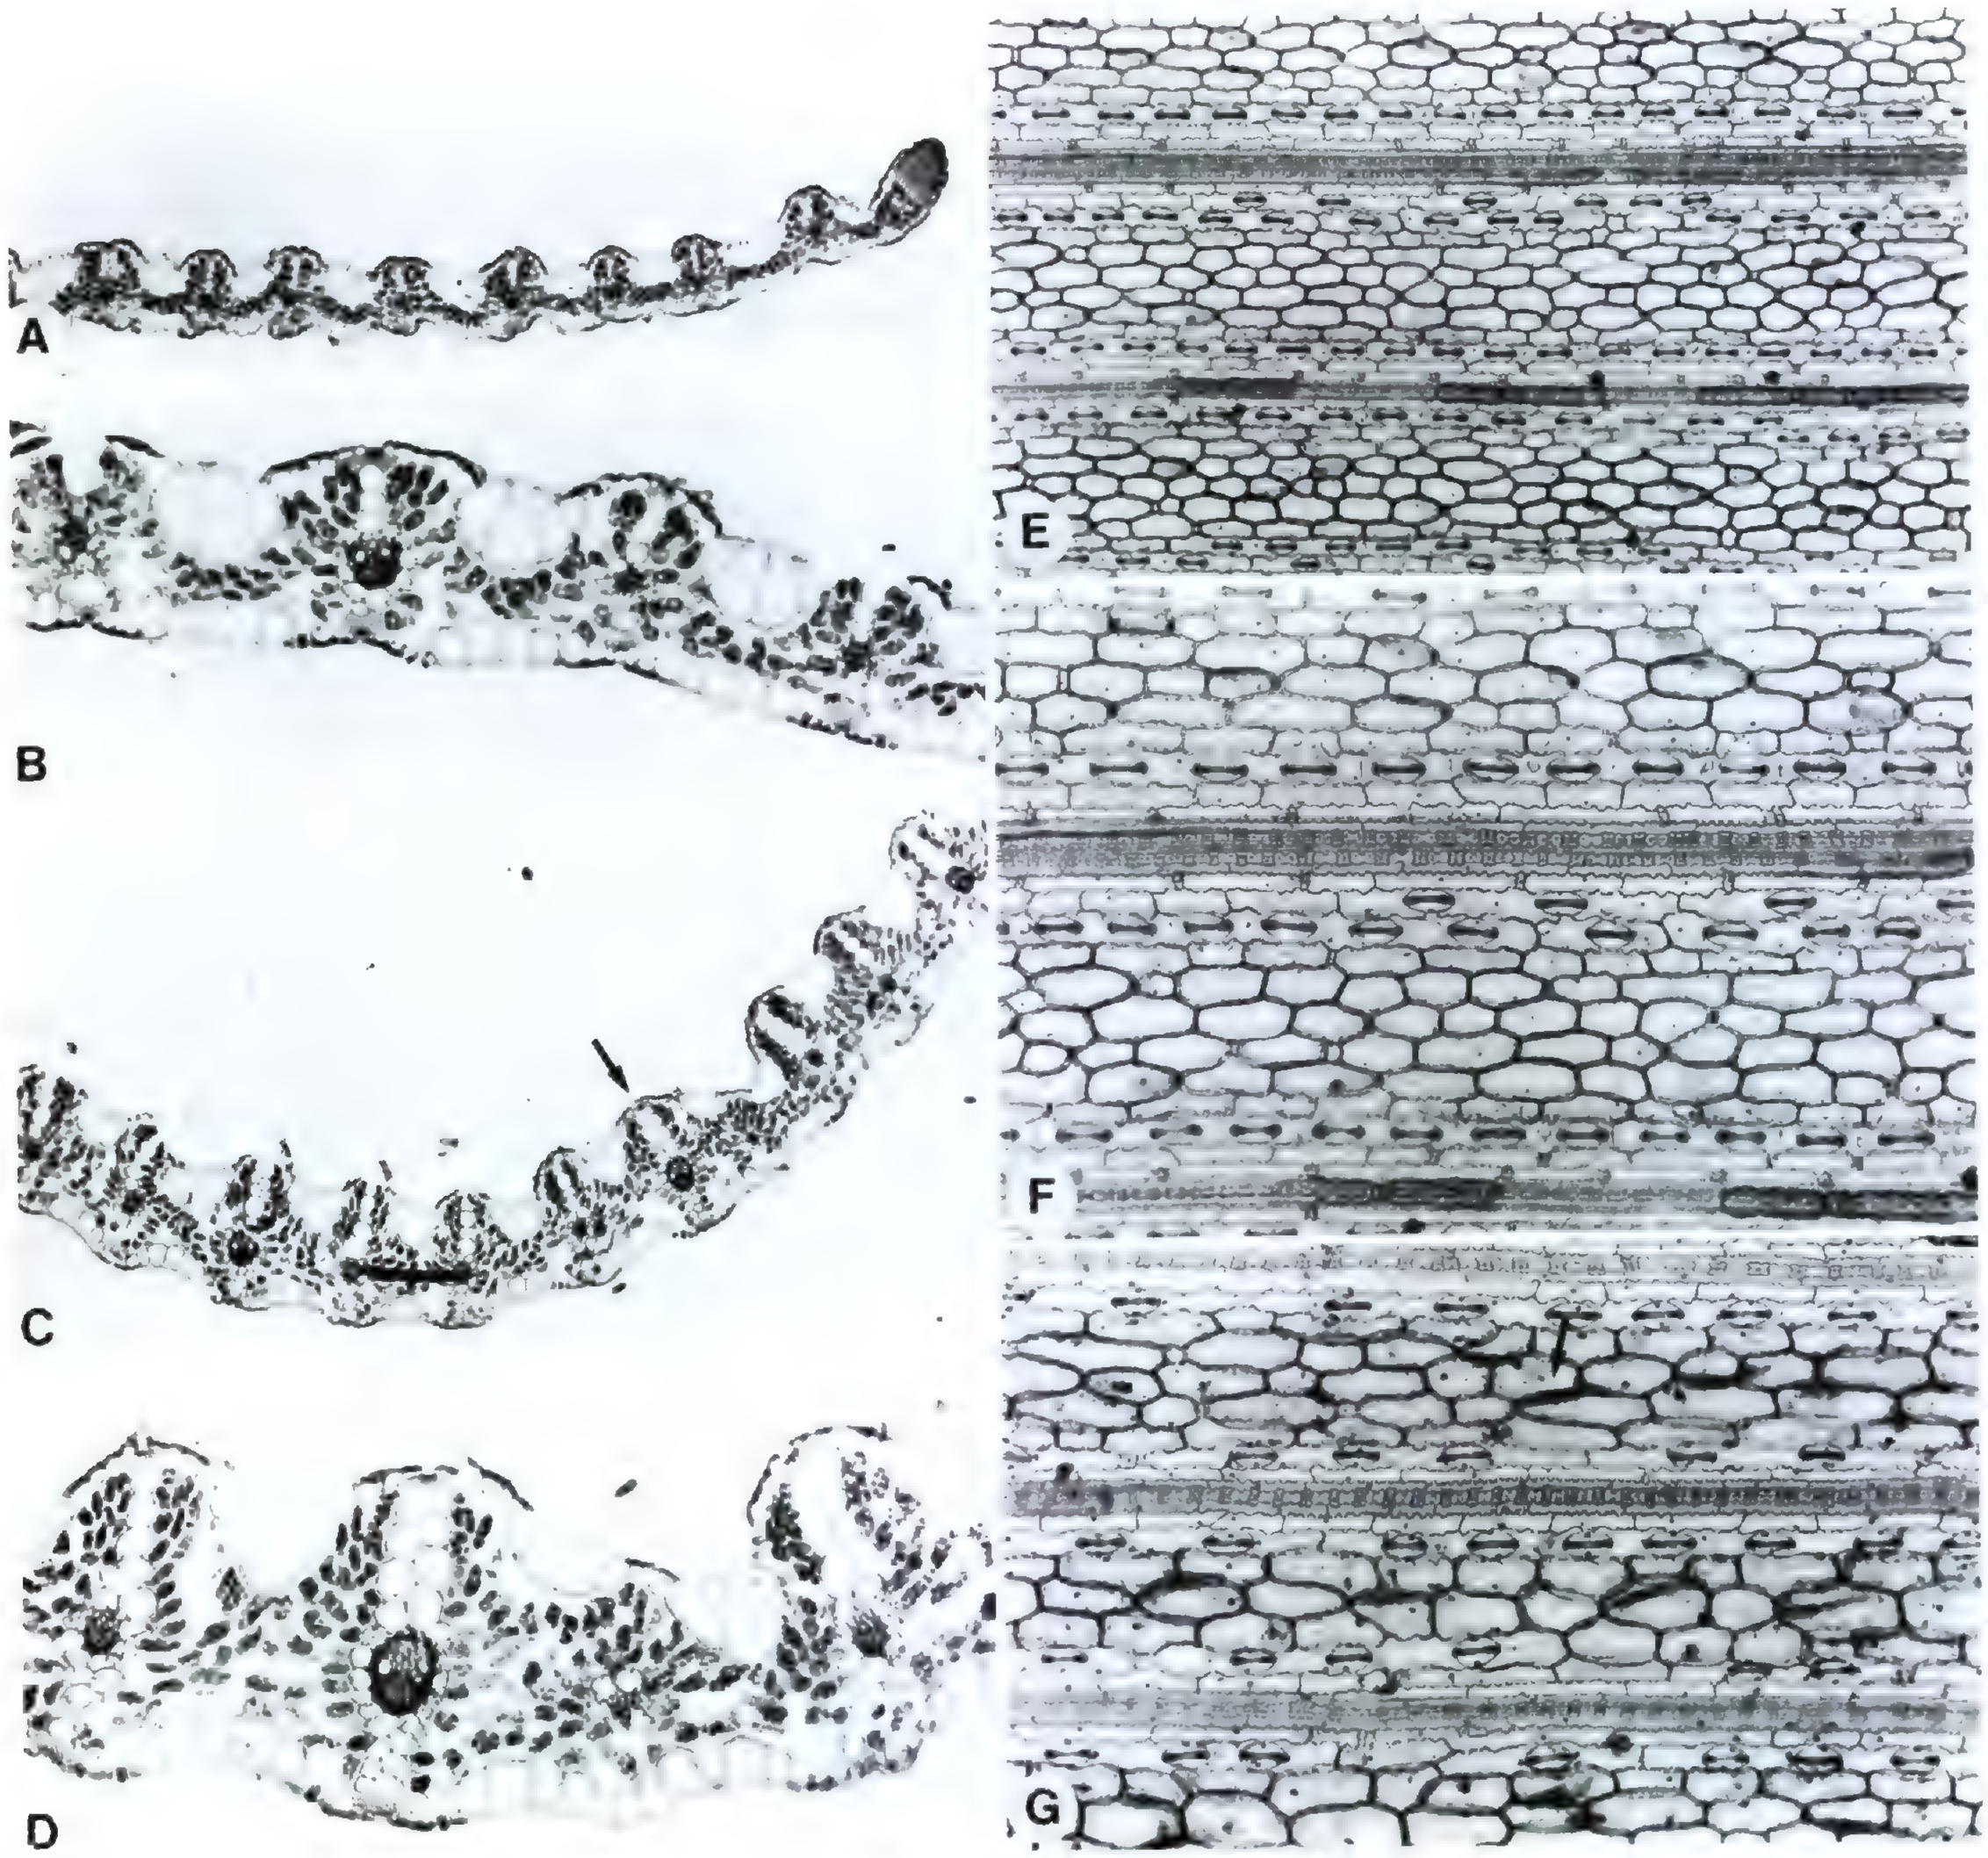

FIGURE 15. Anatomy of *Panicum sphaerocarpon*. A–D. Transectional anatomy.—A. Lateral part of expanded lamina with sclerenchyma cap in margin.—B. Detail showing large, restricted bulliform cells; note uniseriate bundle sheath extensions and thick cuticle.—C. Central part of lamina with median vascular bundle indistinguishable from other first-order bundles (arrowed); note transverse vein connecting two third-order bundles.—D. Bundle sheath extensions unusual in being biseriate (but may be uniseriate); mesophyll characteristic in that spongy and palisade tissue are not differentiated. E–G. Abaxial epidermis.—E. Epidermal pattern showing absence of macrohairs, short intercostal long cells, and two files of stomata per intercostal zone.—F. Costal zones of five cell files, two with dumbbell-shaped silica bodies; intercostal long cells with thickened periclinal cell walls, particularly the bulliformlike centrally located cells; lateral long cells more rectangular in shape with files of stomata; no microhairs evident.—G. Bicellular microhairs present in the central files of the intercostal zones (A, B, G, based on *Zuloaga 4035*; C, D, E, F, based on *Zuloaga 4249*; A, C ×100; E ×160; B, D, F, G ×250).

of characters: lax inflorescences; ellipsoid to obovoid spikelets; upper glume and lower lemma usually 7–11-nerved; upper anthecium apiculate or shortly crested, and simple papillae on the lemma and palea. Anatomically, all species are non-Kranz or $C_3$, with the outer parenchymatous sheath lacking specialized chloroplasts; a complete inner mestome sheath surrounds first-order vascular bundles; mesophyll irregularly radiating, and palisadelike toward the adaxial surface, with 5–8(–10) mesophyll cells between consecutive vascular bundles; extensions of the outer bundle sheath extending toward both epidermides and of 1–4 cells deep; dumbbell-shaped or nodular silica bodies; bicellular microhairs; and the stomatal complex dome-shaped or triangular.

Section *Cordovensia* (A. Hitchc. & Chase) L. Parodi differs from section *Dichanthelium*, as circumscribed here, in the membranous ligules, spikelets with the upper glume and lower lemma usually

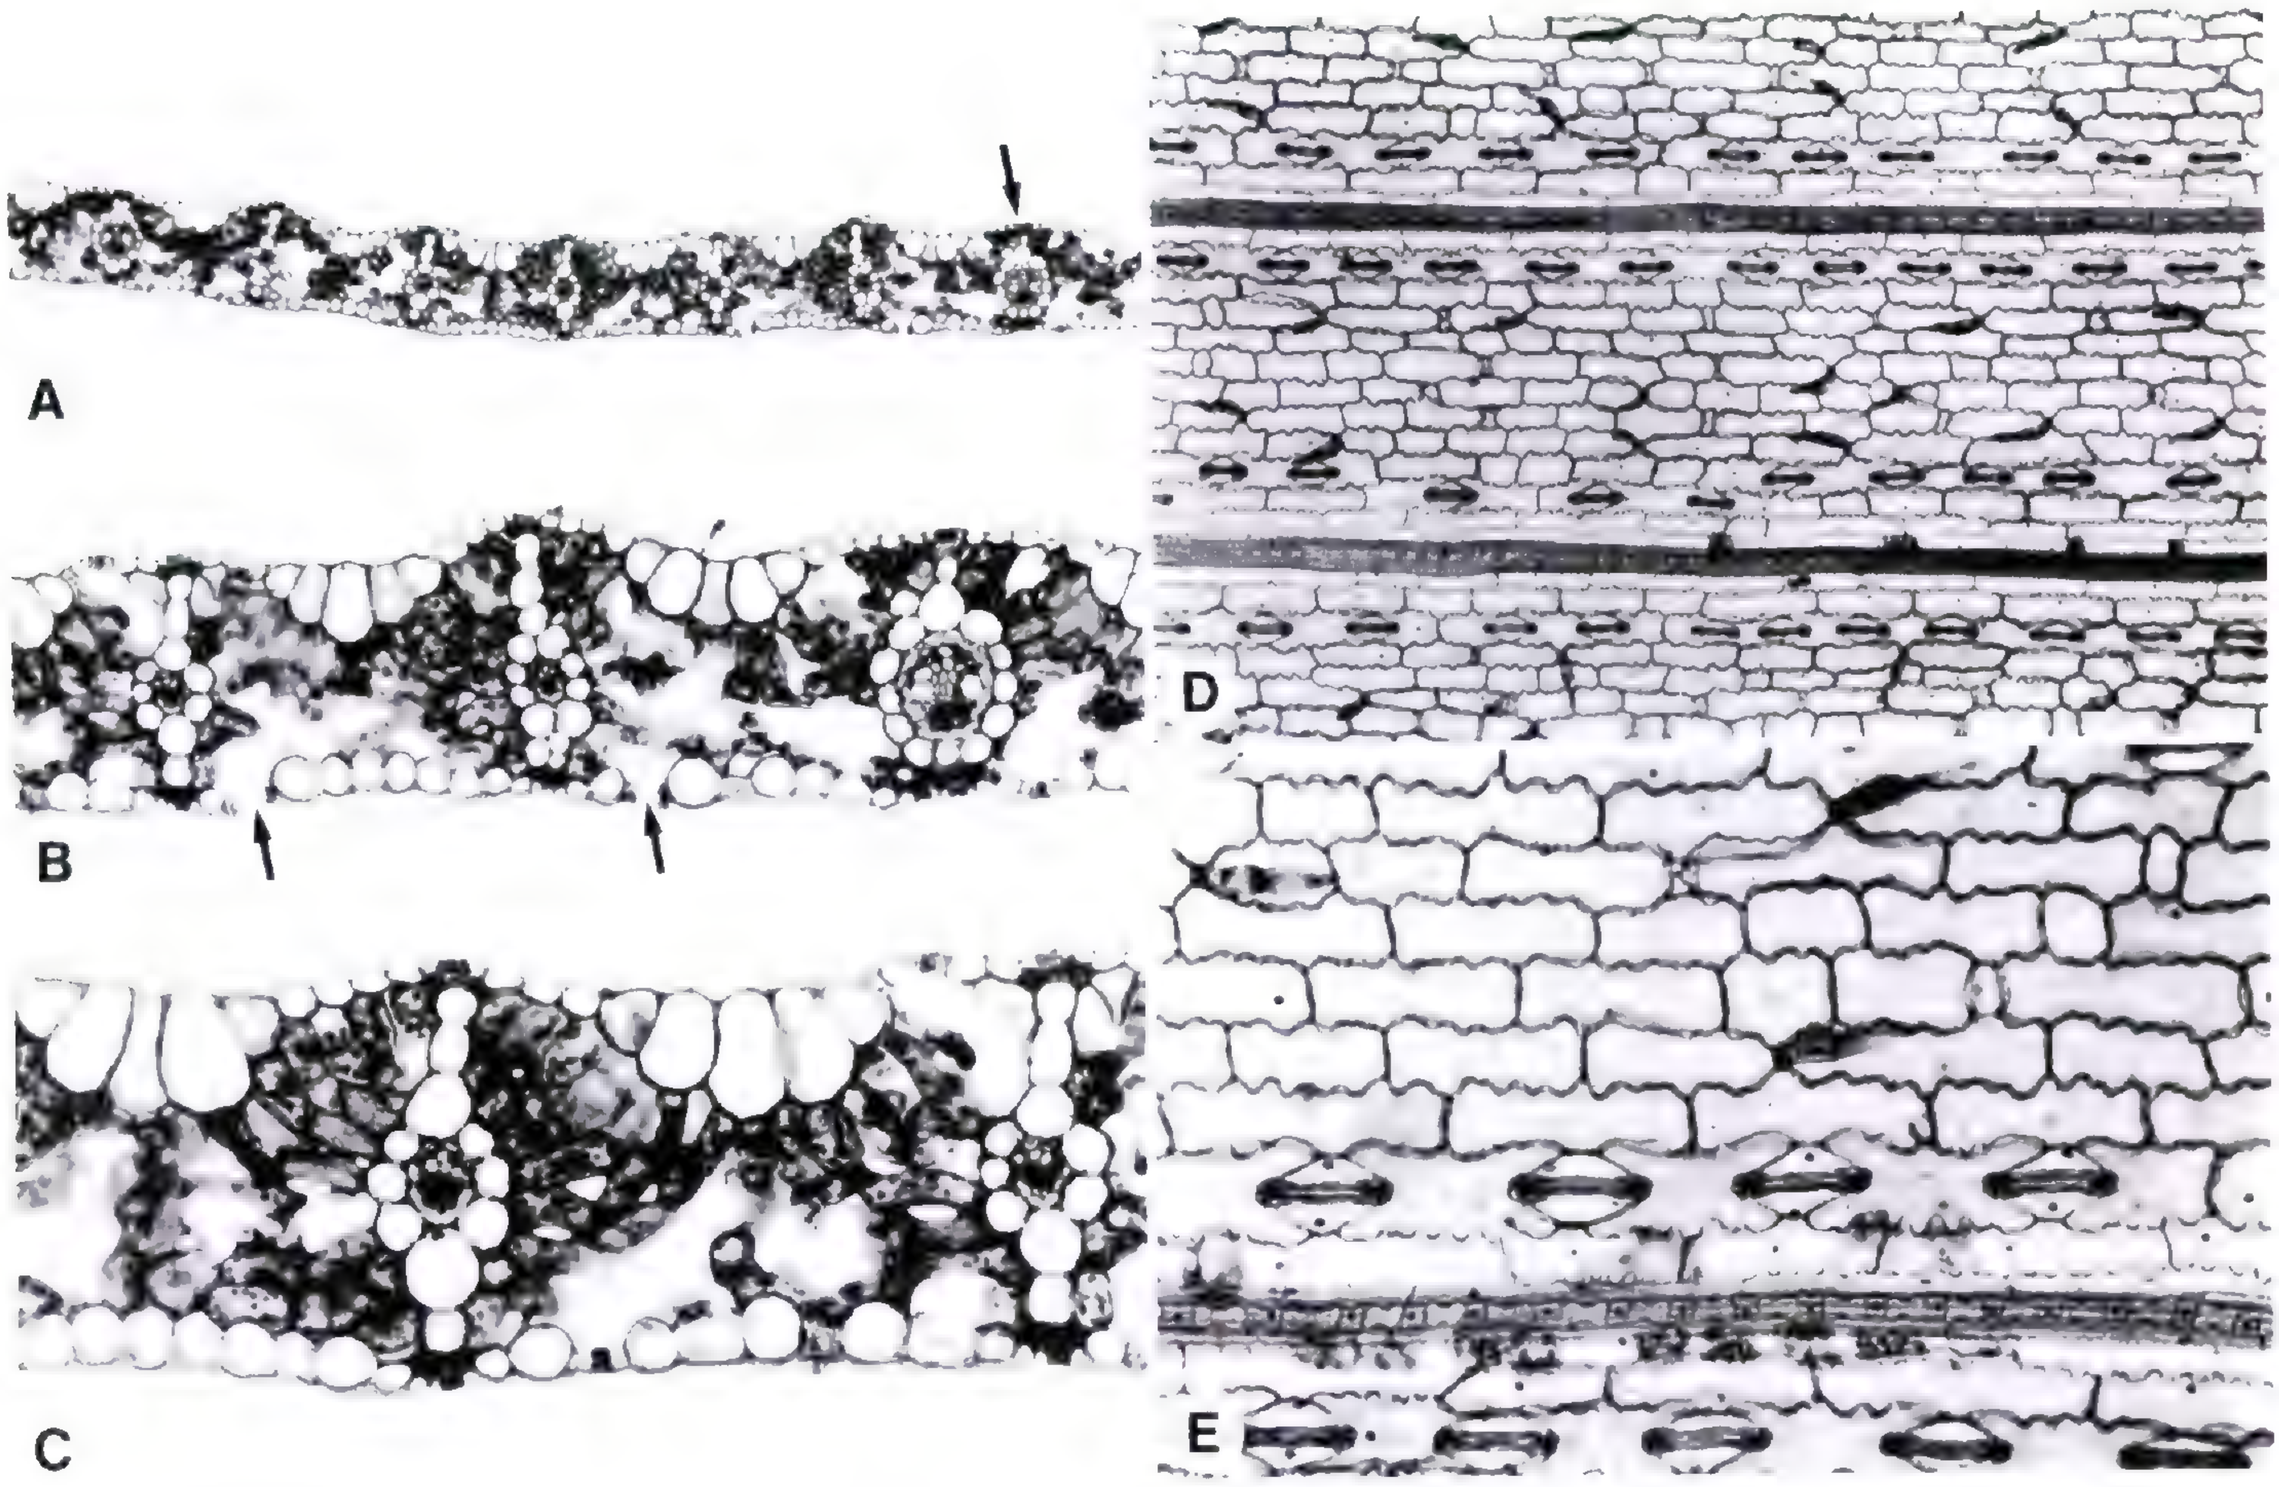

FIGURE 16. Leaf anatomy of *Panicum stigmosum*. A–C. Leaf blade in transverse section.—A. Central part of lamina showing median vascular bundle.—B. Third-order vascular bundles with uniseriate sheath extensions; note abaxial stomata (arrowed).—C. Detail showing diffuse mesophyll with large intercellular air spaces in the spongy tissue. D, E. Abaxial epidermis.—D. Epidermal zonation with wide intercostal zones and very narrow intercostal zones.—E. Detail of stomata with triangular subsidiary cells, rectangular long cells with sinuous walls, bicellular microhairs, and costal zones three cells wide with central file with dumbbell-shaped silica bodies alternating with short cork cells (A–E, based on *Zuloaga et al. 2351*; A ×100; C ×160; B ×250; D, E ×400).

5-nerved, and the lower flower and palea absent. Anatomically, species of section *Cordovensia* have midribs with rounded adaxial and abaxial projections; they have restricted groups of 5–7 large, inflated bulliform cells that lie parallel to the epidermis; the abaxial epidermis has homogeneous intercostal zones; long cells have very deeply undulating cell walls. In section *Cordovensia* the ex-

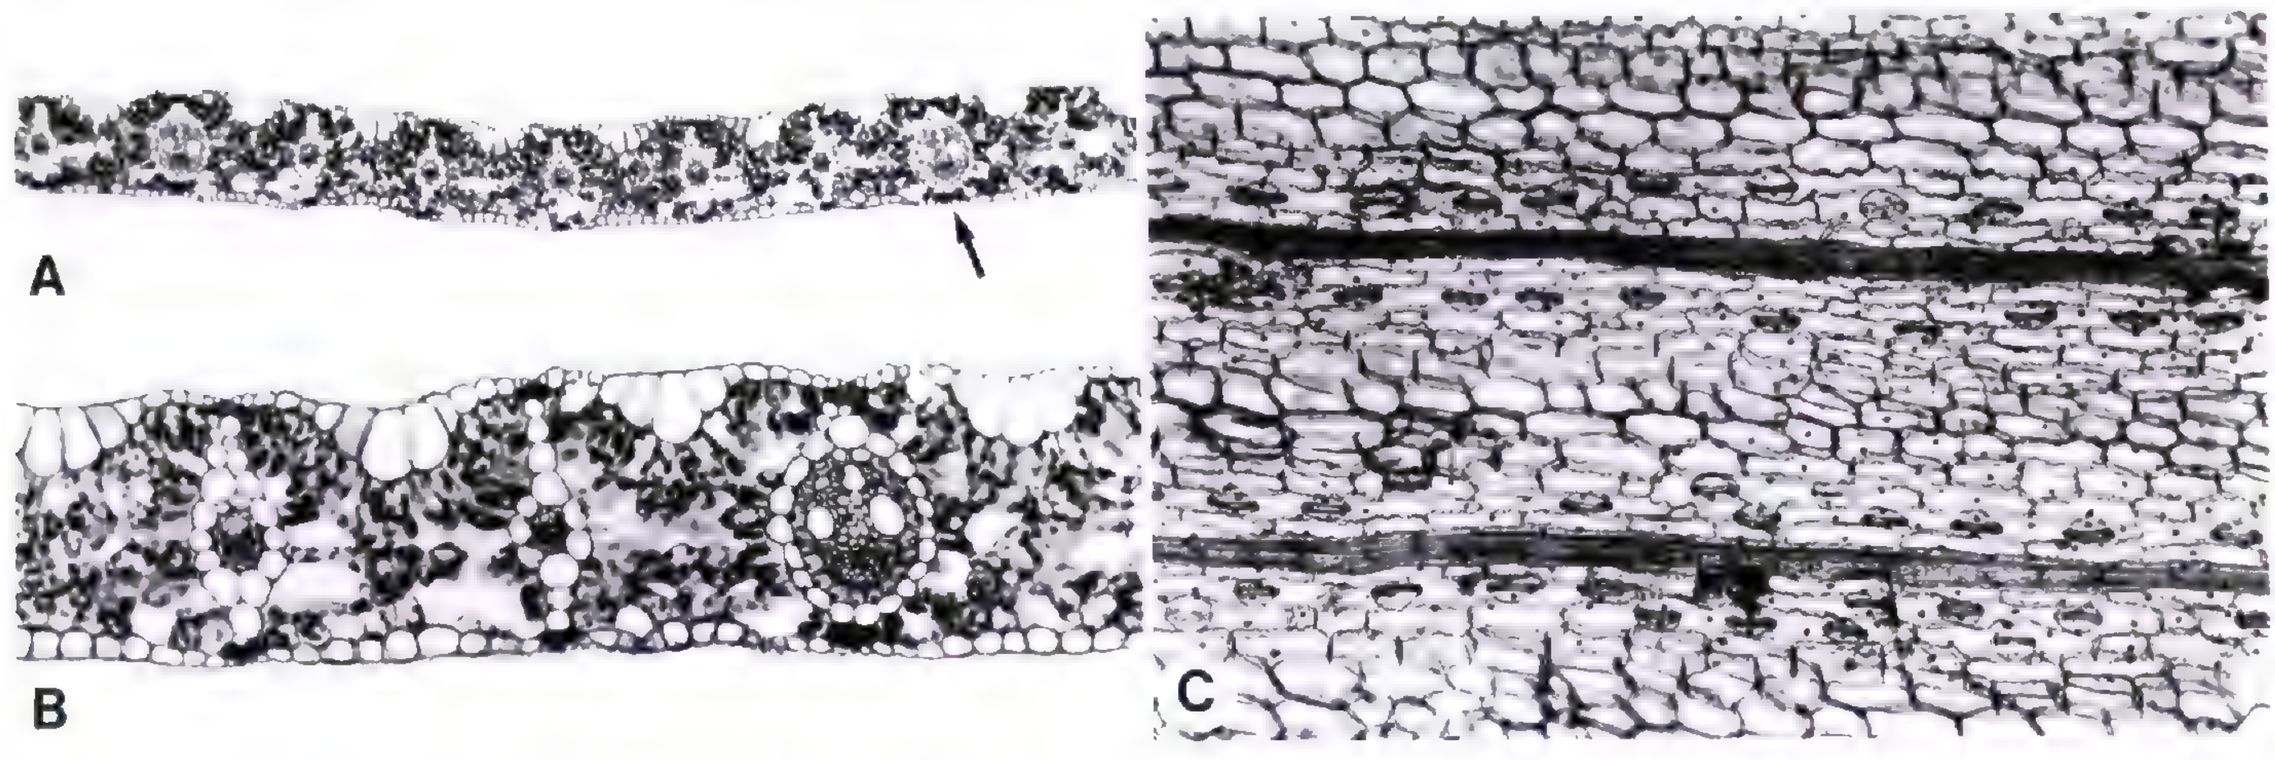

FIGURE 17. Leaf anatomy of *Panicum superatum*. A, B. Transectional anatomy.—A. Median part of blade showing median vascular bundle (arrowed) identical to other first-order vascular bundles. B. Anatomical detail of conspicuous, translucent outer bundle sheath and extension cells and diffuse mesophyll tissue.—C. Abaxial epidermis without macrohairs and with inflated, short intercostal long cells (A–C, based on *Zuloaga et al. 2374*; A ×100; B, C ×250).

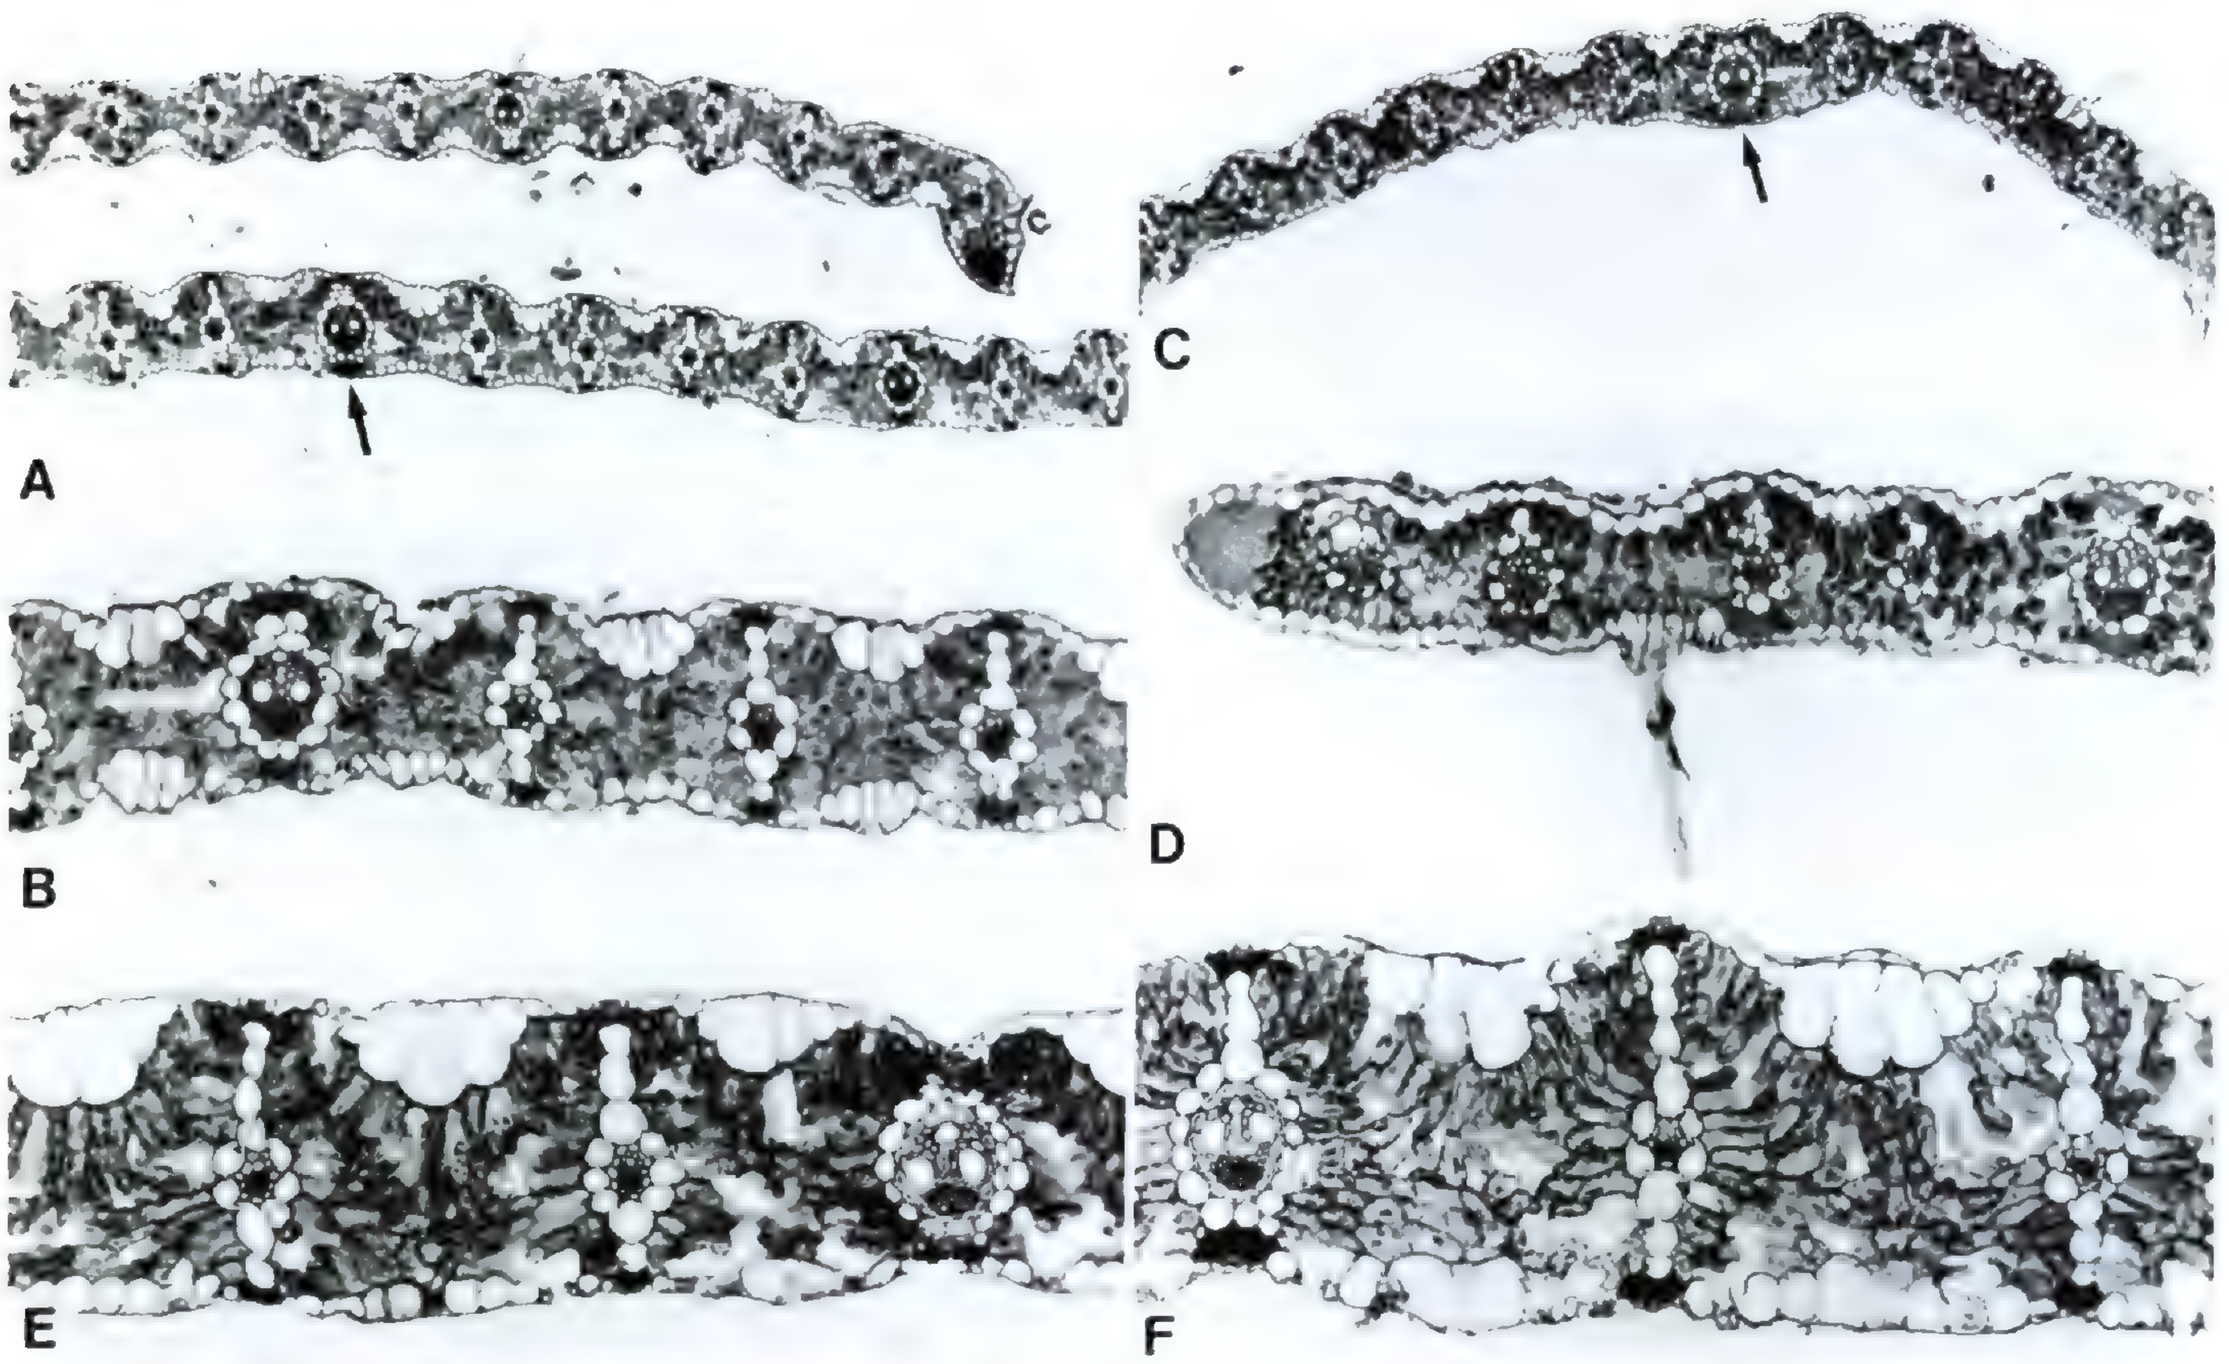

FIGURE 18. Transectional leaf blade anatomy of *Panicum viscidellum*.—A. Lateral and median part of blade showing sclerenchyma cap in margin and median vascular bundle (arrowed).—B. Detail of uniseriate bundle sheath extensions associated with third-order bundles and much shorter, biseriate adaxial extensions from the first-order bundles.—C. Midrib bundle (arrowed) with slightly larger sclerenchyma girders than are associated with the laterally located first-order vascular bundles.—D. Margin showing sclerenchyma cap and cushion-based macrohair.—E. Detail of mesophyll tissue tending to radiate type of arrangement; note intercellular air spaces and uniseriate bundle sheath extensions.—F. Chlorenchyma cell arrangement clearly evident with the adaxial cells somewhat radiately arranged whereas the abaxial tissue is irregular, resembling spongy mesophyll; note uniseriate sheath extensions and small adaxial and abaxial sclerenchyma strands associated with all vascular bundles (A, B, based on *Zuloaga et al. 4532*; C, D, based on *Zuloaga et al. 4530*; E, based on *Davidse 32336*; F, based on *Stevens 25420*; A, C ×100; B, D–F ×250).

tensions of the outer parenchymatous sheath are composed of 1(−2) cells, or are occasionally absent.

## TAXONOMIC TREATMENT

**Panicum** subgenus **Dichanthelium** A. Hitchc. & Chase, Contr. U.S. Natl. Herb. 15: 142. 1910. TYPE SPECIES: *Panicum dichotomum* L.

### **Panicum** section **Dichanthelium**

*Panicum* section *Dichotoma* (A. Hitchc. & Chase) Hsu, J. Fac. Sci. Univ. Tokyo, sect. 3, Bot. 9: 119. 1965. Group *Dichotoma* A. Hitchc. & Chase, Contr. U.S. Natl. Herb. 15: 179. 1910, nom. inval.

Perennials with or without a basal rosette of shorter, broader leaves than those of the culms. Culms erect or decumbent-erect, usually freely branching at the upper nodes; internodes hollow, with or without glands. Sheaths striate, pilose or glabrous, with or without conspicuous glands. Ligules membranous-ciliate, the membranous portion small, the cilia variable in length. Blades linear to ovate-lanceolate, flat or inrolled, densely pilose to glabrous; foliar dimorphism present or absent. Inflorescence terminal and axillary, lax, open, occasionally contracted, axis of the branches with or without glands, pilose or glabrous. Spikelets ellipsoid to obovoid, pilose or glabrous, cleistogamous flowers present or absent. Lower glume of variable length, usually ¼–⅓ the length of the spikelet, up to ¾ in several species, 1–7-nerved, acute or truncate, a short internode between the lower and upper glume present or absent. Upper glume acute to obtuse, usually not covering the apex of the upper anthecium, (5–)7–15-nerved. Lower lemma glumiform, (5–)7–15-nerved. Lower palea conspicuous, as long as its lemma to small, absent in *P. aciculare* and *P. penicillatum*; lower flower staminate or absent. Upper anthecium indurate, smooth, shiny, with simple papillae all over its surface, pilose toward the apex of the lemma or glabrous, shortly

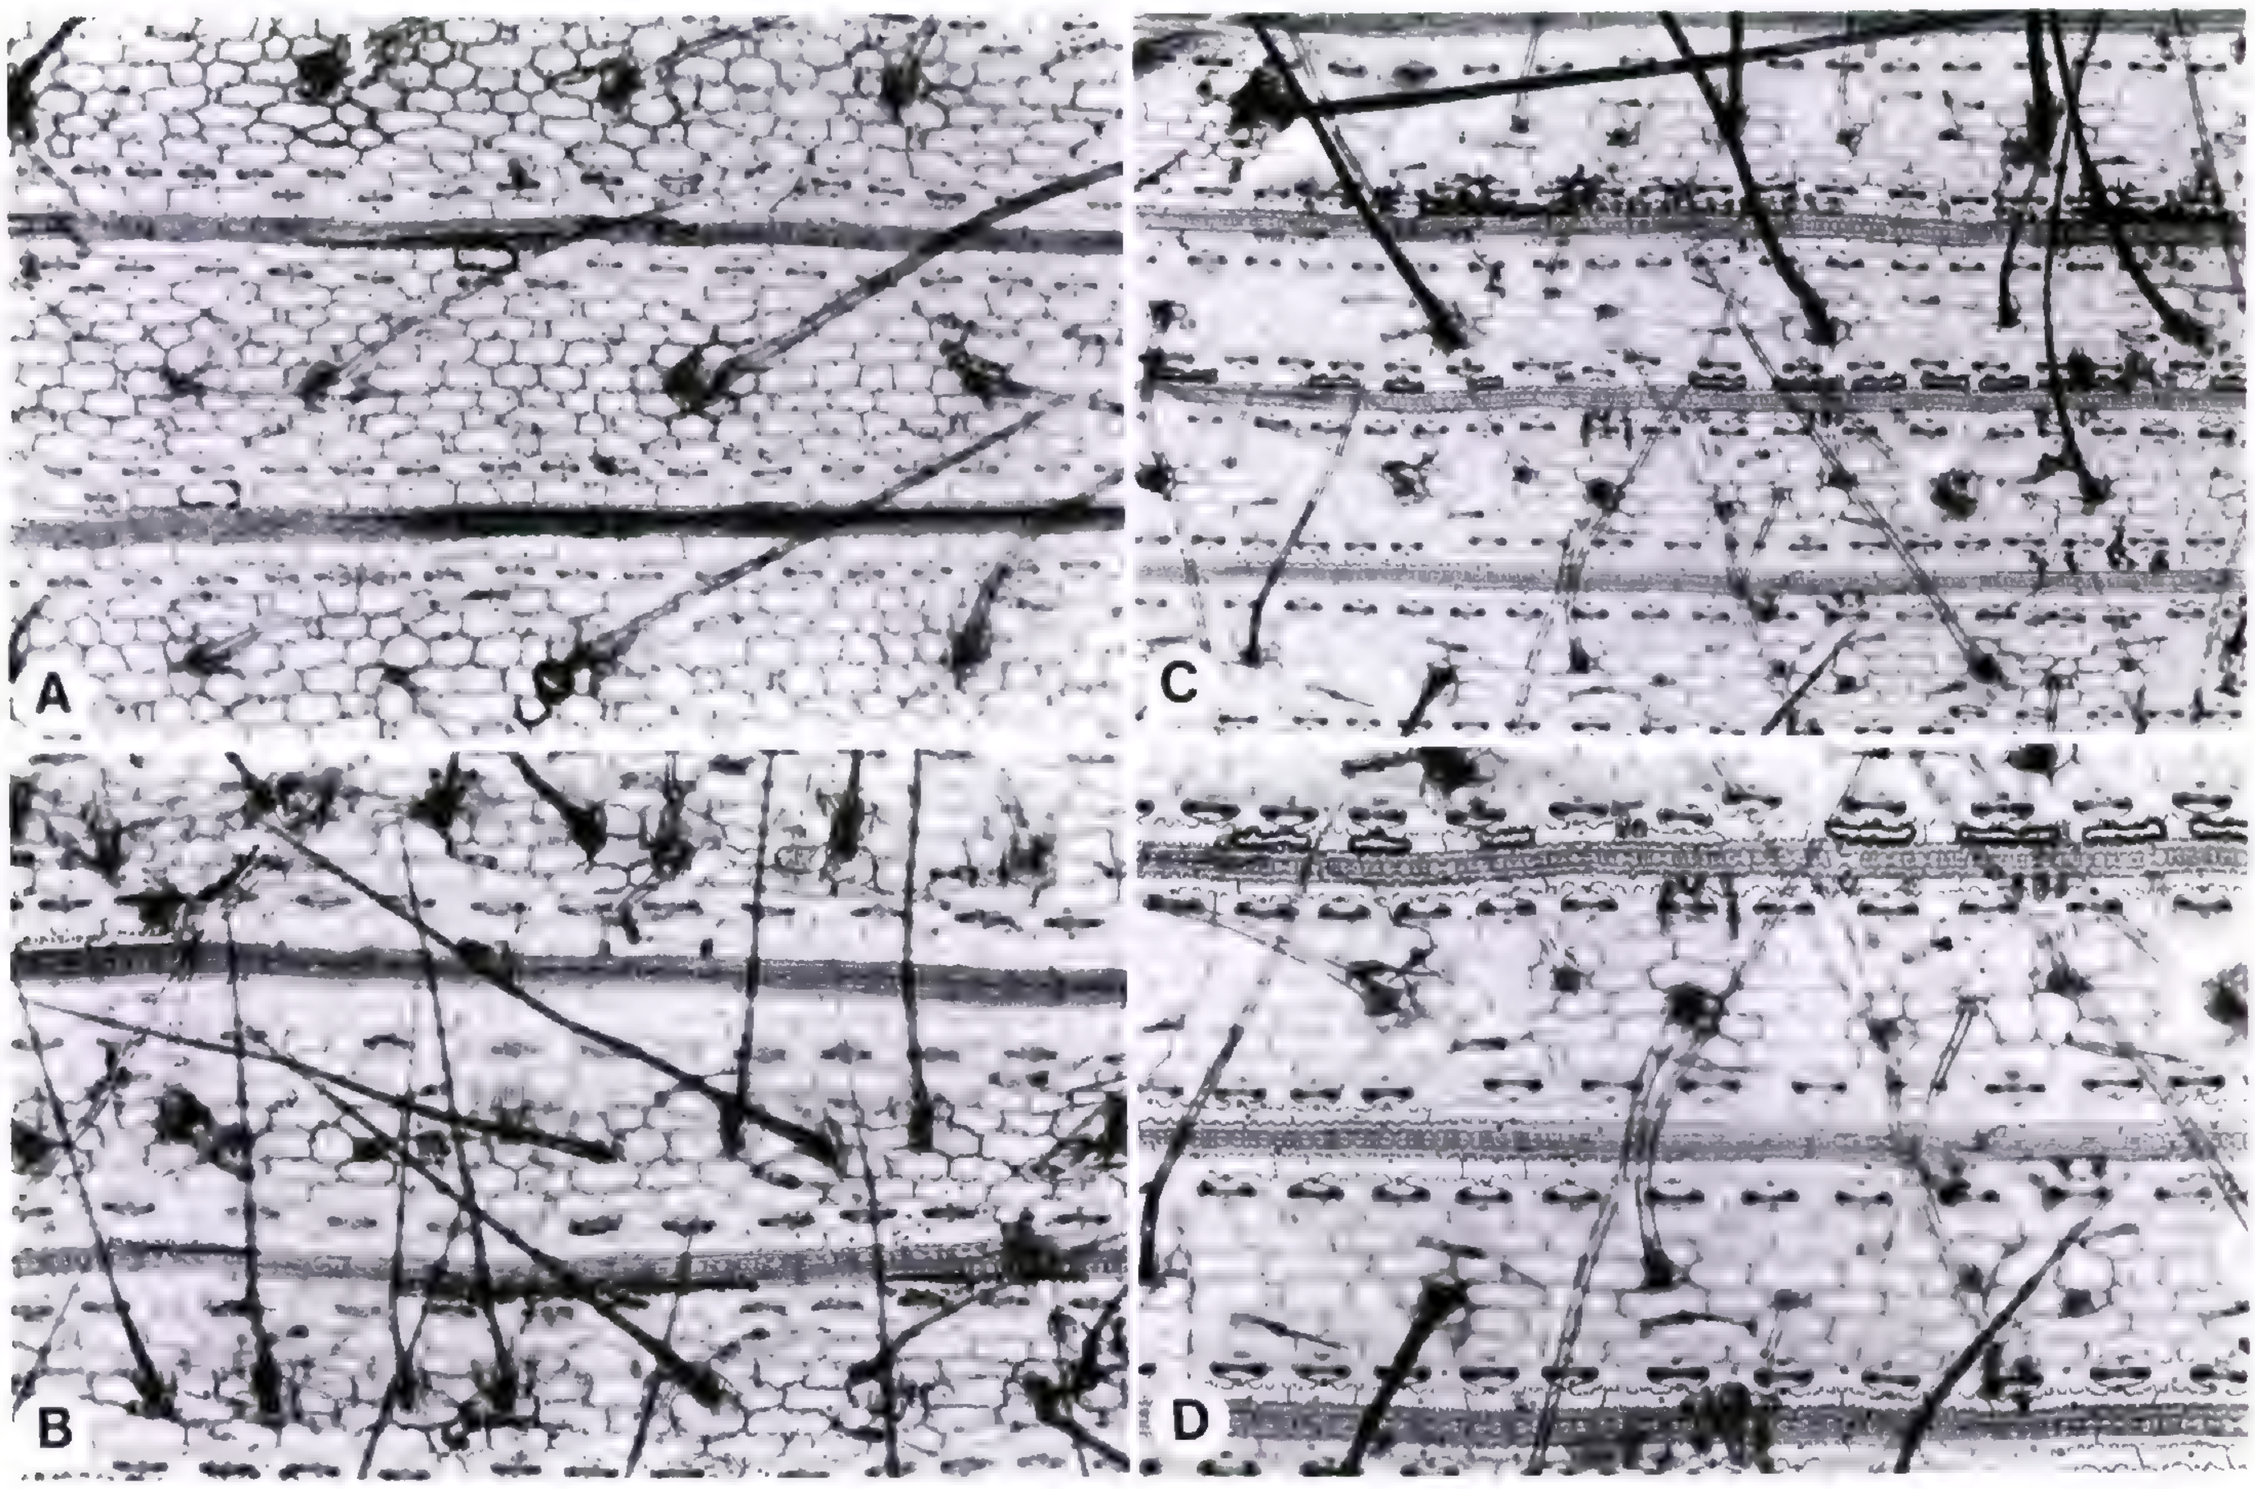

FIGURE 19. Abaxial leaf blade epidermis of *Panicum viscidellum*. — A. Prominent macrohairs common in the central files of the intercostal zones; these hairs have small cushions associated with their bases. — B. Long, slender macrohairs inserted between a few specialized epidermal cells. — C. Epidermal pattern showing narrow costal zones with files of stomata on either side; the central files of the wide intercostal zones with numerous long, slender macrohairs. — D. Detail of macrohair bases that are inserted between three or four inflated epidermal cells; numerous small elongated microhairs (A, based on *Stevens 25420*; B, based on *Zuloaga et al. 4537*; C, D, based on *Zuloaga et al. 4532*; A, C ×160; B, D ×250).

apiculate or crested; lodicules 2, conduplicate, truncate; stamens 3; styles 2, free, the stigmas 2, plumose. Caryopsis with hilum punctiform, embryo ½ or less the length of the caryopsis. Basic chromosome number: $x = 9$. Anatomy: $C_3$, non-Kranz.

A section with 37 species in Mesoamerica, the West Indies, and South America, inhabiting edges of forest in west habitats or in open places, on moist or dry sandy soils.

KEY TO THE SPECIES

1. Upper glume and lower lemma 10–15-nerved ..... 2
1. Upper glume and lower lemma (5–)7–9-nerved ..... 8
2(1). Lower palea absent; culms scandent, leaning on vegetation, to 10 m tall; internodes solid toward the base; leaf blades pseudopetiolate; lower glume as long as or a little shorter than the upper glume ..... 20. *P. penicillatum*
2. Lower palea present; culms decumbent to erect or scandent, 0.15–0.60(–2.2) m tall; internodes hollow; leaf blades not pseudopetiolate; lower glume ½–⅔ the length of the spikelet ..... 3
3(2). Inflorescences contracted; spikelets obovoid ..... 33. *P. superatum*
3. Inflorescences lax, open; spikelets narrowly ellipsoid to ellipsoid ..... 4
4(3). Spikelets 1.5–1.9 mm long ..... 27. *P. sciurotoides*
4. Spikelets 3–6.8 mm long ..... 5
5(4). Culms erect, 15–30(–60) cm tall; spikelets hirsute with papillose-pilose hairs; Mexico ..... 19. *P. pedicellatum*
5. Culms leaning on vegetation, to 2.2 m tall; spikelets glabrous; Brazil ..... 6
6(5). Spikelets 3–3.3 mm long; lower palea 2.1–2.4 mm long; lower glume 3-nerved; leaf blades with scabrous margins, ciliate toward the base; the sheaths and nodes hirsute; Venezuela and northwestern Brazil, Roraima ..... 11. *P. davidsei*
6. Spikelets 4.6–6.8 mm long; lower palea 4–5.5 mm long; lower glume 5-nerved; leaf blades with ciliate margins; the sheaths and nodes glabrous; Brazil, Rio de Janeiro and Espírito Santo ..... 7
7(6). Spikelets 4.6–5 mm long; upper anthecium 4–4.2 mm long; leaf blades 10–12 cm long ..... 17. *P. itatiaiae*
7. Spikelets 5.9–6.8 mm long; upper anthecium 5.2 mm long; leaf blades 14–21 cm long ..... 7. *P. caparaoense*

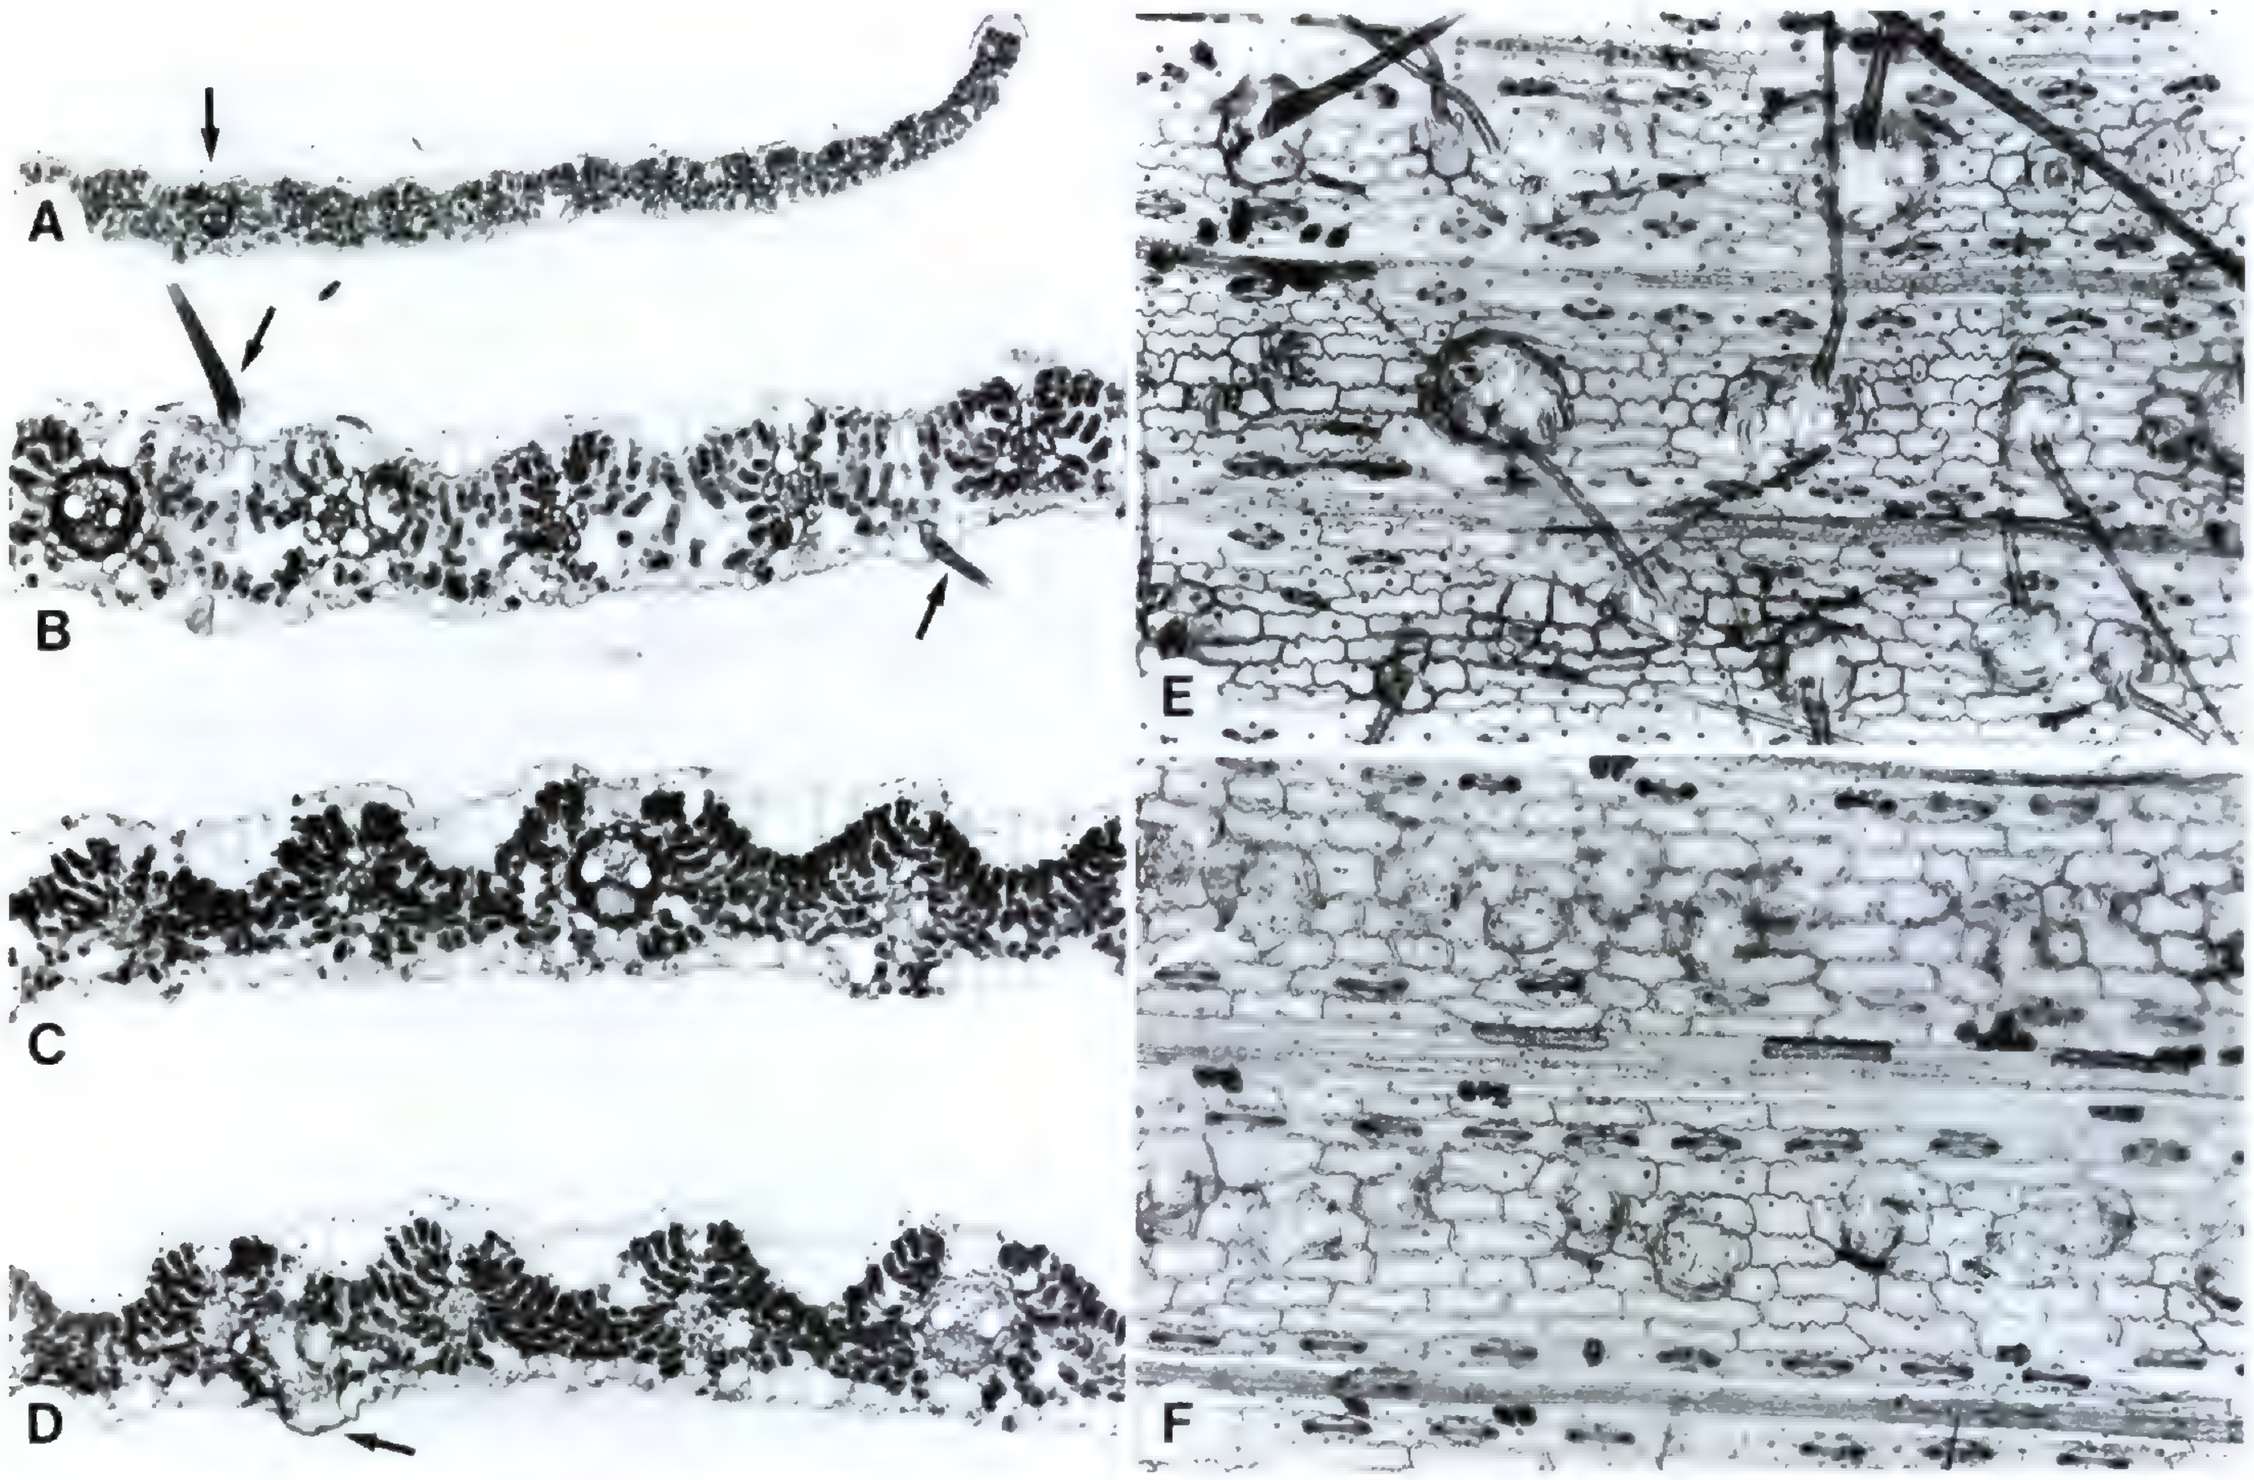

FIGURE 20. *Panicum viscidellum* specimens with silicified cushion bases of the macrohairs. A–D. Transectional leaf anatomy.—A. Leaf section showing margin and median vascular bundle (arrowed).—B. Detail of macrohairs with cushion bases (arrowed): these cushion cells do not appear to be silicified; note the outer bundle sheath cells, which contain chloroplastlike bodies.—C. Section with chloroplasts in bundle sheath and extension cells; mesophyll relatively compact.—D. Section through silicified cushion-base cells (arrowed). E, F. Abaxial epidermis.—E. Prominent macrohairs inserted into cushion bases, the cells of which are refractive, indicating silicification.—F. Specimen with small, indistinct macrohairs, but with conspicuous cushion bases that contain crystalline material resembling opaline silica (A, B, E, based on *Zuloaga & Londoño 4203*; C, D, F, based on *Zuloaga 4184*; A ×100; B–F ×250).

8(1). Spikelets usually geminate, at least in portions of the inflorescence; lower glume dimorphic; upper anthecium black at maturity; blades asymmetrical at the base ..... 15. *P. hebotes*

8. Spikelets not geminate; lower glume isomorphic; upper anthecium whitish to pale, not black at maturity; blades usually symmetrical at the base ..... 9

9(8). Lower palea conspicuous, as long as or nearly as long as the lower lemma; lower flower present or absent ..... 10

9. Lower palea small or absent, shorter than the lower lemma; lower flower absent ..... 14

10(9). Lower glume not embracing the upper glume; stipe inconspicuous between the lower and upper glume; spikelets narrowly ellipsoid, 1.8–2.2 mm long ..... 34. *P. surrectum*

10. Lower glume embracing the upper glume; stipe present between the lower and upper glume; spikelets obovoid to ellipsoid, (1.9–)2–3.2 mm long ..... 11

11(10). Inflorescences contracted, spiciform or with the first-order branches slightly divergent, the spikelets congested on the branches ..... 33. *P. superatum*

11. Inflorescences lax, first-order branches divergent, and spikelets not congested on the branches ..... 12

12(11). Spikelets ellipsoid, 3–3.2 mm long, minutely puberulent; inflorescences short-exserted or included on the upper leaves, 3–5 cm long; Serra do Sol, Venezuela ..... 35. *P. telmatum*

12. Spikelets obovoid, 1.9–3(–3.2) mm long, glabrous; terminal inflorescences exserted, 3–20 cm long; eastern Brazil, Bolivia, Paraguay, Uruguay, Chile, and Argentina ..... 13

13(12). Robust plants leaning on vegetation; leaf blades 10–22 cm long, 1–2.2 cm wide; spikelets glabrous, (1.9–)2.4–3.2 mm long; inflorescence 9–21 cm long, glandular; foliar dimorphism absent ..... 30. *P. stigmosum*

13. Caespitose or decumbent perennials not leaning on vegetation; leaf blades 1–9(–15) cm long, 0.2–1.4(–2) cm wide; spikelets hirsute to glabrous, when glabrous 1.9–2.3(–2.6) mm long; inflorescences 2–10 cm long, the axis glandular or eglandular; foliar dimorphism present ..... 25. *P. sabulorum*

14(9). Plants branching only at the base, with short internodes and basal leaves numerous in a rosette ..... 15

14. Plants normally branching above the base,

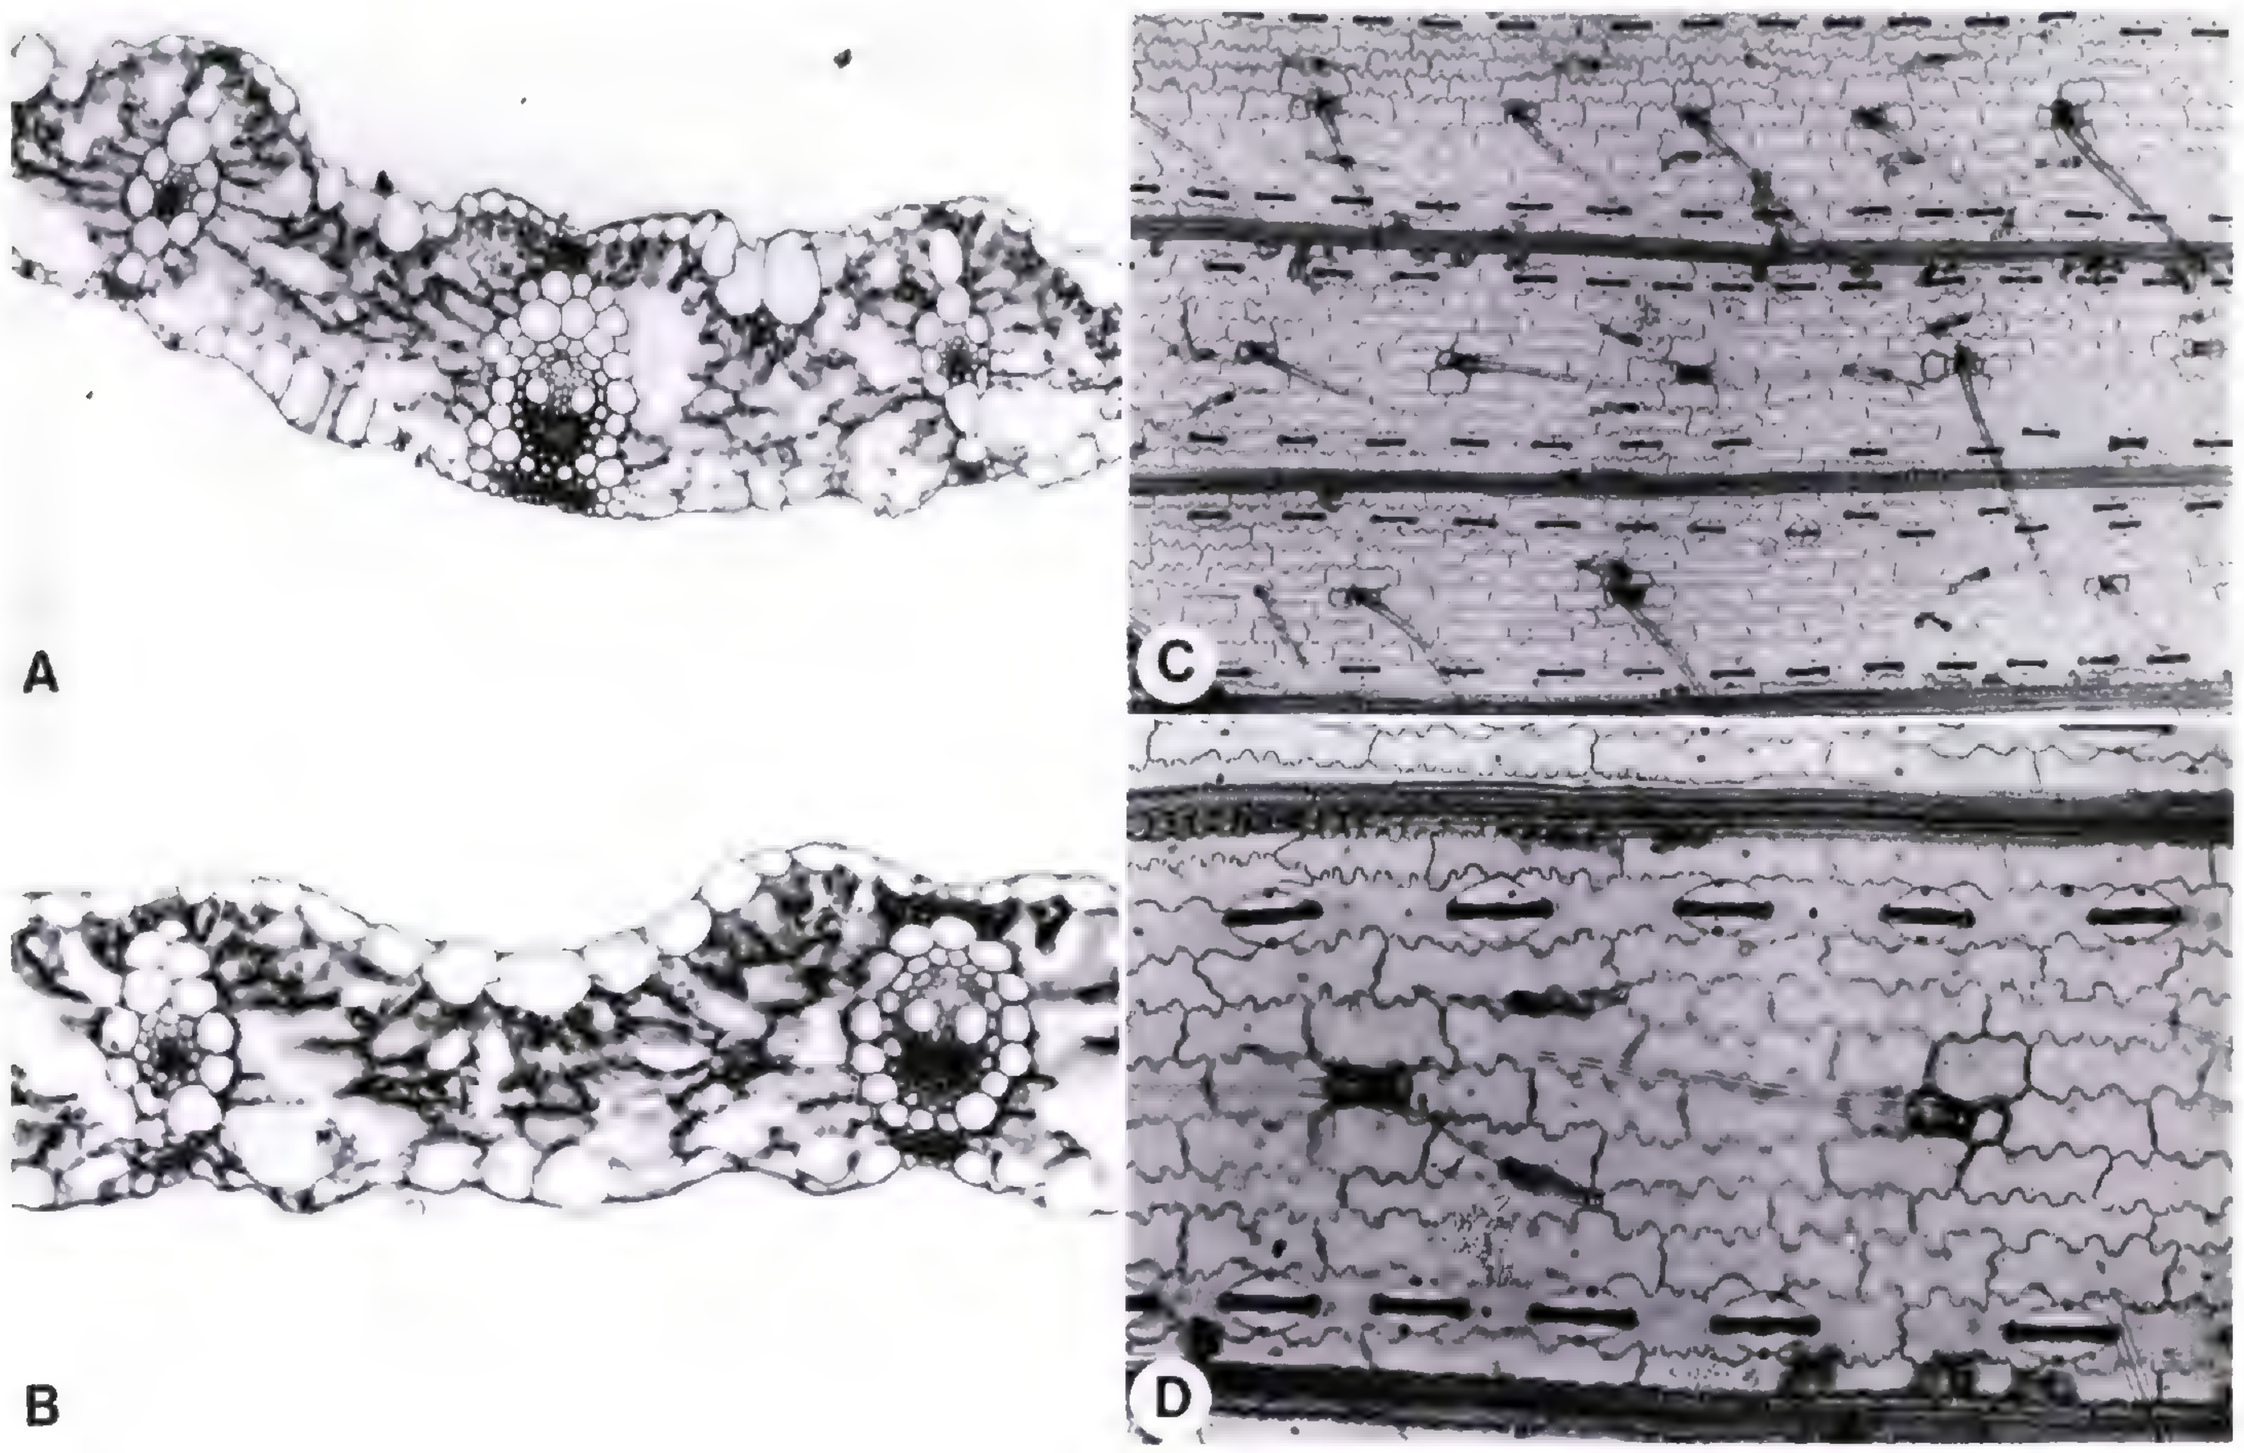

FIGURE 21. Leaf blade anatomy of *Panicum boscii*. A, B. Transectional anatomy.—A. Midrib showing slight keel development due to presence of additional parenchyma cells associated with the median vascular bundle.—B. Widely spaced vascular bundles and very diffuse chlorenchyma tissue. C, D. Abaxial epidermis.—C. Epidermal pattern showing narrow costal zones, wide intercostal zones, stomatal files, and macrohairs.—D. Detail of macrohairs and their associated basal cells, long, fingerlike microhairs, low-triangular subsidiary cells, and rectangular intercostal long cells with sinuous walls (A–D, based on *Davidse 30822*; A ×250; C ×160; B, D ×400).

with internodes elongated and basal leaves not in a rosette ..... 17

15(14). Blades linear, length : width ratio 10–30:1, with scabrous margins; caryopsis black ..... 14. *P. ensifolium*

15. Blades lanceolate to linear-lanceolate, length : width ratio 3–10:1, with long-ciliate margins; caryopsis brownish ..... 16

16(15). Spikelets 1–1.7 mm long, glabrous or puberulous; upper anthecium 1–1.4 mm long; sheaths and blades glabrous to sparsely pilose ..... 32. *P. strigosum*

16. Spikelets 2–2.7 mm long, short-hirsute; upper anthecium 1.8–2.3 mm long; sheaths and blades densely pilose with long papillose-pilose hairs ..... 18. *P. laxiflorum*

17(14). Spikelets obovoid; lower glume 1/5–1/3(–1/2) the length of the spikelet ..... 18

17. Spikelets ellipsoid; lower glume (1/4–)1/2–1/3 the length of the spikelet ..... 24

18(17). Pseudoligule present ..... 2. *P. acuminatum*

18. Pseudoligule absent ..... 19

19(18). Blades linear, length : width ratio 10–20:1; lower palea absent; inflorescences contracted, few-flowered ..... 1. *P. aciculare*

19. Blades ovate-lanceolate to lanceolate or linear-lanceolate, length : width ratio 3–10:1; lower palea present; inflorescences lax, few- to many-flowered ..... 20

20(19). Viscid glandular band present just below the nodes ..... 28. *P. scoparium*

20. Glandular band absent below the nodes ..... 21

21(20). Blades 1–7 cm long, 0.2–0.5(–1.2) mm wide; inflorescences few-flowered, 1–8 cm long, 1–3 cm wide ..... 22

21. Blades 2.5–10(–16) cm long, 0.5–1.7 cm wide; inflorescences multiflowered, (2–)5–22 cm long, 3.5–10 cm wide ..... 23

22(21). Blades narrowed at base; sheaths, nodes, and internodes glabrous to short-pilose; spikelets 0.6–1 mm wide; lower glume 1/4–1/3 the length of the spikelet ..... 12. *P. dichotomum*

22. Blades subcordate; sheaths, nodes, and internodes pilose; spikelets 1.1–1.3 mm wide; lower glume 1/4–1/2 the length of the spikelet ..... 23. *P. portoricense*

23(21). Spikelets 1–1.8 mm long; lower glume 1/3 the length of the spikelet, occasionally 1/4–1/2; axis of the panicles glabrous and glandular; blades glabrous ..... 29. *P. sphaerocarpon*

23. Spikelets (2.1–)2.3–3.2 mm long; lower glume 1/4–1/2 the length of the spikelet; axis of the panicles hispid, occasionally glabrous, with or without glands; blades with papillose-pilose hairs ..... 13. *P. divergens*

24(17). Blades clasping the culm, cordate, the length : width ratio 3–5(–7):1 ..... 25

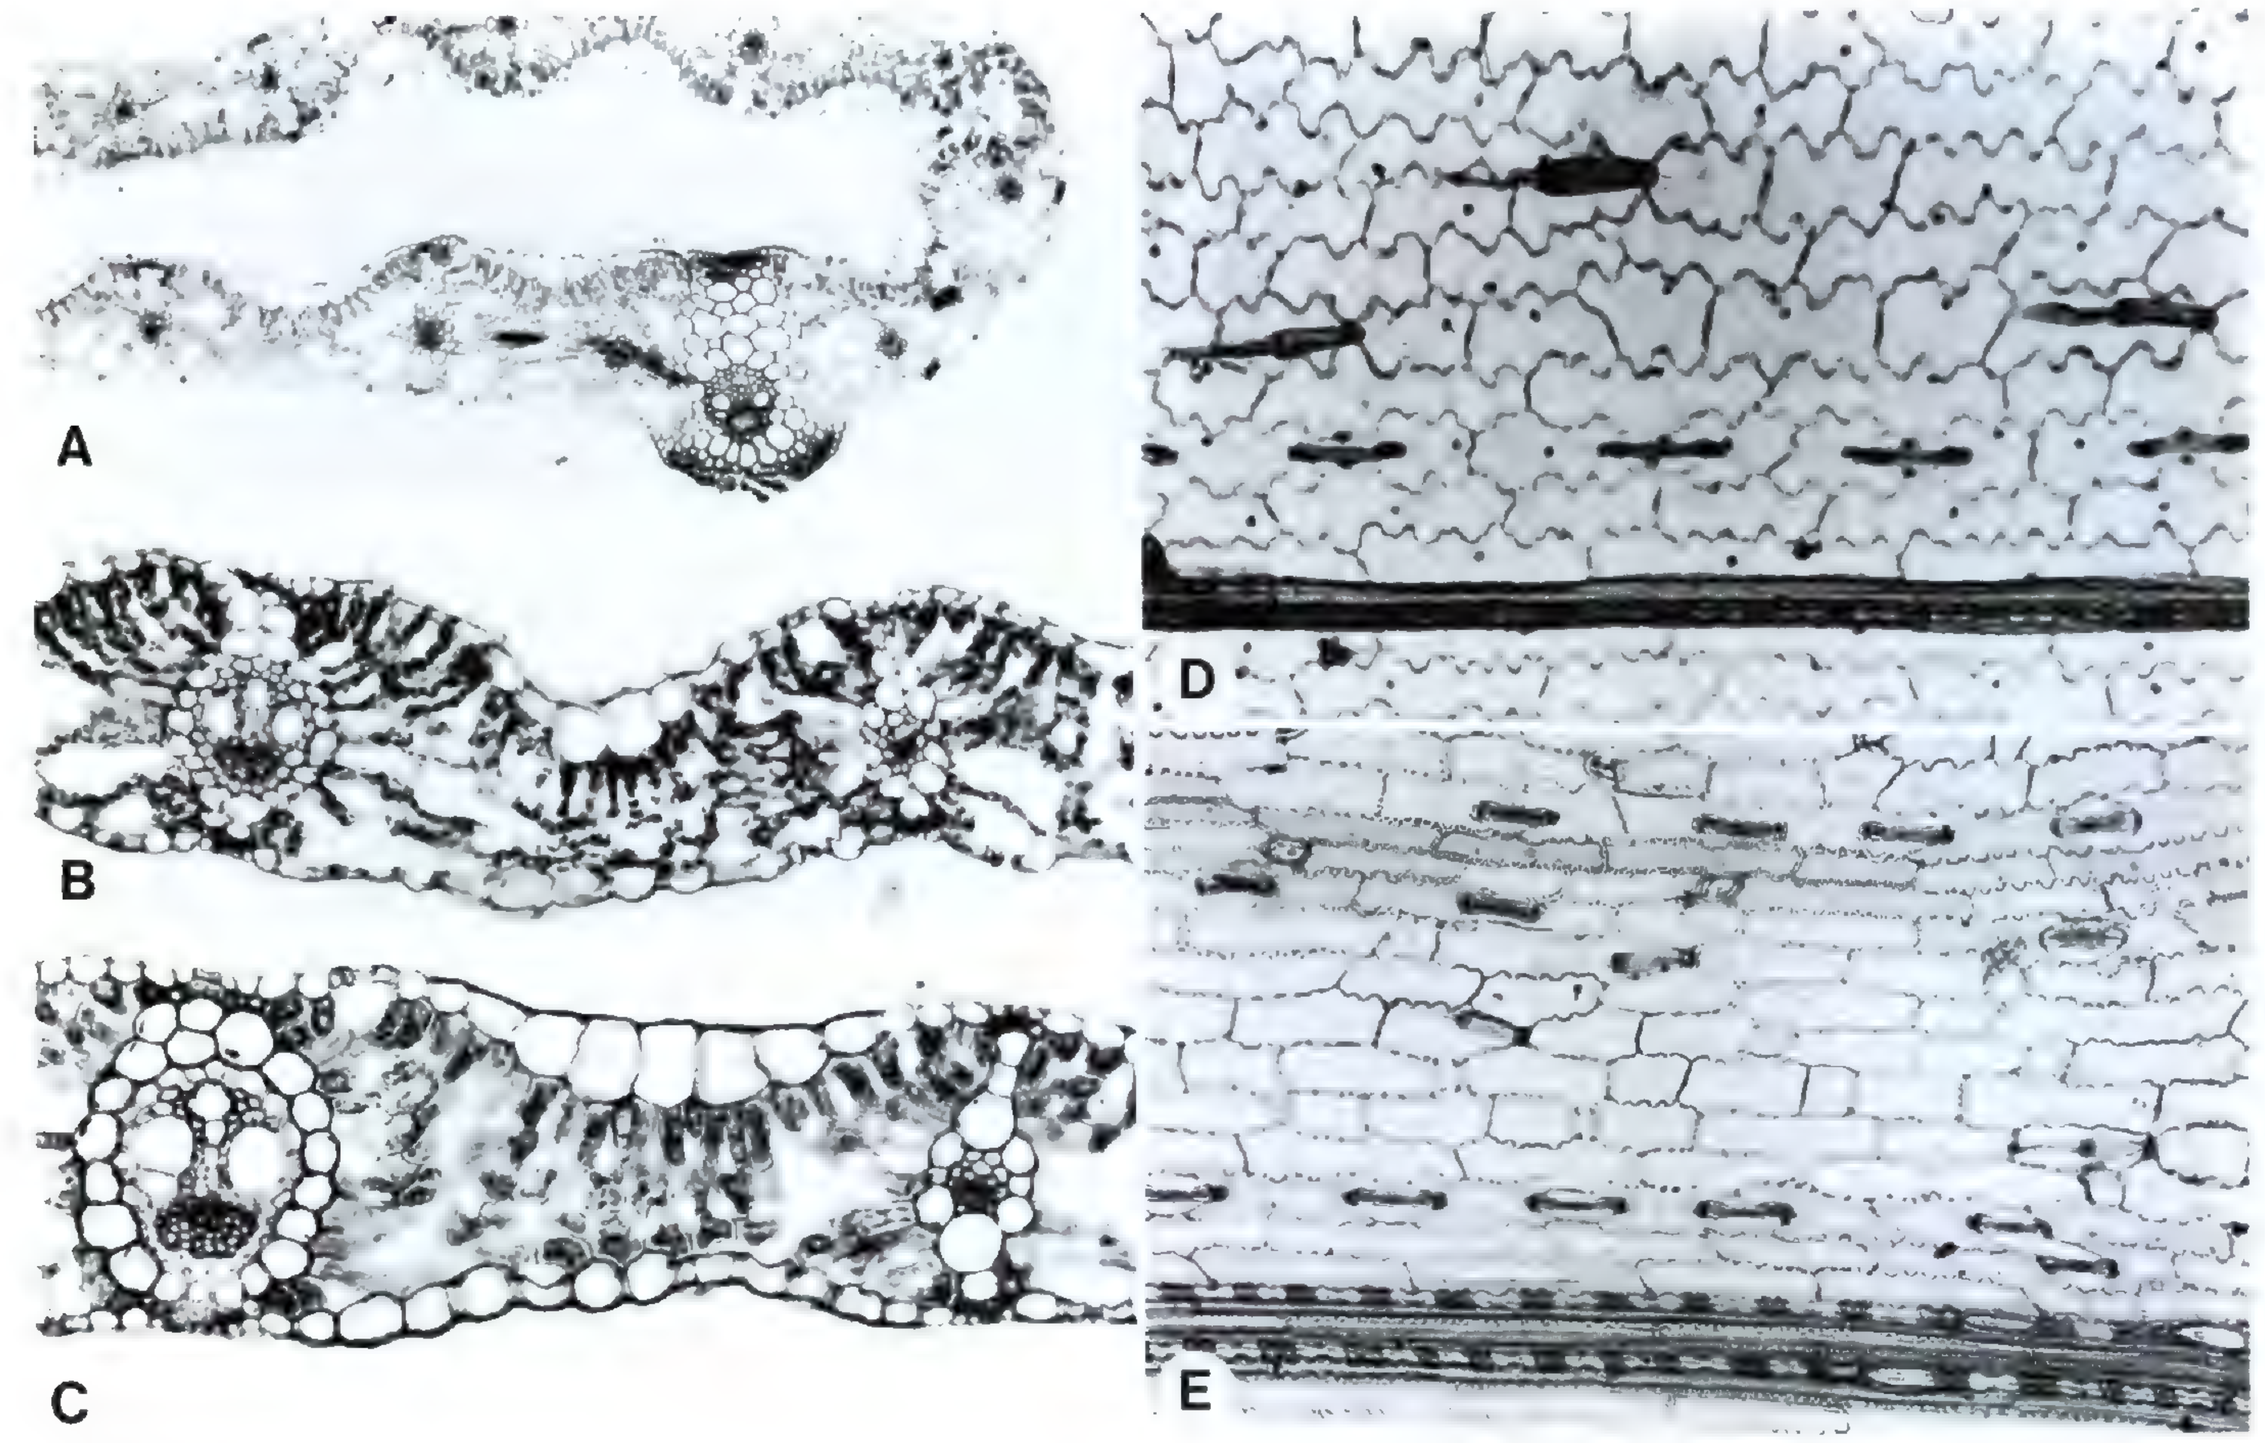

FIGURE 22. Leaf anatomy of *Panicum clandestinum*. A–C. Anatomy in cross section.—A. Central keel including a single vascular bundle.—B. Detail of diffuse mesophyll and short biseriate bundle sheath extensions.—C. Detail of spongy and palisade mesophyll and intercellular air spaces; note absence of extension on first-order bundle. D, E. Abaxial epidermis.—D. Long cells rectangular with very flexuous walls, large bicellular microhairs, and silica bodies irregularly dumbbell-shaped to nodular.—E. Thicker cuticle with less undulating long cell walls and wider costal zones; note microhairs, which are at least twice as long as the stomata (A, B, C, based on *Davidse 30816*, MO; D, E, based on *Davidse 30818*, MO; A ×100; B ×250; C, D, E ×400).

24. Blades not clasping the culm, narrowed to subcordate, the length:width ratio 10–30:1 ..... 34
25(24). Upper glume and lower lemma 5(–7)-nerved, the nerves inconspicuous; lower lemma inflated at base ..... 26. *P. sciurotis*
25. Upper glume and lower lemma 7–9(–11)-nerved, with manifest nerves; lower lemma not inflated at base ..... 26
26(25). Inflorescences few-flowered, 1–2.5(–3) cm long; blades overlapping, 1–3 cm long, 0.3–0.6 cm wide ..... 10. *P. cumbucana*
26. Inflorescences multiflowered, 2.5–12 cm long; blades not overlapping, 2–12 cm long, 0.5–2 cm wide ..... 27
27(26). Pseudoligule manifest with long whitish hairs 28
27. Pseudoligule absent ..... 29
28(27). Spikelets 2.2–2.8 mm long ..... 36. *P. umbonulatum*
28. Spikelets 1.5–2(–2.2) mm long ..... 37. *P. viscidellum*
29(27). Spikelets 1.5–2.5 mm long, without a manifest stipe between the lower and upper glume ..... 30
29. Spikelets 2.2–3.3 mm long, with a stipe between the lower and upper glume ..... 32
30(29). Spikelets short-hispid, 1.5–1.9 mm long; inflorescences 2.5–9 cm long; lower palea 0.7–1 mm long; main axis of the inflorescence densely hirsute ..... 27. *P. sciurotoides*
30. Spikelets glabrous, 1.7–2.5 mm long; inflorescences 10–15 cm long; main axis glabrous or short, sparsely pilose ..... 31
31(30). Blades amplexicaulous, ovate-lanceolate, 1.5–3 cm wide, velutinous; upper anthecium 2.2 mm long ..... 21. *P. peristypum*
31. Blades not amplexicaulous, linear-lanceolate, 0.5–1.3 cm wide, hispid or glabrous; upper anthecium 1.6–1.9 mm long ..... 4. *P. aequivaginatum*
32(29). Blades with margins cartilaginous and covered with manifest cilia ..... 31. *P. stipiflorum*
32. Blades without cartilaginous margins and without cilia on the upper portions of the margins ..... 33
33(32). Lower glume ½–¾ the length of the spikelet; inflorescences 3–6(–10) cm long; Ecuador, Peru, Venezuela, Brazil ..... 24. *P. pycnoclados*
33. Lower glume ¼–⅔ the length of the spikelet; inflorescences (5–)10–22 cm long; United States, Mexico, Honduras ..... 13. *P. divergens*
34(24). Lower glume ¼–½ the length of the spikelet ..... 35
34. Lower glume ¾–⅘ the length of the spikelet ..... 42
35(34). Pseudoligule present ..... 2. *P. acuminatum*

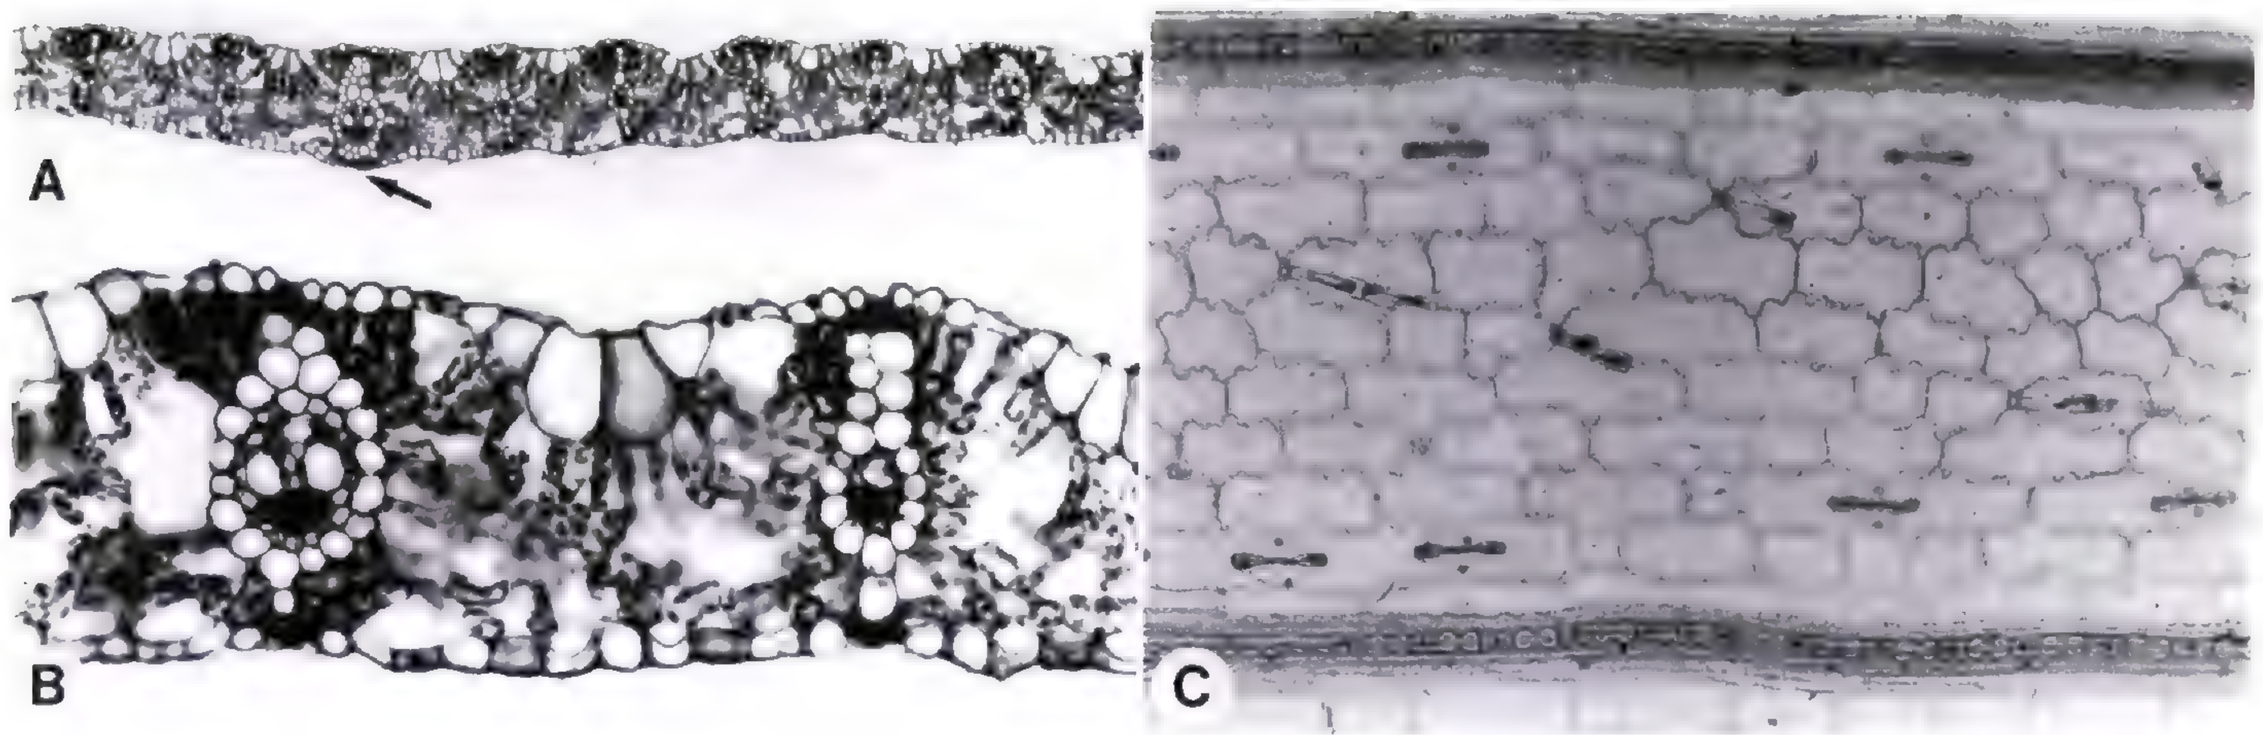

FIGURE 23. Leaf blade anatomy of *Panicum oligosanthes*. A, B. Transectional anatomy.—A. Central part of expanded lamina showing median vascular bundle (arrowed).—B. Detail of diffuse mesophyll and biseriate bundle sheath extensions.—C. Abaxial epidermis with dumbbell-shaped costal silica bodies, low triangular subsidiary cells, and bicellular microhairs; macrohairs absent (A–C, based on *Davidse 30819*, MO; A ×100; B, C ×400).

35. Pseudoligule absent ..... 36
36(35). Lower palea absent; inflorescences contracted, few-flowered; blades linear ..... 1. *P. aciculare*
36. Lower palea present; inflorescences lax, multiflowered; blades lanceolate to linear-lanceolate ..... 37
37(36). Plants densely hispid; spikelets hirsute ..... 38
37. Plants sparsely pilose or glabrous; spikelets short-hispid or glabrous ..... 39
38(37). Blades lanceolate, 3–15 cm long, 0.2–0.8(–1) cm wide, flat, the margins ciliate; spikelets 2–2.7 mm long; lower glume ⅓–½ the length of the spikelet; eastern United States to Costa Rica and the West Indies ..... 18. *P. laxiflorum*
38. Blades linear-lanceolate, 4–6 cm long, 0.2 cm wide, the margins involute, scabrous; spikelets 2–2.3 mm long; lower glume ½ or more the length of the spikelet; Brazil ..... 6. *P. cabrerae*
39(37). Blades 4–6 cm long, 0.3–0.5 cm wide; plants with manifest glands on sheaths, blades and axis of the panicles; panicles 5–7 cm long ..... 3. *P. adenorhachis*
39. Blades 3.5–12(–16) cm long, 0.2–1.3(–1.5) cm wide; plants without glands, occasionally present on the axis of the panicles; panicles 3–22 cm long ..... 40
40(39). Spikelets glabrous, 1.7–2.5 mm long; Venezuela, Guyana, and Brazil ..... 4. *P. aequivaginatum*
40. Spikelets pilose, (2.1–)2.3–4.1 mm long; United States, Mexico, and Honduras ..... 41
41(40). Spikelets papillose-pilose, 3.3–4.1 mm long ..... 19. *P. pedicellatum*
41. Spikelets sparsely pilose, (2.1–)2.3–3.2 mm long ..... 13. *P. divergens*
42(34). Spikelets with a stipe between the lower and upper glume ..... 43
42. Spikelets without a stipe between the lower and upper glume ..... 44
43(42). Spikelets glabrous, 2.2–2.7 mm long; lower glume 1(–3)-nerved; panicles lax, blades regularly spaced on the culms 9. *P. cucaense*
43. Spikelets hirsute, 2.8–3.2 mm long; lower glume 5–7-nerved; panicles contracted, blades congested on the culms ..... 8. *P. congestum*
44(42). Culms 10–25 cm tall; blades 2–5 cm long, 0.1–0.3 cm wide; panicles 2–4 cm long, spikelets glabrous, 2.4–2.6 mm long ..... 22. *P. petropolitanum*
44. Culms 50–1,000 cm tall; blades 4–32 cm long, 0.3–3.2 cm wide; panicles 4–45 cm long, spikelets pilose or glabrous, 2.6–4.2 mm long ..... 45
45(44). Lower palea absent; blades 18–32 cm long, 1.2–3.2 cm wide, pseudopetiolate; panicles 30–45 cm long ..... 20. *P. penicillatum*
45. Lower palea present; blades 4–12 cm long, 0.3–1 cm wide; panicles 4–16 cm long ..... 46
46(45). Spikelets hispid, 2.6–3.1 mm long; upper glume and lower lemma 7-nerved; blades linear lanceolate, 4–5(–12) cm long, 0.3(–1) cm wide, peduncle and main axis hirsute ..... 16. *P. heliophilum*
46. Spikelets glabrous to sparsely pilose between the nerves, 3.3 mm long; upper glume and lower lemma 9-nerved; blades linear-lanceolate, 8–12 cm long, 0.7–1 cm wide, peduncle and main axis glabrous ..... 5. *P. assurgens*

1. **Panicum aciculare** Desv. ex Poiret, Encycl. Suppl. 4: 274. 1816. *Dichanthelium aciculare* (Desv. ex Poiret) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1116. 1978. TYPE: "Habitat in India Orientali" (holotype, P; fragment, US 2808908).

Plants perennial, with or without a basal rosette of broader leaves. *Culms* erect to decumbent and geniculate at base, then erect, freely branching, 10–30(–65) cm tall, internodes hollow, terete, densely covered with short hairs, greenish to purplish, nodes compressed, brownish, pilose to glabrous. *Sheaths* shorter or longer than the inter-

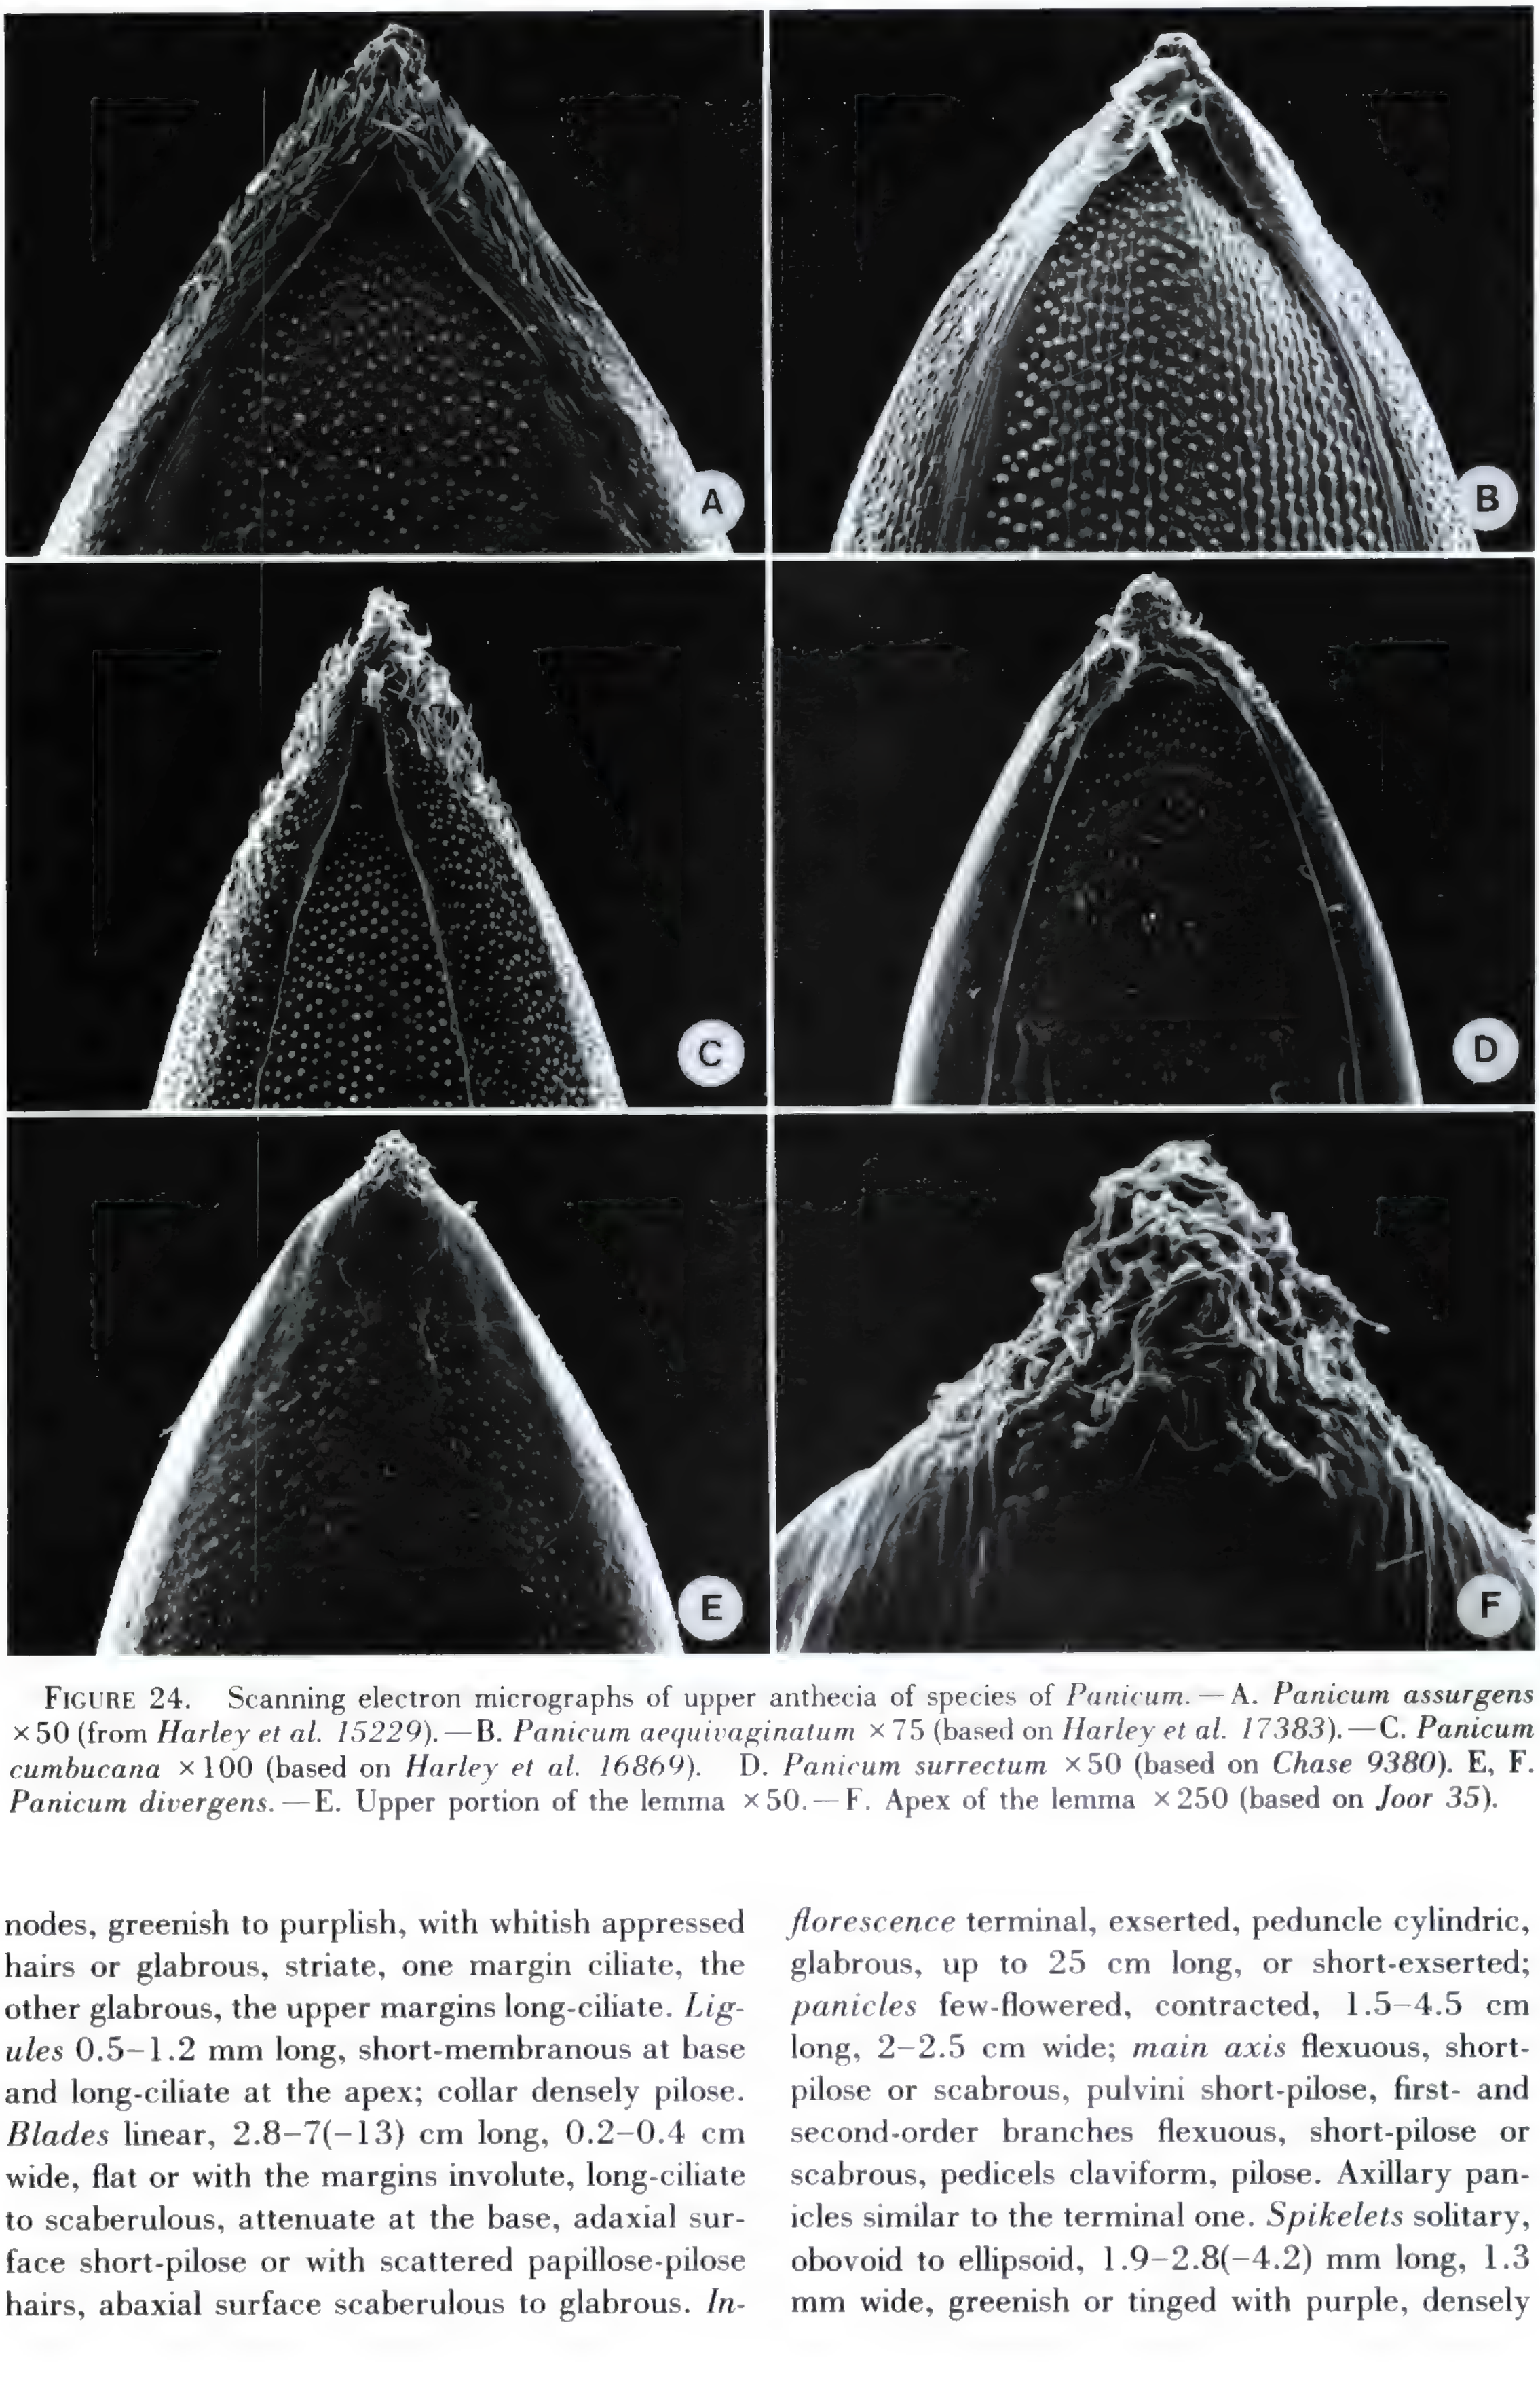

FIGURE 24. Scanning electron micrographs of upper anthecia of species of *Panicum*.—A. *Panicum assurgens* ×50 (from *Harley et al. 15229*).—B. *Panicum aequivaginatum* ×75 (based on *Harley et al. 17383*).—C. *Panicum cumbucana* ×100 (based on *Harley et al. 16869*). D. *Panicum surrectum* ×50 (based on *Chase 9380*). E, F. *Panicum divergens*.—E. Upper portion of the lemma ×50.—F. Apex of the lemma ×250 (based on *Joor 35*).

nodes, greenish to purplish, with whitish appressed hairs or glabrous, striate, one margin ciliate, the other glabrous, the upper margins long-ciliate. *Ligules* 0.5–1.2 mm long, short-membranous at base and long-ciliate at the apex; collar densely pilose. *Blades* linear, 2.8–7(–13) cm long, 0.2–0.4 cm wide, flat or with the margins involute, long-ciliate to scaberulous, attenuate at the base, adaxial surface short-pilose or with scattered papillose-pilose hairs, abaxial surface scaberulous to glabrous. *Inflorescence* terminal, exserted, peduncle cylindric, glabrous, up to 25 cm long, or short-exserted; *panicles* few-flowered, contracted, 1.5–4.5 cm long, 2–2.5 cm wide; *main axis* flexuous, short-pilose or scabrous, pulvini short-pilose, first- and second-order branches flexuous, short-pilose or scabrous, pedicels claviform, pilose. Axillary panicles similar to the terminal one. *Spikelets* solitary, obovoid to ellipsoid, 1.9–2.8(–4.2) mm long, 1.3 mm wide, greenish or tinged with purple, densely

FIGURE 25. Distribution of *Panicum aciculare* var. *aciculare*, *P. congestum*, *P. assurgens*, *P. aequivaginatum*, *P. adenorhachis*, *P. aciculare* var. *arenicoloides*, and *P. penicillatum*.

pilose or glabrescent. *Lower glume* ovate, 1.3 mm long, ⅓–½ the length of the spikelet, acute to truncate, nerveless to 3-nerved, with a small internode between the lower and upper glume. *Upper glume* ovate, obtuse, 7-nerved, hispid on the abaxial surface. *Lower lemma* 7-nerved, acute. *Lower palea* absent; lower flower absent. *Upper anthecium* obovoid, 1.8–2.1 mm long, 1.2 mm wide, pale, shiny, pilose toward the apex of the lemma, short-apiculate, lemma 7-nerved. *Caryopsis* obovoid, brownish, 1.1–1.3 mm long, 1.1 mm wide, hilum punctiform, embryo less than half the length of the caryopsis.

*Distribution and ecology:* southern United States, Mexico, Mesoamerica, the West Indies, Colombia, and Venezuela, at edge of forests or in open, wet, and sandy places between sea level and 2,400 m.

Although Poiret mentioned in the original description that the species was from "India Orientali," it was obviously collected in the West Indies.

KEY TO THE VARIETIES

1. Spikelets 1.9–2.8 mm long, without a manifest internode between the lower and upper glume ..... 1a. var. *aciculare*
1. Spikelets 2.8–3.3(–4.2) mm long, with an internode 0.3–0.6 mm long between the lower and upper glume ..... 1b. var. *arenicoloides*

FIGURE 32. Distribution of *Panicum sabulorum* var. *cordatum*, *P. sabulorum* var. *polycladum*, and *P. sabulorum* var. *sabulorum*.

A sample of five specimens from both North America and South America was studied anatomically. The anatomical variation exhibited by the specimens originating from either continent is no greater than the variation observed between specimens from the same continent. The transectional anatomy clearly shows this trend. Only two of the specimens from the United States have a slightly differentiated midrib (Fig. 3A), whereas the other two North American specimens, as well as the South American specimens, all only have median vascular bundles (Fig. 2A). The semiradiate nature of the chlorenchyma tissue arrangement and bundle sheath extensions are consistent features of all the specimens.

*Panicum acuminatum* is the only species studied in which the anatomy of the basal rosette leaves was compared with that of the upper culm leaves. This comparison indicates that the rosette leaves lack adaxial ribs and furrows and have a denser mesophyll than the upper leaves (Fig. 4).

**2b. Panicum acuminatum** var. **longiligulatum** (Nash) Lelong, Brittonia 36: 270. 1984. *Panicum longiligulatum* Nash, Bull. Torrey Bot. Club 26: 574. 1899. *Dichanthelium acuminatum* (Sw.) ESTELI: along new road from Hwy. 1 (at km 135.5 and ca. 10.6 km W of bridge at La Trinidad) to San Nicolás, ca. 9.5 km from Hwy. 1, 1,200–1,400 m; pine-oak forest, *Stevens & Montiel 14796, 17972* (MO). NUEVO SEGOVIA: 3 km N of Dipilto, pine forest on steep hills, 900 m, *Pohl & Davidse 12199* (MO).

**3. Panicum adenorhachis** Zuloaga & Morrone, Ann. Missouri Bot. Gard. 78: 154. 1991. TYPE: Brazil. Bahia: Mun. Rio de Contas, 6–10 km ao NO de Rio de Contas, na estrada para o Pico das Almas, 13°32′S, 41°53′W, 1,000 m, 21 July 1979, *Mori, King, dos Santos & Hage 12451a* (holotype, CEPEC; isotypes, MO, US). Figure 25.

Plants perennial; *culms* trailing, leaning over vegetation, many-noded, sparingly branched, internodes cylindric, hollow, glabrous, nodes brownish, short-pilose or glabrous. *Sheaths* striate, caducous, glabrous, covered with small glands, the margins long-ciliate; collar short-pilose. *Ligule* 0.2–0.6 mm long, a ciliate membrane. *Blades* narrowly lanceolate, 4–6 cm long, 0.3–0.5 cm wide, flat, subcordate, the adaxial surface scabrous, the abaxial surface glabrous and covered with small glands; margins long-ciliate with tuberculate hairs near base, otherwise scabrous. *Inflorescence* terminal, a lax, diffuse panicle 5–7 cm long, 4–5 cm wide, few-flowered; *main axis* flexuous and glandular, the nodes distant; first-order branches widely divergent, solitary at each node with scabrous and glandular axes and long-pilose axils; spikelets solitary and widely spaced; pedicels claviform, short-pilose. Axillary panicles similar to the terminal one. *Spikelets* narrowly ellipsoid, 2.7–3 mm long, 0.9 mm

wide, upper glume and lower lemma short-hispid and subequal, without a stipe between the lower and upper glume. *Lower glume* 0.7–0.8 mm long, less than ⅓ the length of the spikelet, acuminate, nerveless or 1-nerved, hyaline. *Upper glume* 9-nerved. *Lower lemma* 9-nerved. *Lower palea* lanceolate, 1.8 mm long, 0.4 mm wide, hyaline, ciliolate on the margins; lower flower absent. *Upper anthecium* narrowly ellipsoid, 2.3 mm long, 0.8 mm wide, stramineous, brownish at maturity, papillose with simple papillae in longitudinal rows; lemma short-mucronate and with small microhairs at the apex; rachilla prolonged beyond the upper anthecium as a short mucro. *Caryopsis* ellipsoid, brownish, 1.5 mm long, 0.7 mm wide; hilum punctiform, embryo less than half the length of the caryopsis.

*Distribution and ecology:* known only from Pico das Almas in Bahia, Brazil, growing in campos rupestres on rocky, humid soils, 1,000–1,850 m.

*Additional specimens examined.* BRAZIL. BAHIA: Alto do Pico das Almas, 1,850 m, 20 Feb. 1987, *Harley et al. 24460* (K); Mun. Rio de Contas, Pico das Almas, Vertente leste, subida do pico do Campo do Queiros, 13°32′S, 41°58′W, *Harley et al. 26437* (K, MO, SI).

Affinities of *P. adenorhachis* are discussed in Zuloaga & Morrone (1991).

**4. Panicum aequivaginatum** Swallen, Contr. U.S. Natl. Herb. 29: 271. 1949. TYPE: Brazil. Bahia: between Bom Gosto e Olivença, 15 Mar. 1943, *Fróes 19950* (holotype, US 1910768; photo of the holotype, K; isotype, US 2146782). Figures 5, 24B, 25.

*Panicum appressifolium* Swallen, Mem. New York Bot. Gard. 9: 258. 1957. TYPE: Guyana. Samwaraknatipu (Holi-tipu), Kamarang River, Wenamu Trail, 1,100 m, 10 Nov. 1951, *Maguire & Fanshawe 32564* (holotype, F 1449017; isotypes, K, NY, P, RB).

*Panicum belmonte* Renvoize, Kew Bull. 37: 325. 1982. TYPE: Brazil. Bahia: 24 km SW of Belmonte, on road to Itapebí, 24 Mar. 1974, *Harley et al. 17383* (holotype, CEPEC 10051; isotypes, K, MO, US 2955112).

*Panicum thinophilum* Renvoize, Kew Bull. 39: 180. 1984. TYPE: Brazil. Bahia: Mun. Salvador, Dunas do Abaeté, 17 Dec. 1976, *Araujo et al. 96* (holotype, CEPEC; isotypes, CEN, K).

Apparently annual, 20–100 cm tall. *Culms* decumbent, rooting and branching at the lower nodes, then erect; internodes hollow, 3.5–10.5 cm long, short-hispid or glabrous, nodes compressed, pilose with appressed whitish hairs. *Sheaths* 3–8.5 cm long, usually shorter than the internodes, hispid or glabrous, striate, the margins ciliate. *Ligules* 0.3–0.6 mm long, membranous, the apex ciliate; collar pilose with whitish hairs. *Blades* linear-lanceolate, 3.5–12 cm long, 0.5–1.3 cm wide, ascendent, hispid or glabrous, long-pilose toward the base on the adaxial surface, cordate to subcordate, acute, the margins scaberulous and ciliate, the midnerve conspicuous. *Inflorescences* exserted, a terminal, lax and diffuse panicle 10–15 cm long, 3–7 cm wide; *main axis* glabrous, flexuous, smooth, the pulvini short-pilose or glabrous, first-order branches alternate, divergent from the main axis and flexuous, pedicels smooth and glabrous, flexuous. *Spikelets* paired or solitary, ellipsoid, 1.7–2.5 mm long, 0.7 mm wide, glabrous, with a short, inconspicuous internode between the lower and upper glume. *Lower glume* ovate-acuminate, 0.9–1.3 mm long, ½ or less the length of the spikelet, glabrous, not embracing the upper glume, 3-nerved, the nerves either anastomosing or not toward the apex. *Upper glume* usually not covering the apex of the upper anthecium, 9-nerved, the nerves anastomosing or not toward the apex. *Lower lemma* glumiform, 9-nerved. *Lower palea* linear-lanceolate, small, hyaline, glabrous; lower flower absent. *Upper anthecium* ellipsoid, 1.6–1.9 mm long, 0.6 mm wide, with simple papillae, apiculate; stigmas whitish. *Caryopsis* ellipsoid, brownish, hilum punctiform, embryo ⅓ or less the length of the caryopsis.

*Distribution and ecology:* occurring in Venezuela, in the states of Bolívar and Amazonas, Guyana, and northern Brazil, from 900 to 2,000 m. Frequent in savannas or mountain slopes, in sandy soils in Venezuela; in Brazil it grows in sandy soils of campos rupestres and restingas.

*Additional specimens examined.* BRAZIL. BAHIA: El Salvador, coastal dunes 2 km N of town of Itapua, near sea level, *Plowman & Almeida 10045* (CEPEC, MO, US); Estrada de Bom Gosto a Olivença, *Fróes 19950* (US); Lençois, along BR 242, ca. 15 km NW of Lençois at km 225, *Mori & Boom 14257* (CEPEC, MO); camino de Maraú a Ubaitaba, 15 km de Maraú, *Zuloaga et al. 2469** (MO, RB, SI, US); margen da Rodovia Camacã-Canavieiras, 32 km W de Canavieiras, *Belém 1692* (CEPEC, IAN, NY, SI, UB, US); rodovia Brasília–Fortaleza, BR-242, 8 km da estrada para Lençois, campo rupestre, *Coradin et al. 6530* (CEN, K, MO, SP). RIO DE JANEIRO: restinga de Jacarepaguá, do lado NW da Pedra de Itaúna, *Sucre 5349* (RB, SI); Guanabara, estrada BR-6, *Hoehne 5991* (SI, SP); Rio de Janeiro, próximo ao Recreio dos Bandeirantes, *Hoehne 5789* (SI, SP). RORAIMA: Mt. Roraima, Philipps Camp, 5,200–6,000 ft., *Tate 281* (NY, US). GUYANA. Pakaraima Mountains, Mt. Aymatoi, *Maas et al. 5769* (K, MO, NY, US). VENEZUELA. AMAZONAS: Cerro de la Neblina, Río Yatua, along Cañón Grande E of Cumbre Camp, 1,100 m, *Maguire et al. 42193* (NY, P, US, VEN). BOLIVAR: La Gran Sabana, km 167, S of El Dorado along highway to Santa Elena, 24 km S of La

Ciudadela, *Davidse 4762* (MO, SI, VEN); la Gran Sabana, a 2 km al sur de La Ciudadela, 5°47′N, 61°25′W, 1,300 m, *Zuloaga et al. 4408* (MO, SI, VEN); a 3 km al N de Kamoirán, Gran Sabana, 5°35′N, 61°20′W, 1,100 m, *Zuloaga et al. 4470** (MO, SI, VEN); Uaipán-tepui, near the top of Salto Hacha on plateau at S foot of the peak of Uaipán, *Koyama & Agostini 7391* (VEN); Mun. Gran Sabana, inmediaciones del Monumento al Soldado Pionero, 38.5 km al S del sitio "Piedra de la Virgen," *Huber et al. 12908* (MYF, SI).

This species is related to *P. pycnoclados* and *P. sciurotoides*, but has spikelets intermediate in size between both species. It also differs from *P. sciurotoides* in that the latter species has cordate and amplexicaulous leaves, the main inflorescence axis hirsute, and usually pilose spikelets. *Panicum pycnoclados* differs from *P. aequivaginatum* by its cordate and amplexicaulous, asymmetrical leaf blades, smaller inflorescences, 3–6(–10) cm long, spikelets 2.2–3(–3.3) mm long with a conspicuous internode between the lower and upper glume; lower glume ½–¾ the length of the spikelet.

*Panicum thinophilum* only represents a depauperate variant of *P. aequivaginatum* with profusely branching culms and axillary panicles.

**5. Panicum assurgens** Renvoize, Kew Bull. 37: 325. 1982. TYPE: Brazil. Bahia: on road to Abaira, ca. 8 km to N of the town of Rio de Contas, 13°33′S, 41°47′W, 1,000 m, 18 Jan. 1972, *Harley et al. 15229* (holotype, CEPEC; isotypes, K, MO, NY, US 2955120). Figures 24A, 25.

Probably perennial. *Culms* leaning on adjacent vegetation, to 2 m long, internodes 4–10 cm long, cylindric, glabrous; nodes glabrous, compressed. *Sheaths* 3–7 cm long, shorter than the internodes, striate, sparsely hispid, with one margin ciliate, the other glabrous. *Ligules* membranous, the membranous portion 0.2 mm long, short-pilose at the apex with hairs nearly 0.1 mm long; collar shortly pilose. *Blades* linear-lanceolate, 8–12 cm long, 0.7–1 cm wide, flat, sparsely hispid, attenuate at base and with the apex acute, the margins finely scabrous. *Inflorescences* terminal, long-exserted, lax, diffuse, 12–15 cm long, 7–10 cm wide, first-order branches whorled toward the base of the inflorescence, otherwise subopposite or alternate, axis of the branches flexuous, glabrous, eglandular, pulvini glabrous, pedicels glabrous. *Spikelets* ellipsoid, 3.3 mm long, 1.2 mm wide, glabrous or sparsely pilose between the nerves, greenish, without a conspicuous internode between the lower and upper glume, upper glume and lower lemma subequal. *Lower glume* ovate-lanceolate, 2.1–2.7 mm long, ¾–⅘ the length of the spikelet, not embracing the upper glume at its base, glabrous, 3-nerved, the nerves anastomosing toward the apex. *Upper glume* 2.7 mm long, as long as the lower lemma or a little shorter and not covering the apex of the upper anthecium, 9-nerved. *Lower lemma* 9-nerved, 2.7–2.9 mm long. *Lower palea* lanceolate, 2 mm long, 0.3 mm wide, hyaline, sparsely pilose; lower flower absent. *Upper anthecium* ellipsoid, 2.7 mm long, 1 mm wide, papillose, upper lemma slightly apiculate, the upper margins indurate, sparsely pilose at the apex. *Caryopsis* ellipsoid, 2.1 mm long, 0.9 mm wide; hilum punctiform, embryo ⅓ or less the length of the caryopsis.

*Distribution and ecology:* known only from the type collection, where it grows at edges of forests in the state of Bahia, Brazil, at approximately 1,000 m.

**6. Panicum cabrerae** Zuloaga & Morrone, Ann. Missouri Bot. Gard. 78: 156. 1991. TYPE: Brazil. Bahia: Mun. Rio de Contas, Pico das Almas, a 18 km ao SNW de Rio de Contas, 13°33′S, 41°57′W, 1,600–1,850 m, 22 July 1979, *Mori, King, dos Santos & Hage 12475* (holotype, CEPEC; isotypes, MO, US). Figure 26.

Perennial. *Culms* ca. 50 cm tall, leaning on vegetation, sparingly branching, internodes cylindric, hollow, sparsely pilose with whitish hairs, nodes many, densely pilose with long whitish hairs. *Sheaths* striate, 1.5–2 cm long, longer than the internodes, long-hispid, the margins pilose with whitish hairs, more so toward the upper portion; auricles small, pilose; collar pilose. *Ligules* ciliate-membranous ca. 0.2 mm long. *Blades* linear-lanceolate, 4–6 cm long, 2 mm wide, attenuate at base, acuminate at apex, the margins involute, densely pilose and scabrous, with long, whitish hairs on both surfaces, deciduous at maturity. *Inflorescence* terminal, a lax, diffuse panicle 4.5–6 cm long, 3.5–6 cm wide, peduncles hispid, 5–7 cm long; *main axis* cylindric, densely hispid on the lower portion, otherwise glabrous, the nodes distant; first-order branches alternate, divergent and reflexed, hispid basally, glabrous distally, pulvini pilose to glabrous; pedicels claviform, smooth, glabrous, 2–9 mm long. *Spikelets* solitary, ellipsoid, 2–2.3 mm long, 0.8–0.9 mm wide, plano-convex, hirsute, with whitish hairs on the glumes and lower lemma. *Lower glume* 1.1–1.3 mm long, ½ or more the length of the spikelet, 3-nerved, acute, a small stipe present between the lower and upper glume. *Upper glume* 9-nerved, nerves anastomosing toward the apex.

*Lower lemma* 9-nerved. *Lower palea* lanceolate, 1.5–1.8 mm long, 0.3 mm wide, glabrous, truncate, hyaline; lower flower absent. *Upper anthecium* ellipsoid, 1.9 mm long, 0.7 mm wide, papillose, with simple papillae all over its surface, glabrous or with a few microhairs toward the apiculate apex; lodicules truncate, ca. 0.2 mm long, anthers 3, 1.2 mm long; rachilla prolonged or not beyond the upper anthecium as a short mucro. *Caryopsis* obovoid, 1.1 mm long; hilum oblong, embryo less than ⅓ the length of the caryopsis.

*Distribution and ecology:* growing in campos rupestres, in the state of Bahia, Brazil.

*Additional specimens examined.* BRAZIL. BAHIA: Mun. Rio de Contas, Pico das Almas, vertente leste, subida do pico do campo N do Queiroz, 13°32′S, 41°58′W, 1,600 m, *Harley, Giulietti, Stannard & Hind 26320* (K).

*Panicum cabrerae* shares with *P. aciculare* a similar vegetative pattern, with linear, pilose blades, small panicles and spikelets of more or less the same size. *Panicum cabrerae* differs from *P. aciculare* in that the latter species has obovoid spikelets with the upper glume and lower lemma 7-nerved, and the lower palea absent; also, *P. aciculare* is found from the southern United States to Colombia and Venezuela.

7. **Panicum caparaoense** Zuloaga & Morrone, sp. nov. TYPE: Brazil. Espírito Santo: Mun. Muñiz Freire, Rodovia BR-262, 1,000 m, 21 July 1982, *Hatschbach & Guimaraes 45170* (holotype, K; isotype, MBM not seen). Figure 36.

Ligula membranacea 0.8 mm longa; lamina lanceolata 14–21 cm longa, 1 cm lata, complanata; paniculae laxae, diffusae, 23 cm longae; spiculae modice ellipsoideae, 5.9–6.8 mm longae, glabrae; gluma inferior ⅔ spiculae longitudine, acuminata, 5-nervia; gluma superior 13–15 nervia; lemma inferius 13–15-nervium, palea inferior lanceolata, 5.5 mm longa, 1.2 mm lata, margine longe pilosa; anthoecium longe ellipsoideum, 5.2 mm longum, 1.6 mm latum, papillis simplicibus praeditum, necnon lemmate marginibus superioribus cristato ac piloso.

Plants perennial?, the base not seen; internodes hollow, cylindric, glabrous, nodes dark, compressed, glabrous. *Sheaths* striate, one margin ciliate, otherwise glabrous. *Ligules* membranous at the base and laciniate at the apex, 0.8 mm long, brownish, surmounted by long whitish hairs on the adaxial surface of the blade; collar densely and shortly pilose. *Blades* lanceolate, 14–21 cm long, 1 cm wide, flat, attenuate at the base and apex, the adaxial surface with scattered, appressed hairs, the abaxial surface glabrous, commonly purplish, the margins ciliate. *Inflorescence* terminal, exserted, peduncle terete, ca. 22 cm long, glabrous; panicles lax, diffuse, 23 cm long, ca. 20 cm wide; *main axis* terete, glabrous, the pulvini brownish, glabrous; first-order branches alternate, divergent, the axis of the branches and pedicels smooth, glabrous. *Spikelets* solitary, narrowly ellipsoid, 5.9–6.8 mm long, glabrous. *Lower glume* 4.1 mm long, ⅔ the length of the spikelet, acuminate, 5-nerved, separated from the upper glume by a conspicuous internode. *Upper glume* scaberulous toward the apex, 13–15-nerved, the nerves anastomosing toward the apex. *Lower lemma* scaberulous toward the apex, 13–15-nerved, the nerves anastomosing toward the apex. *Lower palea* lanceolate, 5.5 mm long, 1.2 mm wide, hyaline, the margins long-pilose with whitish hairs; lower flower male, anthers ca. 3 mm long. *Upper anthecium* narrowly ellipsoid, 5.2 mm long, 1.6 mm wide, smooth, shiny, indurate, with simple papillae regularly distributed over the lemma and palea, lemma 9-nerved, crested and pilose on the upper margins, greenish at the apex, palea pilose on the upper margins; lodicules 2, conduplicate, 0.4 mm long; stamens 3, the anthers 3 mm long; styles free, stigma plumose; rachilla prolonged beyond the upper anthecium as a short mucro. *Caryopsis* unknown.

*Distribution and ecology:* known from the state of Espírito Santo in Brazil, where it grows in edge of forests.

*Paratype.* BRAZIL. ESPIRITO SANTO: Castelo, Braço do Sul, *Brade 19172* (US).

*Panicum caparaoense* is related to *P. itatiaiae* and *P. davidsei*. *Panicum itatiaiae* has spikelets 4.6–5 mm long, the lower palea glabrous or sparsely pilose, and the leaf blades subcordate. *Panicum davidsei* has spikelets 3–3.3 mm, lower flower absent, and upper anthecium glabrous or shortly pilose.

The specific epithet makes reference to the type locality of this new species, the Serra do Caparaó in Espírito Santo, Brazil.

8. **Panicum congestum** Renvoize, Kew Bull. 37: 329. 1984. TYPE: Brazil. Bahia: 22 km NW of Lagoinha, which is 5.5 km SW of Delfino, on side road to Minas do Mimoso, 980 m, 6 Mar. 1974, *Harley, Renvoize, Erskine, Brighton & Pinheiro 16869* (holotype, CEPEC 10082; isotypes, K, MO, NY, RB, US 2955113). Figure 25.

Caespitose perennial. *Culms* erect, freely branching at the upper nodes, 30–50 cm tall, rigid;

internodes elongated toward the base of the plant, terete, hollow, densely hirsute, nodes brownish, pilose. *Sheaths* persistent or deciduous, striate, densely hirsute, the margins membranous. *Ligules* membranous-ciliate, ca. 1 mm long, with whitish hairs; collar pilose. *Blades* linear-lanceolate, 1.5–5 cm long, 0.2–0.4 cm wide, congested on the culms, the margins involute, narrowed at base and acuminate at the apex, densely hirsute on both surfaces with rigid whitish hairs. *Inflorescences* with base included within the upper leaves, with a peduncle ca. 0.5 cm long; panicles 2 cm long or smaller, contracted, with only 2–3(–9) spikelets per panicle; *main axis* hirsute, flexuous, first-order branches short, the axis of the branches and pedicels densely hirsute. *Spikelets* solitary, ellipsoid, 2.8–3.2 mm long, 1 mm wide, hirsute, with short-papillose hairs, upper glume and lower lemma subequal or the upper glume a little shorter. *Lower glume* 2.2–2.6 mm long, ¾ or more the length of the spikelet, acute, 5–7-nerved, the nerves anastomosing toward the apex, with a conspicuous internode between the lower and upper glume. *Upper glume* 2.6 mm long, 9-nerved. *Lower lemma* 9-nerved, glumiform. *Lower palea* lanceolate, 1.7 mm long, 0.4 mm wide, hyaline, the margins ciliolate; lower flower absent. *Upper anthecium* ellipsoid, 2.4 mm long, 0.8 mm wide, papillose, with simple papillae regularly distributed over the lemma and palea, apiculate and pilose at the tip of the lemma, lemma 5-nerved; internodes conspicuous between the upper glume and the upper anthecium. *Caryopsis* ellipsoid, brownish, hilum oblong, embryo ⅓ the length of the caryopsis.

*Distribution and ecology:* known only from campos rupestres in the state of Bahia, Brazil, where it is found on sandstone rocks at approximately 1,000 m.

This species is distinguished by its densely hirsute and profusely branching culms, hirsute sheaths and blades, and few-flowered inflorescences that are short-exserted with the base included in the upper leaves.

**9. Panicum cucaense** Zuloaga & Morrone, Ann. Missouri Bot. Gard. 78: 158. 1991. TYPE: Brazil. Rio de Janeiro: Mun. Petrópolis, Morro do Cuca, entre Vale dos Videiras e Araras, campo de altitude, 1,600 m, 27 Jan. 1983, *Martinelli & Simonis 9011* (holotype, RB; isotypes, MO, SI). Figure 27.

Caespitose, shortly rhizomatous perennial. *Culms* 20–30 cm tall, many-noded, erect to geniculate-ascending and rooting at the lower nodes, freely branching; internodes 1–4 cm long, cylindric, striate, glabrous; nodes compressed, glabrous, brownish. *Sheaths* striate, ca. 1.2 cm long, longer than the internodes, strongly distichous, long-pilose on the distal portion, otherwise glabrous, one margin pilose with long, whitish hairs, the other one membranous. *Ligule* ciliate-membranous, the membranous portion ca. 0.1 mm long, the ciliate portion 0.4 mm long. *Blades* linear, 1.5–5.5 cm long, 0.1–0.2 cm wide, folded, attenuate toward the apex, pilose on the adaxial surface toward the ligule, otherwise glabrous, the borders scabrous. *Primary inflorescences* lax, diffuse, few-flowered, 2–3.5 cm long, 1.5–3.5 cm wide; peduncles to 6 cm long, glabrous; *main axis* striate, flexuous, glabrous, somewhat glandular, the branches alternate, divergent and widely spaced, glabrous, the axils of the branches pilose; pedicels glabrous, 1–6 mm long. *Secondary inflorescences* similar to the terminal one. *Spikelets* ellipsoid, 2.2–2.7 mm long, 0.8–0.9 mm wide, gaping at maturity, glabrous. *Lower glume* lanceolate, 1.5–1.9 mm long, ⅔–¾ the length of the spikelet, acuminate, 1(–3)-nerved, a small stipe present between the lower and upper glume. *Upper glume* and *lower lemma* subequal, 7–9-nerved, acute. *Lower palea* lanceolate, 1.7–1.9 mm long, 0.4–0.7 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* narrowly ellipsoid, 2.1–2.3 mm long, 0.7–0.8 mm wide, papillose, with simple papillae evenly distributed over the lemma and palea, apiculate, the apex scabrous, otherwise glabrous; lodicules ca. 0.2 mm long; stamens 3, anthers 1.2 mm long. *Caryopsis* ellipsoid, 1.4 mm long, 0.7 mm wide, brownish; hilum oblong; embryo less than half the length of the caryopsis.

*Distribution and ecology:* inhabiting open and dry habitats, in rocky, granitic soils of high-altitude campos of mountains in eastern Brazil, at 2,000–2,500 m.

*Additional specimens examined.* BRAZIL. RIO DE JANEIRO: Teresópolis, Serra dos Orgãos, Pedra do Sino, 2,100–2,170 m, Feb. 1953, *J. Vidal II-6467, II-6485* (R, SI); Mun. Petrópolis, Vale das Videiras, Morro do Cuca, 1,800 m, 17 Apr. 1976, *Martinelli 814* (RB); without locality, *Glaziou 13319* (W).

Affinities of *P. adenorhachis* are discussed in Zuloaga & Morrone (1991).

**10. Panicum cumbucana** Renvoize, Kew Bull. 37: 332. 1982. TYPE: Brazil. Bahia: by Rio Cumbuca, 3 km S of Mucugê, near site of small dam on road to Cascavel, 850 m, 4 Feb. 1974, *Harley, Renvoize, Erskine, Brighton*

*& Pinheiro 15930* (holotype, CEPEC 10042; isotypes, K, MO, NY, US 2955114). Figures 24C, 27.

Short-rhizomatous perennial. *Culms* long decumbent, then erect, to 35 cm tall, freely branching at the upper nodes, internodes 1–2.8 cm long, hispid, hollow, nodes hispid. *Sheaths* 1–2 cm long, usually shorter than the internodes, hispid or glabrous, one margin long-ciliate, the other short-pilose. *Ligules* 0.4–0.6 mm long, shortly membranous at the base, ciliate at the apex, arcuate; collar shortly pilose. *Blades* lanceolate, 1–3 cm long, 0.3–0.6 cm wide, rigid, ascending and slightly divergent from the culms, cordate and amplexicaulous, acute, glabrous or shortly and densely hispid on both surfaces, with or without long hairs toward the base on the adaxial surface, the margins scaberulous, long-ciliate toward the base of the blades, the midnerve inconspicuous. *Inflorescences* exserted or with the base included within the upper leaves, panicles lax, few-flowered, 1–2.5(–3) cm long, 1–2 cm wide; *main axis* hispid to sparsely pilose, first- and second-order branches shortly pilose, divergent, eglandular, the pulvini pilose; pedicels sparsely pilose. *Spikelets* solitary or paired, ellipsoid, 1.9–2.4 mm long, 0.6–0.8 mm wide, shortly hispid or glabrous, upper glume and lower lemma subequal. *Lower glume* ovate, 1–1.3 mm long, 0.9 mm wide, ½ the length of the spikelet, pilose or glabrous, not embracing the upper glume at its base, (1–)3-nerved, with a conspicuous internode ca. 0.3 mm long between the lower and upper glume. *Upper glume* 1.5–1.9 mm long, pilose, 7–9-nerved, usually not covering the apex of the upper anthecium. *Lower lemma* 1.5–1.9 mm long, glumiform. *Lower palea* linear-lanceolate, 1.2–1.5 mm long, 0.2–0.3 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* ellipsoid, 1.5–1.8 mm long, 0.5–0.7 mm wide, pale, indurate, papillose, and pilose; lemma 5-nerved, palea 2-nerved, anthers 0.9 mm long, purplish. *Caryopsis* ellipsoid, 1.2–1.5 mm long, 0.2–0.3 mm wide; hilum punctiform, embryo less than ½ the length of the caryopsis.

*Distribution and ecology:* found in campos rupestres in the state of Bahia, Brazil, in sandy, rocky soils from 900 to 1,400 m.

*Additional specimens examined.* BRAZIL. BAHIA: 10 km NW of Mucugê, *Mori et al. 12698* (CEPEC, MO, SI, US); Serra do Sincorá, 2–3 km approximately SW of Mucugê on the road to Cascavel, 950 m, *Harley et al. 18829* (CEPEC, MO, NY, US); Mucugê, Serra do Sincorá, 7 km N of Mucugê on road to Andaraí, growing in small patches under Velloziaceae and other plants, *Calderón et al. 2425** (SI, US); Mucugê, Serra do Sincorá, 26 km S of Andaraí, 1,000 m, on rocks, between mosses with water running over, *Calderón et al. 2414* (US); Mun. Mucugê, Rio Apiaba, *Hatschbach 48266* (CTES, K, US); Serra do Rio de Contas, lower N slopes of the Pico das Almas, ca. 25 km WNW of the town of Rio de Contas, *Harley et al. 15420* (CEPEC, K, NY, US); Mun. Mucugê, Rio Mucugê, *Hatschbach 47961* (K); Serra Larga a W de Lençóis, perto de Caeté–Açu, Mun. Lençóis, 1,400 m, 19 Dec. 1984, *Harley et al. s.n.* (K, MO); Mun. Jacobina, scrub and woodland with *Vellozia*, hills of marble rock on N side of Jacobina, 600–650 m, *Webster et al. 25725* (MO); estrada entre Andaraí–Mucugê, *Noblick & Pinto 2870* (K).

*Panicum cumbucana* is closely allied to, and perhaps conspecific with *P. stipiflorum*, which only differs by having leaf blades 2–4.5 cm long, usually not overlapping, and inflorescences 3–4.5 cm long. The culms and leaf blades are usually purplish in *P. cumbucana*, and the blades are, in many cases, overlapping.

Anatomically, the abaxial epidermis of *P. cumbucana* closely resembles that of *P. hebotes*, *P. peristypum*, and *P. sciurotoides* due to the numerous, needlelike macrohairs without cushion bases and because of the short, angular, intercostal cells, which resemble bulliform cells in surface view. However, in transverse section this resemblance is not so evident because *P. cumbucana* does not have well-developed adaxial ribs and furrows and lacks a keel (Fig. 6A, B).

**11. Panicum davidsei** Zuloaga & Morrone, Ann. Missouri Bot. Gard. 78: 158. 1991. TYPE: Venezuela. Bolívar: Cabanayén, La Gran Sabana, wet inundated savanna, 1,300, 3 Dec. 1973, *Davidse, Ramia & Montes 4796* (holotype, MO). Figures 7, 27.

Perennial. *Culms* decumbent, rooting and branching at the lower nodes, then becoming erect, leaning or not on vegetation, to 2.2 m long, internodes 8–22 cm long, cylindric, striate, hispid, compressed, nodes hirsute. *Sheaths* 5–8 cm long, sparsely hirsute with long-tuberculate hairs, one of the margins long-ciliate, the other one membranous; collar long-pilose with whitish hairs. *Ligules* membranous-ciliate, ca. 0.2 mm long. *Blades* narrowly lanceolate, 9–13 cm long, 1–1.3 cm wide, flat, subcordate, the apex acuminate, the adaxial surfaces long-pilose toward the base, otherwise glabrous, the abaxial surfaces sparsely pilose, the margins scabrous and ciliate toward the base, the midnerve conspicuous. *Inflorescence* terminal, long-exserted, a lax, diffuse panicle 12–20 cm long and 7–12 cm wide, peduncle 10–40 cm long; *main axis* cylindric, striate, pilose near the branches, otherwise glabrous, eglandular, lower branches

whorled, the upper ones subopposite to alternate, the axis of the branches flexuous, glabrous, eglandular, the pulvini pilose; pedicels glabrous, flexuous. *Spikelets* ellipsoid, 3–3.3 mm long, 1 mm wide, scaberulous, attenuate toward the base and with a small stipe between the lower and upper glume, upper glume and lower lemma subequal with manifest nerves. *Lower glume* ovate-acuminate, 1.5–1.8 mm long, nearly ½ the length of the spikelet, 3-nerved. *Upper glume* 2.4–2.7 mm long, not covering the apex of the upper anthecium, 11–14-nerved, the nerves anastomosing toward the apex. *Lower lemma* ca. 2.7 mm long, 10–12-nerved, the nerves anastomosing toward the apex. *Lower palea* lanceolate, 2.1–2.4 mm long, 0.3 mm wide, glabrous, hyaline; lower flower absent. *Upper anthecium* ellipsoid, 2.4–2.7 mm long, 1 mm wide, papillose, apiculate, the lemma with a green, scabrous crest on the apex and with the upper margins membranous, prolonged toward the apex as small wings; rachilla prolonged beyond the upper anthecium as a small mucro; lodicules ca. 0.4 mm long; stamens 3, anthers ca. 1.2 mm long. *Caryopsis* ellipsoid, 1.8 mm long, 0.9 mm wide, hilum punctiform, embryo ⅓ the length of the caryopsis.

*Distribution and ecology:* found in Bolívar Venezuela, and Roraima, Brazil, on forest edges (where it leans on the vegetation), or in open places in sandy soils, 1,200–1,300 m.

*Additional specimens examined.* BRAZIL. RORAIMA: Aldeia do Tuchana, *Rondôn s.n.*, July 1927 (RB 110786). VENEZUELA. BOLIVAR: entre piedra de La Virgen y la parte alta de la Escalera, carretera a la Gran Sabana, 6°00′N, 61°25′W, 1,300 m, *Zuloaga et al. 4406** (MO, SI, VEN); a 1 km al S del Puente Sakaika, Gran Sabana, 1,200 m, *Zuloaga et al. 4427** (MO, SI, VEN).

Affinities of *P. adenorhachis* are discussed in Zuloaga & Morrone (1991).

The large number of nerves in the upper glume and lower lemma of this new species suggests a relationship to *P. itatiaiae* and *P. caparaoense*, species from eastern Brazil with spikelets 4.6–6.8 mm long.

*Panicum davidsei* has a thick leaf blade without a midrib, well-developed adaxial ribs and furrows, and conspicuous, long bundle sheath extensions (due to the thickness of the lamina) (Fig. 7A–C).

**12. Panicum dichotomum** L., Sp. Pl.: 58. 1753. *Dichanthelium dichotomum* (L.) Gould, Brittonia 26: 59. 1974. TYPE: United States. Virginia: "Habitat in Virginia," *Clayton 458* (lectotype, BM not seen; photo and fragment, US 2808912).

Perennial. *Culms* decumbent, 10–25(–80) cm long, fasciculate and densely branching at the middle and upper nodes, internodes glabrous, cylindric, hollow, nodes glabrous or short-pilose. *Sheaths* glabrous, glandular or eglandular, the margins membranous, one margin long-ciliate. *Ligules* membranous-ciliate, 0.1–0.6 mm long; collar glabrous. *Blades* linear-lanceolate, 2–7 cm long, 0.2–0.5(1.2) cm wide, flat or slightly involute, glabrous to sparsely pilose, narrowed at the base, attenuate at the apex, the margins scaberulous, cartilaginous or not, usually ciliate toward the base, otherwise glabrous. *Inflorescences* terminal, short- to long-exserted, peduncle glabrous, 3–16 cm long; panicles 1–5 cm long, 1–3 cm wide, lax, few-flowered; *main axis* scabrous or glabrous, glandular or eglandular, the pulvini glabrous, first-order branches alternate, divergent, glandular or eglandular; pedicels flexuous, 2–9 mm long, scabrous or glabrous. Axillary panicles similar to the terminal one. *Spikelets* solitary, obovoid or ellipsoid, 1.4–2.3 mm long, 0.6–1 mm wide, glabrous or shortly hispid, greenish or tinged with purple, the upper glume and lower lemma subequal. *Lower glume* ovate, 0.3–0.7 mm long, ¼ to ⅓ the length of the spikelet, obtuse to truncate, glabrous, nerveless or 1-nerved. *Upper glume* 1.2–1.8 mm long, not covering the apex of the upper anthecium, 7-nerved, separated from the lower lemma by a short internode. *Lower lemma* 1.2–1.7 mm long, glumiform, 7-nerved. *Lower palea* lanceolate, small, 0.8–1 mm long, 0.3 mm wide, glabrous, hyaline; lower flower absent. *Upper anthecium* obovoid, 1.1–1.7 mm long, 0.7–1 mm wide, pale, indurate, acute, papillose, scaberulous toward the apex. *Caryopsis* obovoid, dark, 1.2 mm long, 0.8 mm wide; hilum punctiform, embryo less than ½ the length of the caryopsis.

KEY TO THE VARIETIES

1. Blades without cartilaginous margins; spikelets 1.8–2.3 mm long ..... 12a. var. *dichotomum*
1. Blades with cartilaginous margins; spikelets 1.4–1.6 mm long ..... 12b. var. *tenue*

*Panicum alsophilum* Swallen, Contr. U.S. Natl. Herb. 29: 422. 1950. TYPE: Guatemala. Jalapa: collected in oak woods around the top of Cerro Alcoba, just

E of Jalapa, 1,300–1,700 m, 2 Dec. 1939, *Steyermark 32513* (holotype, F; isotype, US 2236475).

*Panicum hintoni* Swallen, Contr. U.S. Natl. Herb. 29: 419. 1950. TYPE: Mexico. México: collected at Bejucos, Temascaltepec, 610 m, 8 Nov. 1932, *Hinton 2527* (holotype, US 1867697; isotype, US 1865776).

Short-rhizomatous perennial without basal rosettes of broader leaves, or rosettes occasionally present. *Culms* geniculate, decumbent and branching at the lower nodes to erect, freely branching at the middle and upper nodes, (15–)40–120 cm tall, internodes hollow, terete, short-pilose or glabrous, nodes dark, pilose. *Sheaths* striate, short papillose-pilose with caducous hairs or glabrous, one margin long-ciliate, the other glabrous. *Ligules* short-membranous at base and short- to long-ciliate at the apex, 0.2–0.4(–1) mm long; collar densely pilose. *Blades* lanceolate, 4–10(–16) cm long, 0.7–1.2(–1.7) cm wide, flat, clasping, asymmetric and cordate or subcordate at base, the apex attenuate, densely papillose-pilose with caducous hairs or glabrous, densely pilose toward the base on the adaxial surface, the margins ciliate toward the base, otherwise scabrous. *Inflorescences* terminal, exserted, peduncle glabrous, 20–30 cm long; *panicles* lax, diffuse, (3–)10–22 cm long, 6–10 cm wide; *main axis* flexuous, greenish to purplish, glabrous or short-hispid, glandular or eglandular, the pulvini brownish or purplish, glabrous, first-order branches alternate or subopposite, divergent, the axis of the branches and pedicels smooth, flexuous, scaberulous, glandular or eglandular. Axillary panicles present or absent, similar to the terminal one. *Spikelets* solitary, narrowly ellipsoid to obovoid, (2.1–)2.3–3.2 mm long, 1.2–1.3 mm wide, planoconvex, greenish to purplish, shortly and sparsely hispid. *Lower glume* 0.5–1.5 mm long, ¼ to less than ½ the length of the spikelet, ovate, 1-nerved, separated from the upper glume by a short internode. *Upper glume* covering the upper anthecium or not, acute, 7–9-nerved, the nerves anastomosing toward the apex. *Lower lemma* acute, 7–9-nerved, the nerves anastomosing toward the apex. *Lower palea* lanceolate, 1.3–2 mm long, 0.4 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* ellipsoid or obovoid, 2.3–3 mm long, 1–1.1 mm wide, smooth, whitish, indurate, shiny, papillose, the apex of the lemma shortly apiculate and with unicellular macrohairs. *Caryopsis* obovoid, 1.3 mm long, 1 mm wide; hilum punctiform, embryo less than ½ the length of the caryopsis.

*Distribution and ecology:* eastern United States to Mexico and Guatemala and the West Indies (see discussion of the possible presence in Ecuador); it grows at the margins of pine or oak woods or in open field borders, to 2,700 m.

VERACRUZ: Jalapa, *Hitchcock s.n., Amer. Gr. Hb. 225* (MO).

The type locality of *P. divergens* is, according to Humboldt, Bonpland & Kunth, Sangolguí in Pichincha province, Ecuador. This is probably a label error since Humboldt also made collections in Mexico, where this species is commonly found. Another possible explanation is that the species has, as in the case of *P. umbonulatum*, a disjunct distribution.

**14. Panicum ensifolium** Baldwin ex Elliott, Sketch Bot. S. Carolina 1: 126. 1816. *Panicum nitidum* Lam. var. *ensifolium* (Elliott) Vasey, U.S.D.A. Div. Agrost. Bull. 8: 29. 1889. *Dichanthelium ensifolium* (Elliott) Gould, Brittonia 26: 59. 1974. *Dichanthelium dichotomum* (L.) Gould var. *ensifolium* (Elliott) Gould & Clark, Ann. Missouri Bot. *Panicum chamaelonche* Trin., Gram. Panic. 242. 1826. TYPE: "V. Spp. Am. bor. (*Trattinick ex coll. Enslini*)," (holotype, LE not seen).

Densely tufted perennial. *Culms* erect, 8–30 cm tall, frequently unbranched above the base; internodes terete, greenish to purplish, pilose, nodes shortly pilose. *Sheaths* striate, greenish or purplish, glabrous, the margins membranous, ciliate or only pilose near the ligule. *Ligules* 0.4 mm long, membranous-ciliate, the membranous portion reduced. *Blades* linear, 2–6.5 cm long, 0.1–0.3 cm wide, rounded at base, flat to slightly involute, greenish or purplish, sparsely pilose on the adaxial surface or glabrous, the margins scabrous. *Inflorescences* terminal and axillary from the uppermost nodes,

short-exserted, peduncles up to 5 cm long, cylindric, glabrous; panicles 1–4.5 cm long, main axis purplish, flexuous, glandular or eglandular, scabrous or glabrous; pulvini glabrous, the branches alternate, divergent, axis of the branches and pedicels flexuous, scabrous or glabrous, greenish or purplish, glandular or eglandular. Axillary panicles numerous, similar to the terminal one. *Spikelets* obovoid to ellipsoid, 1–1.4 mm long, 0.5–0.6 mm wide, greenish to purplish, shortly hispid or glabrous. *Lower glume* 0.4 mm long, ⅓ the length of the spikelet, truncate to acute, nerveless, hyaline. *Upper glume* obtuse, shorter than the lower lemma and not covering the upper anthecium, 5–7-nerved. *Lower lemma* as long as the spikelet, 5-nerved. *Lower palea* lanceolate, 0.5–0.7 mm long, 0.3 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* ellipsoid, 0.9–1.2 mm long, 0.4–0.6 mm wide, indurate, smooth and shining, pale, papillose; lemma 5-nerved. *Caryopsis* obovoid, black, 0.6–0.8 mm long, 0.5 mm wide; hilum punctiform, embryo ⅓–⅖ the length of the caryopsis.

*Distribution and ecology:* United States, Belize, and Cuba, in pine white-sand savannas, 0–100 m.

*Selected specimens cited.* BELIZE. 3 mi. W of Boomtown, *O'Neill 8500* (MO, US); pine ridge N of aviation field, *Bartlett 11236* (MO, US). CUBA. The type material of *P. hebotes* and *P. mirandum*, together with the other specimens examined, indicate that there are no differences between these taxa. Geminate spikelets, characteristic of Venezuelan specimens, are also occasionally present in other specimens from Bolivia and Brazil.

*Panicum subtiliracemosum* is also considered to be a synonym of *P. hebotes*. The Brazilian specimens cited by Renvoize (1987) under *P. subtiliracemosum* include *Dombrowski 2899* and *Hatschbach 38052*, which are included under *P. schawckeanum* Mez, a species of section *Parvifolia* (A. Hitchc. & Chase) Pilger. *Hatschbach et al. 13731* (K), considered by Renvoize as an intermediate specimen between *P. stigmosum* and *P. subtiliracemosum*, is indeed *P. surrectum*. *Chase 9408* has peculiar cordate blades; however, it shares similar spikelets, dark anthecia, and asymmetrical blades with other specimens of *P. hebotes*.

Anatomically, *P. hebotes* has a distinctive keel incorporating three vascular bundles (Fig. 8A, C). Adaxial ribs and wide, shallow furrows are present, and the mesophyll is diffuse but nevertheless of the semiradiate type (Fig. 8B, D). The three-celled microhairs (Fig. 9B, D) are unique to this species in the section and occur on all three specimens examined anatomically.

**16. Panicum heliophilum** Chase ex Zuloaga & Morrone, Ann. Missouri Bot. Gard. 78: 152. 1991. TYPE: Brazil. Minas Gerais: Chapéu do Sol, Serra do Cipó, 110 km NE of Belo Horizonte, 900 m, 28 Mar.–1 Apr. 1925, *Chase 9147* (holotype, US; isotypes, F, GH, MO, NY). Figure 27.

Short-rhizomatous perennial. *Culms* 50–70(–100) cm tall, tangled, leaning on vegetation, the basal portion decumbent and geniculate, the upper portion erect, freely branching; internodes cylindric, pilose, solid toward the base, otherwise hollow; nodes many, villous. *Sheaths* striate, 0.5–4 cm long, strongly distichous, hispid with short hairs, the margins long-ciliate; auricles small, pilose; collar brownish or purplish, covered with short whitish hairs. *Ligule* a ciliate membrane, 0.2–0.7 mm long, the cilia 0.1–0.6 mm long. *Blades* linear-lanceolate, 4–5(–12) cm long, 0.3(–1) cm wide, flat or folded, subcordate, densely hirsute on both surfaces, the margins cartilaginous, scabrous and short-ciliate. Primary *inflorescences* terminal, exserted, peduncles hispid, to 8 cm long; *panicles* lax, diffuse, 4–16 cm long, 3–13 cm wide; *main axis* flexuous, sparsely hirsute, eglandular, the pulvini brownish, hispid; first-order branches opposite or alternate, the lower ones whorled or not, diverging from the axis; axis of the branches short-hirsute or glabrous; pedicels smooth, glabrous, 2–13 mm long. Axillary panicles similar to the terminal one, smaller. *Spikelets* solitary, ellipsoid, 2.6–3.1 mm long, 1–1.1 mm wide, hirsute, greenish, without a stipe between the lower and upper glume. *Lower glume* 2–2.7 mm long, ¾ the length of the spikelet, acuminate, not embracing the upper glume at its base, 3-nerved, the nerves anastomosing toward the distal portion. *Upper glume and lower lemma* subequal, 7-nerved. *Lower palea* elliptic, 2 mm long, 0.3 mm wide, hyaline; lower flower absent. *Upper anthecium* narrowly ellipsoid, 2.4–2.7 mm long, 0.8–0.9 mm wide, stramineous, brownish at maturity, papillose, with simple papillae evenly distributed over the lemma and palea, densely pilose, with appressed, long hairs toward the apex of the lemma and palea; lemma 5–7-nerved, rachilla prolonged or not into a short mucro above the upper anthecium; lodicules ca. 0.6 mm long; stamens 3, the anthers ca. 1.3 mm long, purplish. *Caryopsis* ellipsoid, 1.4 mm long,

0.8 mm wide, brownish; hilum oblong, embryo ⅓ the length of the caryopsis.

*Distribution and ecology:* campos rupestres in Minas Gerais, Brazil, in sandy soils between 900 and 1,400 m.

*Additional specimens examined.* BRAZIL. MINAS GERAIS: Diamantina, summit of Serra de San Antonio, 1,400 m, *Chase 10354* (US); Mun. Jaboticatubas, Lagoa Santa a Conceição do Mato Dentro, *Sendulsky & Burman 1920* (SI, SP); km 114 ao largo da rodovía Lagoa Santa–Conceição do Mato Dentro, 1,160 m, *Sendulsky 1609* (SP); Saramenha, *Gomes 3955* (US); Serra de Santo Antonio, 2–5 km ao E de Diamantina, 1,050–1,100 m, *Burman & Sendulsky 696, 697, 709* (SI, SP); Serra do Cipó, ao longo da rodovia Lagoa Santa–Conceição, *Sendulsky 446* (SP); Serra do Cipó, *Burman 525* (SP), *Burman 485* (SP); Serra de Itatiaia e Serra de Lavras Novas, *Burman 384* (SP); Serra de Ouro Branco, *Castellanos 25628* (HB); Serra de Cipó, Mun. Jaboticatubas, km 116 ao longo da rodovia Lagoa Santa, 6 June 1970, *Joly et al. 100* (SP); Metallúrgica, Serra de Ouro Branco, 1,250–1,600 m, *Chase 10289* (MO).

Affinities of *P. adenorhachis* are discussed in Zuloaga & Morrone (1991).

**17. Panicum itatiaiae** Swallen, Phytologia 14: 82. 1966. TYPE: Brazil. Rio de Janeiro: Parque Nacional Itatiaia, Picada Macieiras, 1,700–1,800 m, 18 Jan. 1925, *Chase 8327* (holotype, US 1255836; isotypes, F 561591, GH, NY, US 1258426). Figures 28, 36.

Perennial. *Culms* geniculate, decumbent and rooting at the lower nodes, ascendent and branching at the upper nodes, more than 1 m tall, internodes 3–14 cm long, terete, rigid, hollow, glabrous, nodes purplish, glabrous. *Sheaths* 3–8 cm long, usually shorter than the internodes, glabrous with only one margin ciliate. *Ligules* 0.3–0.4 mm long, membranous at the base and short-ciliate or laciniate at the distal portion; collar purplish, short-pilose. *Blades* lanceolate or ovate-lanceolate, 10–12 cm long, 1–1.4 cm wide, flat, subcordate, glabrous, with long hairs close to the ligular region, the midnerve manifest, the margins ciliate and scabrous. *Inflorescences* terminal, exserted, peduncles cylindric, to 40 cm long, glabrous; *panicles* lax, diffuse, 13–18 cm long, 10–20 cm wide; *main axis* flexuous, smooth, glabrous, pulvini brownish, glabrous, first-order branches divergent, alternate or opposite, the axis of the branches triquetrous, purplish, scabrous; pedicels smooth, glabrous, purplish, 3–8 mm long. *Spikelets* solitary, narrowly ellipsoid, 4.6–5 mm long, 1.6–1.7 mm wide, glabrous, greenish, tinged with purple, the upper glume and lower lemma subequal. *Lower glume* 2.6–3.2 mm long, ½ or more the length of the spikelet, acuminate, 5-nerved, glabrous, separated from the upper glume by a short internode. *Upper glume* 4–4.3 mm long, usually not covering the apex of the upper anthecium, obtuse, (11–)13-nerved, the nerves anastomosing toward the apex, the outer surface scaberulous, herbaceous. *Lower lemma* 4.3–4.6 mm long, 13-nerved, the nerves anastomosing toward the apex, acute, scaberulous. *Lower palea* ovate-lanceolate, 4–4.1 mm long, 1–1.1 mm wide, membranous, the margins short-ciliate; lower flower male, the stamens 3, the anthers 2.2 mm long. *Upper anthecium* lanceolate, 4–4.2 mm long, 1.3–1.6 mm wide, apiculate, scabrous and sparsely pilose toward the apex, otherwise glabrous, papillose, with small simple papillae regularly distributed over its entire surface; lemma 7-nerved, the palea scabrous at its apex. *Caryopsis* obovoid, 2.5 mm long, 1.5 mm wide, brownish; hilum punctiform, embryo ⅛ the length of the caryopsis.

*Distribution and ecology:* known only from the type collection made in the Sierra de Itatiaia, in Rio de Janeiro, Brazil, in forests at 1,700–1,800 m; collected under bamboo, with the base long-decumbent.

When describing this species, Swallen indicated that spikelets were 4–4.5 mm long, but none of the types examined had any spikelets within this range.

**18. Panicum laxiflorum** Lam., Encycl. 4: 748. 1798. *Dichanthelium laxiflorum* (Lam.) Gould, Brittonia 26: 60. 1974. *Panicum dichotomum* L. var. *laxiflorum* (Lam.) Beal, Grasses N. Amer. 2: 139. 1896. TYPE: United States. Without locality and collector (holotype, P-LAM; fragment and photo, US 2808927). Figure 27.

*Panicum xalapense* HBK, Nov. Gen. & Sp. 1: 103. 1816. TYPE: Mexico. Veracruz: near Jalapa, *Humboldt & Bonpland s.n.* (holotype, P).

*Panicum ruprechtii* Fourn., Mexic. Pl. 2: 21. 1886, non Fenzl, 1854. TYPE: Mexico. Veracruz: Jalapa, *Galeotti 5733* (holotype, BR not seen).

*Panicum caricifolium* Scribner ex Ashe, J. Elisha Mitchell Sci. Soc. 15: 57. 1898. TYPE: United States. Maryland: Great Falls, *Kearney Jr.*, 23 May 1897 (isotype, NY).

*Panicum pyriforme* Nash, Bull. Torrey Bot. Club 26: 579. 1899. TYPE: United States. Florida: Lake County, Eustis, 12–31 Mar. 1894, *Nash 239* (holotype, NY; isotype, US 221672).

*Panicum xalapense* HBK var. *strictirameum* A. Hitchc. & Chase, Contr. U.S. Natl. Herb. 15: 161. 1910. TYPE: United States. Mississippi: in small close bunches, Jackson, 28 Apr. 1906, *Hitchcock 1311* (holotype, US 558449).

Perennial. *Culms* densely caespitose, fasciculate, internodes very short at base of the plants, culms decumbent, profusely branching at the lower nodes, then erect, few-noded, 5–30(–40) cm tall; internodes terete, glabrous, hollow; nodes brownish, densely pilose with long whitish hairs. *Sheaths* striate, hirsute with rigid papillose-pilose hairs, the margins membranous. *Ligules* membranous-ciliate, 0.3–0.9 mm long, the pseudoligule absent; collar pale, densely pilose. *Blades* lanceolate, 3–15 cm long, 0.2–0.8(–1) cm wide, flat, narrowed at base, acuminate, the margins long-ciliate, papillose-pilose on both surfaces or only on the upper portion of the adaxial surface or glabrous, the midnerve not manifest. Terminal and axillary *inflorescences* similar, short-exserted or included on the upper leaves; peduncle terete, hirsute or glabrous, to 15 cm long; *panicles* lax, 2–9 cm long, 2–7 cm wide; *main axis* flexuous, densely hirsute or glabrous, glandular or eglandular; pulvini long-pilose, first-order branches alternate, divergent, the axis of the branches smooth, sparsely hirsute or glabrous, glandular or eglandular; pedicels long, sparsely hispid. *Spikelets* solitary, plano-convex, ellipsoid to more commonly obovoid, 2–2.7 mm long, 1–1.4 mm wide, short-hirsute, greenish, upper glume and lower lemma subequal. *Lower glume* ovate-acuminate, 0.8–1.3 mm long, ⅓–½ the length of the spikelet, 1–3-nerved. *Upper glume* acute, 9-nerved, covering the apex of the upper anthecium or not. *Lower lemma* glumiform, 9-nerved. *Lower palea* elliptical, 1–1.4 mm long, 0.5–0.7 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* broadly ellipsoid, 1.8–2.3 mm long, 1–1.4 mm wide, indurate, smooth, shiny, papillose, lemma apiculate, the apex greenish. *Caryopsis* broadly obovoid, brownish, 1.3 mm long, 1.2 mm wide; hilum punctiform, embryo a little less than ½ the length of the caryopsis.

*Distribution and ecology:* eastern United States and Mexico to Guatemala, El Salvador, Honduras, Nicaragua, Costa Rica, and the West Indies, in Cuba, the Dominican Republic, and Haiti. Inhabits moist banks and edge of pine and oak woods or mixed hardwood forest, between 700 and 2,700 m.

*Panicum transiens* Swallen, J. Wash. Acad. Sci. 21: 436. 1931. TYPE: Mexico. Tamaulipas: Sierra de San Carlos, Mesa de Tierra, vicinity of San José, 1,000 m, 19 July 1930, *Bartlett 10454* (holotype, US 1501526).

Tufted perennial. *Culms* erect to ascending, 15–30(–60) cm tall, simple at the base, freely branching at the middle and upper nodes; internodes cylindric, hollow, shortly pilose with tuberculate hairs, the margins membranous, glabrous or shortly pilose. *Ligules* membranous-ciliate, 0.3–0.6 mm long; collar shortly pilose. *Blades* lanceolate, 5–8.5 cm long, 0.2–0.8(–1.3) cm wide, flat, subcordate, the

lower margins long-ciliate, the adaxial surface pilose with appressed, whitish hairs, the abaxial surface shortly pilose or glabrous. *Inflorescence* terminal and axillary from the uppermost nodes, short to long-exserted, peduncle cylindric, 5–20 cm long, shortly pilose; *panicles* few to multiflowered, 3–8(–10) cm long; *main axis* flexuous, shortly pilose, the pulvini shortly pilose, branches alternate, divergent, the axis of the branches pilose; pedicels paired, unequal, 2–12 mm long, triquetrous, pilose or scaberulous. *Spikelets* narrowly ellipsoid, 3.3–4.1 mm long, 1.3–1.5 mm wide, short-papillose-pilose, greenish to purplish. *Lower glume* ovate-acuminate, 1.8–2.2 mm long, ½ the length of the spikelet or less, 3–5-nerved, separated from the upper glume by a distinct internode, not embracing the upper glume. *Upper glume* obovate or ovate, 3.2 mm long, obtuse, not covering the apex of the upper anthecium, 9–11-nerved, the nerves anastomosing toward the apex. *Lower lemma* 9-nerved, pilose. *Lower palea* 1.2–1.9 mm long, 0.4 mm wide, lanceolate, hyaline, glabrous; lower flower absent. *Upper anthecium* narrowly ellipsoid, 3–3.5 mm long, 1.2 mm wide, indurate, smooth, shining, papillose and with prickle hairs at the apex. *Caryopsis* unknown.

*Distribution and ecology:* United States, in Texas, Mexico, and occasionally in Guatemala, growing in moist, shaded places, on rocky slopes, bordering rivers or in open pine or oak woods, to 2,500 m.

*Additional specimens examined.* GUATEMALA. EL PROGRESO: hills between Finca Piamonte and slopes SE of Finca Piamonte, *Steyermark 43463* (F). MEXICO. COAHUILA: middle and upper reaches of Cañón de la Hacienda, almost due S of Rancho Cerro de la Madera, N slope of Sierra de la Madera, 2,000–2,500 m, 27°03′N, 102°25′W, *Chiang et al. 9452* (MO), *Johnston et al. 10974* (MO). RIO DE JANEIRO: Antonio, *Glaziou 5718* (K, P, US); Corcovado, *Chase 9752* (MO); Serra dos Orgãos, *Luetzelburg 6051* (NY). Without locality, *Riedel 2151* (K, US), *Glaziou 16626, 18633* (US), *16628* (P, US), *22612* (G).

*Panicum penicillatum* has a peculiar, bamboo-like habit, with rigid culms leaning on the vegetation and reaching up to 10 m high (T. Filgueiras, pers. comm.). The spikelet also lacks a lower palea.

**21. Panicum peristypum** Zuloaga & Morrone, Novon 1: 113. 1991. TYPE: Brazil. Espírito Santo: Mun. Domingos Martins, Domingos Martins, selva en cerro del Dr. Kautsky, 600–850 m, 7 May 1985, *Zuloaga, Martinelli & Vázquez Avila 2398** (holotype, RB; isotypes, MO, SI, US). Figures 10, 28.

Short-rhizomatous perennial. *Culms* decumbent and rooting at the lower nodes, then erect, ca. 80 cm tall, internodes 7–12 cm long, compressed, striate, glabrous; nodes compressed, glabrous, brownish. *Sheaths* striate, 5–9(–18) cm long, usually shorter than the internodes, glabrous, shiny, the margins membranous, ciliate toward the distal portion. *Ligules* 0.3 mm long, membranous at the base, then shortly ciliate, collar shortly pubescent. *Blades* ovate-lanceolate, 7–15 cm long, 1.5–3 cm wide, cordate, amplexicaulous, acute, velutinous, the lower margins long-ciliate, otherwise ciliate. *Inflorescences* terminal, exserted, *panicles* lax, diffuse, 15 cm long, 8 cm wide; *main axis* sparsely pilose, eglandular, the pulvini pilose, first-order branches alternate or subopposite, the axis of the branches scabrous, flexuous, eglandular; pedicels claviform, flexuous, scaberulous. *Spikelets* narrowly ellipsoid, 2.4–2.5 mm long, 1 mm wide, nonstipitate, glabrous, greenish or tinged with purple, the upper glume and lower lemma subequal. *Lower glume* ovate, 1.2–1.4 mm long, ½ or a little more the length of the spikelet, glabrous, 1–3-nerved, not embracing the upper glume. *Upper glume* 1.9–2.3 mm long, (7–)9-nerved, with manifest nerves, not covering the tip of the upper anthecium. *Lower lemma* glumiform, 2–2.3 mm long, 9-nerved. *Lower palea* lanceolate, 1.7 mm long, 0.4 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* ellipsoid, 2.2 mm long, 0.8 mm wide, indurate, papillose, lemma crestate, scaberulous; the stamens 3, anthers 1.4 mm long, stigma pink. *Caryopsis* unknown.

*Distribution and ecology:* known only from the type collection in edge of forest in Espírito Santo, Brazil, at 650–850 m.

Related to *P. sciurotoides*, *P. peristypum* has amplexicaulous, 1.5–3-cm-wide leaves, spikelets 2.4–2.5 mm long, and lower palea 1.7 mm long. It differs from *P. sabulorum* and *P. stigmosum* by having narrowly ellipsoid spikelets (obovoid in *P. sabulorum* and *P. stigmosum*), lower glume not embracing the upper glume at its base, and without a short stipe between the lower and upper glume. *Panicum peristypum* also lacks the foliar dimorphism present in *P. sabulorum* and has, as another difference with *P. stigmosum*, amplexicaulous leaves.

The keel structure of *P. peristypum* deserves comment. Two different leaves of *Zuloaga et al. 2398* were examined, and the leaf illustrated (Fig. 10A) clearly has a keel containing three vascular bundles as well as extensive adaxial parenchyma tissue. However, the other leaf from the same plant is without a keel or even a midrib, having a median vascular bundle distinguishable only by its central location in the lamina.

**22. Panicum petropolitanum** Zuloaga & Morrone, Ann. Missouri Bot. Gard. 78: 161. 1991. TYPE: Brazil. Rio de Janeiro: Mun. Petrópolis, Araras, base de Pedra Maria Comprida, saxícola, heliófila, crescendo em beira de Rio, 23 Mar. 1968, *Sucre & Braga 2553* (holotype, RB). Figure 28.

Stoloniferous perennial? *Culms* geniculate, rooting and branching at the lower nodes, then becoming erect, freely branching, 10–25 cm tall, few-noded; internodes 1–4 cm long, cylindric to compressed, hollow, glabrous; nodes compressed, brownish, covered with long hairs to glabrous. *Sheaths* striate, 1.5–5.5 cm long, longer than the internodes, one of the margins long-ciliate with whitish hairs, the other one membranous or with long hairs in the upper portion, the rest of the surface glabrous. *Ligules* membranous-ciliate, ca. 0.2 mm long; collar brownish, glabrous. *Blades* linear-lanceolate, 2–5 cm long, 0.1–0.3 cm wide, flat, glabrous, the margins scaberulous, the apex attenuate. *Inflorescences* terminal, exserted, peduncles to 16 cm long; *panicles* lax, diffuse, 2–4 cm long, 1–3.5 cm wide; *main axis* flexuous, cylindric, glabrous, the pulvini glabrous, first-order

branches alternate, divergent, and distant, the axis of the branches glabrous, eglandular; pedicels triquetrous, scaberulous, 1–7 mm long. *Spikelets* solitary, narrowly ellipsoid, 2.4–2.6 mm long, 0.9 mm wide, glabrous, the upper glume and lower lemma subequal, without a stipe between the lower and upper glume. *Lower glume* 1.8–2 mm long, ¾ the length of the spikelet, lanceolate, not embracing the upper glume, 1(–3)-nerved, the midnerve scabrous toward the apex. *Upper glume* (7–)9-nerved, acute, embracing the lower lemma. *Lower lemma* 9-nerved, embracing the upper anthecium. *Lower palea* lanceolate, 1.5 mm long, 0.3–0.4 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* narrowly ellipsoid, 2.3 mm long, 0.7 mm wide, glabrous, shiny, with simple papillae evenly distributed over its entire surface; lemma apiculate, apicule ca. 0.2 mm long, pilose; lodicules ca. 0.3 mm long, embracing the lower margins of the palea; the stamens 3, anthers 1 mm long. *Caryopsis* ellipsoid, 1.2 mm long, 0.6 mm wide; hilum punctiform, embryo less than ⅓ the length of the caryopsis.

*Distribution and ecology:* Brazil, in mountains of the state of Rio de Janeiro, growing in open and humid places on borders of streams, on rocky soils.

*Panicum petropolitanum* differs from *P. cucaense* in its stoloniferous habit; culms geniculate, few-noded, rooting and branching at the lower nodes and then becoming erect; linear-lanceolate, flat leaf blades; and inflorescence with a peduncle to 16 cm long.

**23. Panicum portoricense** Desv. ex Ham., Prodr.: 11. 1825. *Dichanthelium portoricense* (Ham.) Hansen & Wunderlin, Ann. Missouri Bot. Gard. 75: 1649. 1988. TYPE: Puerto Rico. Without locality, *Desvaux Herb. s.n.* (holotype, P). Figure 27.

*P. wilmingtonense* Ashe, J. Elisha Mitchell Sci. Soc. 16: 86. 1900. TYPE: United States. North Carolina: New Hanover County, near Wilmington, 17 May 1899, *Ashe s.n.* (holotype, NCU not seen; isotype, US).

*P. pauciciliatum* Ashe, J. Elisha Mitchell Sci. Soc. 16: 87. 1900. TYPE: United States. North Carolina: New Hanover County, near Wilmington, 20 May 1899, *Ashe s.n.* (lectotype, NCU not seen; isolectotype, US).

Caespitose perennials, with a basal rosette of broader leaves present or absent. *Culms* decumbent to erect, 4–30 cm tall, freely branching at the upper nodes, internodes cylindric, greenish to purplish, hollow, shortly and densely pilose; nodes shortly pilose. *Sheaths* striate, greenish to purplish, shortly pilose, the margins ciliate. *Ligules* membranous-ciliate, 0.3–0.7 mm long. *Blades* lanceolate, 1–5 cm long, 0.2–0.6 cm wide, flat, subcordate, the apex acuminate, greenish or occasionally purplish, shortly and densely or sparsely pilose on both surfaces, the lower margins long-ciliate or completely ciliate. *Inflorescences* terminal, exserted or partially included in the upper leaves, peduncles cylindric, shortly pilose, to 4 cm long; *panicles* lax, few to multiflowered, 1–4 cm long; *main axis* flexuous, shortly pilose, first-order branches alternate or subopposite, divergent, the axis of the branches and pedicels shortly pilose. Axillary panicles similar to the terminal one. *Spikelets* solitary, obovoid, 1.6–2.4 mm long, 1–1.3 mm wide, shortly hispid, the upper glume and lower lemma subequal, or the upper glume shorter and not covering the upper anthecium. *Lower glume* 0.7–1.1 mm long, ⅓ or more the length of the spikelet, ovate, obtuse to truncate or acute, 1–3-nerved. *Upper glume* 7–9-nerved, obtuse. *Lower lemma* 7-nerved, obtuse. *Lower palea* lanceolate, 0.6–0.8 mm long, 0.4 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* obovoid, 1.2–1.5 mm long, 0.6–0.8 mm wide, pale, smooth, shiny, indurate, with simple papillae, the lemma 7-nerved, shortly apiculate, pilose at the apex. *Caryopsis* obovoid, 0.7–1.3 mm long, 0.5–1 mm wide; hilum punctiform, embryo less than ½ the length of the caryopsis.

*Distribution and ecology:* United States, Mexico to Belize and the West Indies, in moist sandy pinelands, to 1,400 m.

*Additional specimens examined.* BELIZE. Pine Ridge N of aviation field, *Bartlett 11225* (US). CUBA. ISLA DE LA JUVENTUD: vicinity of Siguanea, *Britton et al. 15379* (US). ORIENTE: Sierra Maestra, La Gran Piedra, 1,200

**24. Panicum pycnoclados** Tutin, J. Bot. 72: 340. 1934. TYPE: Guyana. Kaieteur savanna, Potaro River, 1,100 ft., 20 Aug. 1933, *Tutin 508* (holotype, BM not seen; isotypes, K, US). Figures 11, 28, 34.

*Panicum albociliatum* Swallen, Brittonia 3: 149. 1939. TYPE: Venezuela. Bolívar: Mount Auyan-tepui, 2,200 m, *Tate 1286* (holotype, US 1723625; fragment, VEN 222501; isotype, NY).

*Panicum tiricaense* Swallen, Mem. New York Bot. Gard. 9: 400. 1957. TYPE: Venezuela. Bolívar: upper falls of Río Tirica above summit camp, alt. 1,940–1,950 m, central section, Chimantá Massif, 7 Feb. 1955, *Steyermark & Wurdack 535* (holotype, US 2182126; isotypes, F 1480635, K, NY).

*Panicum tiricaoides* Swallen, Mem. New York Bot. Gard. 9: 401. 1957. TYPE: Venezuela. Bolívar: frequent in thickets along Río Tirica, below summit camp, central section, Chimantá Massif, 1,925 m, 5 Feb. 1955, *Steyermark & Wurdack 475* (holotype, US 2182124; isotypes, G, K, NY).

Perennial. *Culms* leaning on vegetation, decumbent, rooting and branching at the lower nodes, then ascendent to erect, freely branching at the upper nodes, 12–60 cm tall; internodes 3–15 cm long, terete, hollow, glabrous or hirsute, nodes compressed, pubescent with retrorse hairs. *Sheaths* 2–5 cm long, glabrous or hirsute, delicate, the margins long-ciliate. *Ligules* membranous at the base and short to long-ciliate at the apex, (0.2–0.3–)1–1.5 mm long; collar pilose with whitish hairs. *Blades* lanceolate or ovate-lanceolate, 2–4.5(–12) cm long, 0.5–1.8 cm wide, herbaceous, flat, divergent, glabrous or sparsely pilose to densely hispid, cordate, the base amplexicaulous and asymmetric, the apex acute, the margins scabrous, the lower margins long-pilose. *Inflorescences* terminal, exserted, peduncle hispid to glabrous, 6–20 cm long; panicle lax, 3–6(–10) cm long, 1.5–6 cm wide; *main axis* glabrous or hirsute with long papillose-pilose hairs, eglandular, the pulvini pilose or glabrous, first-order branches flexuous, ascendent, alternate or subopposite, occasionally whorled toward the base, glabrescent, eglandular; pedicels pilose toward the distal portion or glabrous, smooth. *Spikelets* ellipsoid, 2.2–3(–3.3) mm long, 0.8–0.9 mm wide, glabrous or pilose, acute and attenuate at the base, with a stipe between the lower and upper glume, upper glume and lower lemma subequal. *Lower glume* ovate-acuminate, (0.7–)1.2–1.8 mm long, ½–¾ the length of the spikelet, 3(–5)-nerved, embracing the upper glume. *Upper glume* 1.9–2.7 mm long, 9-nerved, not covering the apex of the upper anthecium. *Lower lemma* glumiform, 7–9-nerved. *Lower palea* linear-lanceolate, 1.5–1.8 mm long, 0.3 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* ellipsoid, 1.8–2.1 mm long, 0.8 mm wide, indurate, pale, lemma slightly crested at the apex, scabrous and pilose; stamens 3, anthers 0.8 mm long. *Caryopsis* ellipsoid, 1.5 mm long, 0.8 mm wide, hilum punctiform, embryo ⅓ the length of the caryopsis.

*Distribution and ecology:* Ecuador, Peru, Venezuela, Guyana, Surinam, and Brazil, on forest edges, often leaning on vegetation, or in open places, between 500 and 2,600 m.

*Additional specimens examined.* BRAZIL. Zuloaga & Judziewicz (1991) mentioned that the specimen *Tutin 651* is marked as type of *P. pycnoclados* in BM.

This is one of the species of *Panicum* found at higher elevations, being present in Ecuador to 2,600 m.

Swallen (1939, 1957) described three species from Venezuela: *P. albociliatum*, *P. tiricaense*, and *P. tiricaoides*. No morphological differences were observed between these species and *P. pycnoclados*.

*Panicum pycnoclados* is characterized by having asymmetrical, lanceolate or ovate-lanceolate leaves and spikelets 2.2–3(–3.3) mm long with a conspicuous internode between the lower and upper glume. While most of the specimens of *P. pycnoclados* examined have glabrous spikelets, some populations have spikelets with short hairs.

*Panicum pycnoclados* shows close affinities to *P. stipiflorum*, and the latter species may represent a variant of *P. pycnoclados*. *Panicum pycnoclados* has spikelets with the lower glume ½–¾ the length of the spikelet, and blades with only the lower margins pilose. *Panicum stipiflorum* has spikelets with the lower glume usually ½ the length of the spikelet and blades with long-ciliate margins.

Anatomically, the specimen studied has a definite keel that is structurally distinguishable from the other first-order vascular bundles due to the presence of additional sclerenchyma tissue in the form of adaxial and abaxial girders (Fig. 11A). The cushion-based macrohairs of *P. pycnoclados* are of interest, as this hair type is not common in the section. The hair bases are clearly sunken between numerous raised and modified epidermal cells which form the cushion (Fig. 11B). The hairs themselves are also much thicker than the needlelike hairs that occur on other species such as *P. cumbucana* (Fig. 6C), *P. hebotes* (Fig. 9A–D), and *P. peristypum* (Fig. 10C, D). The thick, cushion-based macrohair type is best developed in *P. pycnoclados*, although similar hairs do occur in *P. viscidellum* (Fig. 19), some specimens of *P. acuminatum* (Fig. 3E, F), and near the leaf blade margin in *P. davidsei* and *P. sabulorum* (Fig. 12A).

**25. Panicum sabulorum** Lam., Encycl. 4: 744. 1798. *Dichanthelium sabulorum* (Lam.) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1112. 1978. TYPE: Uruguay. Montevideo: Montevideo, *Commerson s.n.* (holotype, P; fragment, BAA; isotypes, R, US). Figure 12.

Short-rhizomatous perennials, with two different kinds of *culms*: young culms simple, erect, with broad, cordate, lanceolate leaves; older culms erect to decumbent, occasionally rooting and profusely branching at the lower and upper nodes, to 1 m long, with leaves smaller than those of the primary culms; internodes hollow, cylindric, hirsute, nodes densely pilose to glabrous, dark. *Sheaths* 2.5–6 cm long, hirsute to glabrous, the margins ciliate, glands present or absent, more conspicuous toward the distal portion. *Ligules* membranous-ciliate, 0.4–1.1 mm long. *Leaves* lanceolate, 1–9(–15) cm long, 0.2–1.4(–2) cm wide, flat, the base subcordate or cordate, amplexicaulous, the apex acuminate, rigid to herbaceous, hispid, with short, stiff hairs or with papillose-pilose hairs, or glabrous, the lower margins long-ciliate, otherwise scabrous, the midnerve inconspicuous. Primary *inflorescences* lax, diffuse, few- to multiflowered, *panicles* 2–10 cm long, 2–8 cm wide; *main axis* hirsute or glabrous, glandular or eglandular, first-order branches alternate, divergent, the axis of the branches long-hirsute to scabrous and glandular or eglandular; pedicels claviform, hirsute, glandular or eglandular; axillary panicles similar to the terminal one, smaller. *Spikelets* obovoid, biconvex, 1.9–3 mm long, 0.9–1.4 mm wide, paired or solitary, shortly stipitate, greenish and tinged with purple, hirsute to glabrous, glumes and lower lemma with manifest nerves. *Lower glume* ½–¾ the length of the spikelet, 3–5-nerved, the nerves anastomosing toward the apex, ovate, obtuse to acute and embracing the upper glume on its base. *Upper glume* 7–9-nerved, obtuse, not covering the apex of the upper anthecium. *Lower lemma* glumiform, 7–9-nerved. *Lower palea* ovate, 1.6 mm long, 0.8 mm wide, hyaline, the margins short-ciliate; lower flower male or absent. *Upper anthecium* broadly ellipsoid, 1.8–2.5 mm long, 0.7–1.2 mm wide, stramineous, shiny, shortly apiculate, with simple papillae in regular rows; lemma 5-nerved. *Caryopsis* broadly ellipsoid, 1.5 mm long, 1 mm wide; hilum punctiform, embryo less than half the length of the caryopsis.

KEY TO THE VARIETIES

1. Leaf blades clasping the culm 25c. var. *cordatum*
1. Leaf blades not clasping the culm ..... 2

*Panicum sabulorum* var. *polycladum* usually grows in humid and shady places, on forest edges or streams. It differs from variety *sabulorum* by having smaller spikelets (1.9–2.3(–2.6) mm long) that are glabrous or with scattered hairs toward the apex; herbaceous and usually glabrous blades; and panicles with the main axis and branches commonly glandular.

*Glaziou 4305*, from Rio de Janeiro, Brazil, was cited by Doell (1877) as *P. nodiflorum* Lam. (= *P. dichotomum* L. var. *dichotomum*).

**25c. Panicum sabulorum** var. **cordatum** Zuloaga & Morrone, Novon 1: 117. 1991. TYPE: Brazil. Paraná: Carvalho, *Dusén 13336* (holotype, US; isotype, W). Figure 32.

*Additional specimens examined.* BRAZIL. PARANA: Serrinha, *Jönson 1076a* (US), *Dusén 15596* (NY, SI, US); Trancheira, *Jönson 1099a* (US). SANTA CATARINA: Pilões, 200 m, *Reitz & Klein 3225* (NY, US); Mun. Praia Grande, *Valls 10087* (CEN, SI).

In this variety the spikelets are glabrous, 2–2.2 mm long; manifest glands are present on the glabrous sheaths and axis of the inflorescences; and the leaf blades are amplexicaulous, cordate, asymmetrical at base, glabrous and up to 15 cm long and to 2 cm wide.

**26. Panicum sciurotis** Trin., Gram. Panic. 228. 1826. *Dichanthelium sciurotis* (Trin.) Davidse, Novon 2: 104. 1992. TYPE: Brazil: "V. sp. Brasil," *Chamisso s.n.* (holotype, LE). Figure 28.

*Panicum rostellatum* Trin., Mém. Acad. Imp. Sci. Saint-Pétersbourg, Sér. 6, Sci. Math., Seconde Pt. Sci. Nat. 3(2): 288. 1834. TYPE: Brazil. Bahia: "In arenosis prope Ilheos (Brasil) Sep. 1821," without collector, 232 (holotype, LE; fragment, US 974732).

*P. cordifolium* Steudel, Syn. Pl. Glumac. 1: 85. 1853, non Desv. 1831. *Panicum sciurotis* Trin. var. *breviglume* Doell in C. Martius, Fl. Bras. 2(2): 250. 1877. TYPE: Paraguay. Without locality, *Rengger s.n.* (holotype, P).

*P. trichopiptum* Steudel, Syn. Pl. Glumac. 1: 85. 1853. TYPE: Brazil. Bahia: without locality, *Salzmann s.n.* (lectotype, P; fragment, US 2903508).

*P. diffusulum* Salzm. ex Steudel, Syn. Pl. Glumac. 1: 89. 1853. TYPE: Brazil. Bahia: without locality, in sabulosis umbrosis, *Salzmann 684* (holotype, P; fragments, US 967933, 974705, 2903510; isotypes, G, K, MO, P, W).

*P. sciurotis* Trin. var. *molliusculum* Doell in C. Martius, Fl. Bras. 2(2): 250. 1877. TYPE: Brazil. "In Insula S. Catharinae," *Chamisso s.n.* (lectotype, here designated, LE).

Annual. *Culms* geniculate, decumbent, rooting and branching at the lower nodes, then becoming erect, 5–25 cm tall; internodes hollow, compressed, hirsute, 2–8 cm long; nodes dark, densely pilose with retrorse whitish hairs. *Sheaths* striate, 1–5 cm long, hirsute, with long whitish hairs, the margins ciliate. *Ligules* membranous-ciliate, ca. 0.4 mm long; collar pilose, brownish. *Blades* ovate-

lanceolate, 1.5–9 cm long, 0.8–2.8 cm wide, herbaceous, flat, hirsute, papillose-pilose with short, rigid hairs, the base amplexicaulous, the margins ciliate, the midnerve inconspicuous. *Inflorescence* terminal, exserted; peduncle 5–7.5 cm long, flexuous, hirsute; *panicles* lax, diffuse, 2–7 cm long, 1–5 cm wide; *main axis* flexuous, papillose-pilose with long hairs; pulvini pilose; first-order branches divergent, alternate or opposite, the axis of the branches flexuous, smooth, glabrous or with scattered long hairs; pedicels smooth, glabrous; axillary panicles present, similar to the terminal one. *Spikelets* solitary, ellipsoid, 1.5–1.7 mm long, 0.7–0.8 mm wide, hirsute, with short hairs, the upper glume and lower lemma subequal or the upper glume shorter, the nerves inconspicuous. *Lower glume* 0.3–0.4 mm long, ¼ or less the length of the spikelet, nerveless, truncate, not embracing the upper glume at the base. *Upper glume* obtuse, not covering the apex of the anthecium, 5(–7)-nerved, the nerves anastomosing, obtuse. *Lower lemma* glumiform, obtuse, slightly inflated at the base, 5-nerved, the nerves anastomosing toward the distal portion. *Lower palea* lanceolate, 0.9 mm long, 0.2 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* ellipsoid, 1.4–1.5 mm long, 0.5–0.7 mm wide, glabrous, smooth and shiny, short-apiculate, with simple papillae all over its surface. *Caryopsis* obovoid; hilum punctiform; embryo ⅓ the length of the caryopsis.

*Distribution and ecology:* restricted to northeastern Brazil, where it grows in sandy soils, in open places or forest edges.

*Additional specimens examined.* BRAZIL. BAHIA: Bahia, *Chase 7901* (F, RB, SI, US, W); Cruz das Almas, *Pinto 941* (US). CEARA: Campo Grande, *Swallen 4539* (RB, SI, SP, US); Campo Salles to Crato, *Swallen 4303* (K, R, SP); Serra do Araripé, *Luetzelburg 26101* (M, US); Serra do Araripé, Novo Exú, *Luetzelburg 26141* (M). PERNAMBUCO: Carvarú, *Tenorio 66-197* (US); Garánhuns, *Chase 7791* (US); vicinity of Recife, *Chase 7732 1/2* (US); Recife, *Tavares 788* (US). RIO GRANDE DO NORTE: Natal, *Swallen 4677* (SP, US); Nova Cruz to Montanhas, *Swallen 4823* (RB, SP, US); entre Parnamirim e São Jose de Mipibú, *Emygdio 1663* (R, US); without locality, *Riedel s.n.* (K, M, P, US 974737).

The type locality of the species, Santa Catarina, Brazil, is probably erroneous, since *P. sciurotis* has only been found in northeastern Brazil, in Ceará, Pernambuco, Bahia, and Rio Grande do Norte. The same is probably true for the type material of one of its synonyms, *P. cordifolium*, which was originally cited from Paraguay.

*Panicum sciurotis* differs from *P. sciurotoides* in having spikelets with the lower glume nerveless and truncate; upper glume and lower lemma 5(–7)-nerved with the nerves not manifest; upper anthecium inserted laterally in relation to the axis of the rachilla; and lower lemma inflated at the base.

*Panicum litigosum* Steudel, a species often associated with *P. sciurotis*, is a synonym of *P. brevifolium* L., an African species in Bahia, Brazil.

**27. Panicum sciurotoides** Zuloaga & Morrone, Novon 1: 1. 1991. *Dichanthelium sciurotoides* (Zuloaga & Morrone) Davidse, Novon 2: 104. 1992. TYPE: Brazil. Minas Gerais: Distr. Diamantina, Christais, near Corriga Duas Pontes, 1,160 m, 13 May 1931, *Mexía 5819* (holotype, MO; isotypes, G, K, M, P, R). Figures 14, 28.

Annual. *Culms* decumbent, geniculate, rooting and branching at the lower nodes, erect portion 10–85 cm tall, branching at the upper nodes; internodes 2.5–11.5 cm long, terete, hollow, hispid to glabrous; nodes dark, compressed, densely pilose with retrorse whitish hairs. *Sheaths* striate, 3–6.5 cm long, sparsely papillose-pilose to glabrous, the margins ciliate or one margin ciliate and the other one membranous. *Ligules* membranous-ciliate, small, surmounted by long hairs at the base of the blade; collar pilose. *Blades* ovate-lanceolate, 3–10 cm long, 0.8–2 cm wide, flat, the base cordate, clasping and asymmetric, either densely hirsute with short to long appressed tuberculate hairs or short-hispid on the abaxial surface, or glabrous, the margins ciliate toward the base, otherwise scabrous. *Inflorescence* terminal, lax, diffuse, pyramidal, 2.5–9 cm long, 1.5–8.5 cm wide; *main axis* flexuous, hirsute, with long papillose-pilose hairs; branches alternate, flexuous, the axis of the branches smooth, glabrous; pedicels glabrous. *Spikelets* solitary, narrowly ellipsoid, 1.5–1.9 mm long, 0.5–0.7 mm wide, greenish, short-hispid, the upper glume and lower lemma subequal. *Lower glume* ovate, 0.4–0.9 mm long, usually ⅓–½ or more the length of the spikelet, acute to truncate, 1–3(–7)-nerved. *Upper glume* 7–9(–11)-nerved, not embracing the lower lemma. *Lower lemma* glumiform, 7–9-nerved, acute, not inflated at the base. *Lower palea* lanceolate to truncate, 0.7–1 mm long, 0.2–0.3 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* ellipsoid, 1.2–1.7 mm long, 0.4–0.6 mm wide, smooth, shiny, short-apiculate, with simple papillae over its entire surface. *Caryopsis* 1.1 mm long, 0.7 mm wide.

*Distribution and ecology:* widely distributed from Belize and Panama to Bolivia and Brazil; common on forest edges, with the culms straggling in low vegetation, often in disturbed and open places in sandy soils; from 100 to 1,400 m.

*Panicum sciurotoides* is related to *P. sciurotis* Trin., from which it differs in having the lower glume ⅓–½ or more the length of the spikelet and 1–3(–7)-nerved; the upper glume 7–9(–11)-nerved; the lower lemma 7–9-nerved and not inflated at base; and the upper anthecium inserted basally. *Panicum viscidellum* differs from *Panicum sciurotoides* in its pseudoligule composed of long hairs.

Anatomically, all specimens examined are very similar in leaf anatomy (Fig. 14). The keel of this species is distinctive, containing only a single vascular bundle (Fig. 14A). The asymmetrical, S-like nature of the lamina on either side of the keel is of particular interest, as this structure does not occur in any other taxon of section *Dichanthelium*, yet is common in section *Cordovensia*, also of subgenus *Dichanthelium*.

Large-spikelet form of *P. sciurotoides*: BRAZIL. RIO DE JANEIRO: between Alta Bôa Vista and Silvestre, vicinity of Rio de Janeiro, 450–520 m, 23 Jan. 1925, *Chase 8374* (F, NY, US); camino Dos Macacos, Jardim Botânico to Alta Bôa Vista, vicinity of Rio de Janeiro, 100–200 m, 12 Feb. 1925, *Chase 8446* (US); Corcovado, Sep. 1920, *Kuhlmann & Ducke 16233* (SI); Corcovado, vicinity of Rio de Janeiro, 700 m, 11 Jan. 1925, *Chase 8169* (F, GH, MO, NY); Corcovado, 6 Mar. 1924, *Bailey & Bailey 742* (US); Tijuca, 1,000 m, 28 Apr. 1930, *Chase 12158* (US).

These specimens, included provisionally in *P. sciurotoides*, have spikelets 1.9–2.2 mm long and panicles 3.5–8 cm long. They were collected in Rio de Janeiro, Brazil, in mountains of the Serra do Mar, scandent on the forest margins.

**28. Panicum scoparium** Lam., Encycl. 4: 744. 1798. *Dichanthelium scoparium* (Lam.) Gould, Brittonia 26: 60. 1974. TYPE: United States. South Carolina: without locality, *Michaux s.n.* (holotype, P-MICH; photo and fragment, US 2808935). Figure 28.

Plants perennial with a rosette of winter leaves. *Culms* ascending, slightly decumbent at the base, to erect, to 1.6 m tall, simple and then freely branching at the upper nodes; internodes cylindric, hollow, villous, covered with appressed whitish hairs, purplish to greenish, nodes densely pilose, covered with retrorse whitish hairs, with a glandular zone below. *Sheaths* striate, densely papillose-pilose and covered with conspicuous glands, the margins shortly pilose. *Ligules* membranous-ciliate, 1.5–2.5 mm long, membranous portion inconspicuous or to 0.5 mm long. *Blades* lanceolate, (2–)10–19 cm long, (0.3–)1.5–1.8 cm wide, flat, the base subcordate, the apex attenuate, hispid on both surfaces, the margins shortly pilose, the midnerve conspicuous. *Inflorescences* terminal and axillary from the uppermost nodes, terminal inflorescence exserted, peduncle hispid, ca. 25 cm long; *panicles* lax, open, diffuse, 10–18 cm long; *main axis* flexuous, hispid and covered with conspicuous glands, the branches alternate to opposite, divergent, the

axis of the branches hispid toward the base, otherwise glabrous, glandular; pedicels solitary, 1–15 mm long, glabrous and covered with glands; terminal panicles with chasmogamous flowers; axillary panicles ca. 4 cm long, similar to the terminal one. *Spikelets* solitary, obovoid, 2.5–2.8 mm long, 1.3–1.6 mm wide, greenish to purplish. *Lower glume* truncate to ovate, 0.4–0.8(–1.5) mm long, ⅐–¼ or occasionally slightly longer than ½ the length of the spikelet, nerveless to 1-nerved. *Upper glume and lower lemma* subequal or the upper glume shorter and not covering the upper anthecium, obtuse, 9-nerved. *Lower palea* lanceolate, hyaline, 1.3 mm long, 0.6 mm wide; lower flower absent. *Upper anthecium* ellipsoid, 2–2.2 mm long, 0.9–1.4 mm wide, smooth, shining, pale, glabrous, papillose, shortly apiculate. *Caryopsis* obovoid, 1.5 mm long, 1.2 mm wide, olivaceous and with dark spots; hilum punctiform, embryo less than ½ the length of the caryopsis.

*Distribution and ecology:* southeastern United States, Mexico, and the West Indies, in marshes, moist pinewoods, and roadsides.

*Selected specimens cited.* CUBA. ORIENTE: Chanascal de la Cueva, Sierra de Nipe, *León 19856* (MO); crest of Sierra Nipe, *Morton & Acuña 3082* (US); pine woods, iron mine, S of Guaro, *Hitchcock 23414* (US). DOMINICAN REPUBLIC. **29. Panicum sphaerocarpon** Elliott, Sketch Bot. S. Carolina 1: 125. 1816. *Dichanthelium sphaerocarpon* (Elliott) Gould, Brittonia 26: 60. 1974. *Panicum dichotomum* L. var. *sphaerocarpon* (Elliott) Alph. Wood, Class-Book Bot., ed. 1861: 786. 1861. *Panicum microcarpon* Muhlenb. var. *sphaerocarpon* (Elliott) Vasey, Grass. U.S.: 12. 1883. TYPE: United States. Georgia: without locality, *Baldwin s.n.* (holotype, CHARL not seen; photo and fragment, US 81121).

Caespitose perennial, with or without a basal rosette of short, broad leaves. *Culms* decumbent and geniculate, branching at the base, to erect, branching at the upper nodes, 15–40(–60) cm tall; internodes short toward the base, compressed, hollow, glabrous; nodes short-pilose or glabrous. *Sheaths* striate, greenish to purplish, shortly ciliate on the margins, glabrous in the rest of the surface. *Ligules* absent or to 0.8 mm long, short-membranous at base, then long-ciliate, or absent; collar brownish, glabrous. *Blades* lanceolate to ovate-lanceolate, 2.5–9 cm long, 0.5–1.5 cm wide, flat, rigid, glabrous, the base subcordate to cordate, the apex acuminate, the margins scabrous, short-ciliate to ciliate toward the base. *Inflorescences* terminal, exserted, peduncles 6–25 cm long, glabrous; *panicles* lax, diffuse to contracted, (2–)5–11 cm long, 3.5–7 cm wide; *main axis* flexuous, glabrous, glandular; first-order branches alternate, divergent or appressed, distant, the axis of the branches smooth, glabrous, glandular; pedicels long, greenish to purplish, glabrous, smooth, glandular; axillary panicles similar to the terminal one. *Spikelets* solitary, obovoid to broadly ellipsoid, 1.1–1.8 mm long, 0.9–1 mm wide, short-hirsute, the upper glume and lower lemma subequal. *Lower glume* broadly ovate, obtuse, 0.2–0.4(–0.9) mm long, ⅕ the length of the spikelet or occasionally to ⅓–½ the length of the spikelet, nerveless or 1(–3)-nerved separated from the upper glume by a short stipe. *Upper glume* 1.3–1.7 mm long, obtuse, shiny on the inner surface, short-hirsute, 7-nerved, the nerves anastomosing toward the base. *Lower lemma* glumiform, 1.2–1.7 m long, 7-nerved, the nerves anastomosing toward the apex. *Lower palea* ovate-lanceolate, 0.6 mm long, 0.3 mm wide, hyaline, the margins sparsely pilose or glabrous, lower flower absent. *Upper anthecium* broadly ellipsoid, 1–1.3 mm long, 0.6–0.9 mm wide, glabrous, smooth, shiny, indurate, papillose with simple papillae; cleistogamous flowers present or absent. *Caryopsis* obovoid, 0.7 mm long, 0.5 mm wide, brownish; hilum punctiform, embryo ⅓ the length of the caryopsis.

*Panicum sphaerocarpon* is a species with a distinctive anatomy. The absence of differentiation between the spongy and palisade mesophyll separates this species from all others in the section. The chlorenchyma cells are also characteristic in that their cytoplasm is centrally concentrated and adaxial air spaces are present (Fig. 15B, D). In addition, the adaxial bulliform cells are in discrete fans consisting of only 3–4 cells.

1. Spikelets 1.4–1.8 mm long ..... var. *sphaerocarpon*

**29a. Panicum sphaerocarpon** var. **sphaerocarpon**

*Panicum inflatum* Scribner & Smith, U.S.D.A. Div. Agrostol. Circ. 16: 5. 1899. *Panicum sphaerocarpon* Elliott var. *inflatum* (Scribner & Smith) A. Hitchc., in A. Hitchc. & Chase, Contr. U.S. Natl. Herb. 15: 253. 1910. TYPE: United States. Mississippi: Harrison County, Biloxi, *Tracy 4622* (holotype, US).

*Panicum vicarium* Fourn., Mex. Pl. 2: 20. 1886. TYPE: Mexico. Veracruz: Córdoba, *Schaffner 285* (holotype, P).

*Panicum auburne* Ashe, North Carolina Agric. Exp. Sta. Bull. 175: 115. 1900. TYPE: United States. Alabama: Lee County, Auburn, 1898, *Earle & Baker 1527* (isotype, NY; fragment, US 2383621).

*Distribution and ecology:* United States, Mexico, Mesoamerica, and northern South America (Colombia and Venezuela). Grows in forest edges, gravelly banks, or in open sites, in partially disturbed areas, between 600 and 2,700 m.

*Selected specimens cited.* BELIZE. BELIZE: 4 km of Hattieville along the western hwy. to Belmopan, 810 m, *Davidse & Brant 32994* (MO, SI). COLOMBIA. CAUCA: de El Estrecho a Balboa, a 18 km de El Estrecho, 1,280 m, *Zuloaga & Londoño 4249** (COL, SI). ANTIOQUIA: Río Negro, 2,110 m, *Archer 240* (US); Santa Elena, 1,500–2,000 m, *Archer 1167* (US). CUNDINAMARCA: Subida a Alto del Tigre, *Zuloaga 4035** (COL, SI). COSTA RICA. CARTAGO: 3 km S of Agua Caliente, 1,400 m, *Pohl & Davidse 11377* (US). HEREDIA: Volcán Barba, Cordillera Central, *Pohl & Davidse 10535* (MO). SAN JOSE: ca. 2 km SE of Tarbaca on road to San Gabriel, 1,600 m, *Pohl & Davidse 11046* (US). ECUADOR. TUNGURAHUA: Baños al Topo, *Acosta-Solís 20832* (US). EL SALVADOR. CHALATENANGO: E slope of Los Esemiles, *Tucker 1056* (P). SANTA ANA: summit of Cerro Monte Cristo, juncture of Salvador, Honduras, and Guatemala, *Pohl 12572* (MO). GUATEMALA. BAJA VERAPAZ: 6 km N of El Chol, *Harmon & Dwyer 3165* (MO). EL QUICHE: NE of Nebaj, *Metzler 6* (MO). SAN MARCOS: Finca Armenia, San Rafael, pie de la Cuesta, *Dwyer 15207* (MO). HONDURAS. EL PARAISO: Monserrat mountain, *Molina & Molina 27489* (MO). INTIBUCA: Cerro San Cristóbal, La Esperanza, *Ordoñez 85* (MO). FRANCISCO MORAZAN: 2.5 km N of Zambrano, on road to San Francisco de Soroguara, *Pohl & Davidse 12131* (MO). OCOTEPEQUE: common in pine forest and rocky hillsides of Machuca, Honduras and Guatemala border, *Molina & Molina 27870* (MO). OLANCHO: Río El Salto, 5 km al W, Campamento, *Amador 89* (MO); Montaña Los Zapotes, 10 km W de Campamento, *Galeano 98* (MO). MEXICO. CHIAPAS: Mun. Teopisca, marsh near Teopisca, *Breedlove & Davidse 54814* (MO); Mun. La Trinitaria, 9 km S of Comitan on Mexican Hwy. 190, *Breedlove & Davidse 54954* (MO). GUERRERO: 3.5 km al N de Zoyotepec, brecha maderera, *Martínez-Salas & Torres 2562* (MO). JALISCO: E of San Sebastián, Hacienda del Ototal, *Mexía 1812* (MO). MICHOACAN: ca. 10 mi. W of Ciudad Hidalgo, near km Post 160 on Hwy. 15 to Morelia, *Davidse & Davidse 9842* (MO). VERACRUZ: Orizaba, *Hitchcock s.n.*, Amer. Gr. Hb. 155 (MO, P); sand bluffs near Jalapa, 4,000 ft., *Pringle 8344* (MO, P). NICARAGUA. ESTELI: along new road from Hwy. 1 (at km 135.5 and ca. 10.6 km W of bridge at La Trinidad) to San Nicolás, *Stevens 14802, 18000* (MO). PANAMA. CHIRIQUI: E slope of Volcán de Chiriquí (Barú), WNW of Boquete, *Davidse & D'Arcy 10153* (MO). VENEZUELA. ARAGUA: Distr. Ricaurte, ca. Colonia Tovar, a 600 m del desvío al Jarillo, vía Colonia Tovar, 2,170 m, *Zuloaga & Ortíz 4280** (MO, SI, VEN). DISTRITO FEDERAL: mountainside between El Junquito and Colonia Tovar, 6,000 ft., *Soderstrom 960* (VEN); ca. 2.5 km down road to Carayaca as measured from intersection with main road between El Junquito and Colonia Tovar, *Davidse & Tillett 4079* (MO).

**29b. Panicum sphaerocarpon** var. **floridanum** Vasey, U.S.D.A. Div. Agrost. Bot. Bull. 8: 33. 1889. *Panicum floridanum* (Vasey) Chapman, Fl. South U.S., ed. 3: 585. 1897, non Trin., 1835. *Panicum erectifolium* Nash, Bull. Torrey Bot. Club 23: 148. 1896. *Dichanthelium erectifolium* (Nash) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1105. 1978. *Dichanthelium sphaerocarpon* (Elliott) Gould var. *floridanum* (Vasey) Davidse, Novon 2: 104. 1992. TYPE: United States. Florida: "Moist pine barrens, Mosquito Inlet," May 1879, *Curtiss 3599* (lectotype, US 81122; isolectotype, MO). Figure 29.

*Distribution and ecology:* open white-sand savannas and moist pine woods of southeastern United States, Belize, and Cuba, 0–100 m.

*Additional specimens examined.* BELIZE. BELIZE: 12.5 mi. NW of Belize along Northern Hwy., *Croat 23259* (MO), *Dwyer 10716* (MO); savanna near Ridge Lagoon Plantation, 11 mi. from Belize on Northern Hwy., *Gentry 7860* (MO). CUBA. ISLA DE LA JUVENTUD: about 5 km S of Santa Bárbara, *Blanco s.n.* (US 2183813), *Killip 44825* (US); along road to San Francisco de las Piedras, *Killip 43723, 44193* (US). ORIENTE: Moa, champ d'aviation, *Victorin et al. 21448* (US). PINAR DEL RIO: Herradura, at a small laguna, *Ekman 11599* (US); La Grifa, in open places, *Ekman 11242* (US); between Guane and Remates, near sea level, edge of Laguna de Cebo, *Killip 32328a* (US). SANTA CLARA: Motembo, *León et al. 8615* (US).

Variety *floridanum* differs from variety *sphaerocarpon* by its smaller spikelets 1–1.5 mm long, erect leaves that are appressed to the culms, glabrous nodes, and ligules 0.3–0.4 mm long.

**30. Panicum stigmosum** Trin., Gram. Panic. 194. 1826. TYPE: Brazil. Minas Gerais: "ad rip. rivuli Pibanha, in Serra dos Orgaos, l. mis. mense Aprili *Riedel*" (holotype, LE not seen; photo of the type, K, fragment, US 974621). Figures 16, 29.

*P. mollicomum* Kunth, Revis. Gramin. 1: Suppl. 9. 1830. *P. lanuginosum* J. S. Presl, Reliq. Haenk. 1: 306. 1830, non Elliott, 1816. TYPE: "Peru," without locality, *Haenke s.n.* (PR, holotype not seen; fragment of the type, US 974627).

Perennial, (30–)50–100 cm tall. *Culms* decumbent, branching and rooting at the lower nodes, then ascendent, leaning on vegetation, branching at the upper nodes; internodes 4–19 cm long, compressed, glabrous, with glands toward the distal portion; nodes compressed, brownish, pilose or glabrous. *Sheaths* 3–11 cm long, shorter than the internodes, hispid or glabrous, glandular, one margin ciliate, the other one ciliate toward the apex but otherwise glabrous. *Ligules* (0.3–)1–1.6 mm long, shortly membranous at the base, then ciliate; collar villous or puberulous, brownish. *Blades* linear-lanceolate, 10–22 cm long, 1–2.2 cm wide, the base subcordate or cordate, slightly asymmetrical, the apex attenuate, sparsely pilose or glabrous on the adaxial surface or hispid on both surfaces, the margins shortly ciliate, scabrous, the abaxial surface glandular or eglandular. *Inflorescences* exserted, peduncle (6–)9–34 cm long, cylindric, glabrous or sparsely pilose, glandular; panicles lax, diffuse, 9–21 cm long, 6–15 cm wide; *main axis* flexuous, glabrous or sparsely pilose, glandular, the pulvini pilose, first-order branches divergent, alternate or subopposite, flexuous, the axis of the branches flexuous, scaberulous, glandular; pedicels claviform, shortly hirsute or scabrous. *Spikelets* ellipsoid or obovoid, (1.9–)2.4–3.2 mm long, (0.9–)1.1–1.3 mm wide, greenish to purplish, glabrous, shortly stipitate, the upper glume and lower lemma subequal. *Lower glume* ovate, 1.1–1.8 mm long, ½–¾ the length of the spikelet, embracing the upper glume, (1–)3-nerved, glabrous. *Upper glume* (1.6–)2–2.4 mm long, not covering the apex of the upper anthecium, glabrous, 7–9-nerved, the nerves manifest. *Lower lemma* glumiform, (1.6–)2–2.4 mm long, 7–9-nerved. *Lower palea* lanceolate, (1.6–)1.8–2.1 mm long, 0.6–0.7 mm wide, hyaline, glabrous, the margins ciliate; lower flower present or absent, male when present; stamens 3, anthers to 0.9 mm long. *Upper anthecium* ellipsoid, 1.9–2.1 mm long, 0.9–1 mm wide, acuminate, stramineous, indurate, with simple papillae all over its surface; lodicules ca. 0.3 mm long; stamens 3, the anthers 0.7 mm long. *Caryopsis* ellipsoid, 1.3 mm long, 1 mm wide; hilum punctiform, embryo ⅓ the length of the caryopsis.

*Distribution and ecology:* Brazil, in the states of Espírito Santo, Minas Gerais, Rio de Janeiro, Santa Catarina, and São Paulo, on forest edges in tangled colonies, 1,000–2,200 m.

*Additional specimens examined.* BRAZIL. ESPIRITO SANTO: Serra do Caparaó, *Chase 10106*, *10112* (US). MINAS GERAIS: Parque Nac. Itatiaia, camino para las Agulhas Negras, *Zuloaga et al. 2382* (RB, SI, US); Serra da Gramma, 1,100 m, *Chase 9543* (US), 1,700 m, *Chase 9556* (NY); Serra do Caparaó, 2,100–2,200 m, *Chase 9662* (F, NY, US); Itacolumí, E of Ouro Preto, *Chase 9381* (NY, US), *9421* (US). RIO DE JANEIRO: Floresta Regime de Preservaçao Permanente do IBDF, entre Vale dos Princesas y Rocio, 1,000–1,200 m, *Zuloaga et al. 2389* (SI); Macieiras, Serra de Itatiaia, *Chase 8261* (F, NY, US), *8322* (US), *Zuloaga et al. 2351**, *2358** (SI), Rio Campo Belo, *Zuloaga et al. 2363* (RB, SI); Petrópolis, Rio Itamaraby, *Glaziou 17946* (US, W); below Macieiras, Serra de Itatiaia, 1,200–1,800 m, *Chase 8322* (US); Rio de Janeiro, *Glaziou 18629* (US, W). SANTA CATARINA: 41 km S of Campo Alegre, on the road to Jaraguá do Sul, *Smith & Klein 7334* (US). SÃO PAULO: Salesópolis, Estaçao Biológica de Boracéia, *Mattos & Mattos 14248* (P, US). Without state and locality, *Riedel 226* (G).

*Panicum stigmosum* is closely related and perhaps conspecific with *P. sabulorum*, differing only in: the plants being bigger, scandent; foliar dimorphism is absent; the inflorescence is bigger ((6–)9–34 cm long); and leaf blades and axis of the inflorescence are glandular. There are several intermediate specimens between both species, however, such as *Zuloaga et al. 2351*, *2382*, *Glaziou 17946*, *18629*, *Chase 9361*, *9381*, *9421*, and *Mattos & Mattos 14248*.

Macrohairs are lacking in the two specimens examined in the anatomical study (Fig. 16D, E). The mesophyll is characteristically very diffuse with large intercellular air spaces.

*Panicum stigmosum* var. *parviflorum* Doell is a dubious name. Doell included in his original diagnosis two specimens: *Sellow 4906* and *Regnell III-1360*. There is a fragment of the latter specimen at US which is *P. pantrichum* Hackel (sect. *Cordovensia*).

Small-spikelet form of *P. stigmosum*: BRAZIL. ESPIRITO SANTO: Serra do Caparaó, *Chase 10105* (MO, US). MINAS GERAIS: Serra da Gramma, E of Araponga, 1,200 m, *Chase 9531* (F, GH, MO, NY, US). RIO DE JANEIRO: Serra de Itatiaia, Macieiras, 1,700–1,800 m, *Chase 8321* (GH, NY, US).

These specimens have spikelets 1.9–2.1 mm long, but are otherwise similar in all characters to other material *P. stigmosum*. The rachilla is prolonged as a short mucro above the upper anthecium in *Chase 10105*.

**31. Panicum stipiflorum** Renvoize, Kew Bull. 37: 329. 1982. TYPE: Brazil. Bahia: 16 km NW of Lagoinha, which is 5.5 km SW of Delfino on side road to Minas do Mimoso, 950–1,000 m, 8 Mar. 1974, *Harley, Renvoize, Erskine, Brighton & Pinheiro 17019* (holotype, CEPEC; isotypes, K, NY, US 2955108). Figure 29.

Annual? *Culms* decumbent at the base, then ascendent, 20–30(–80) cm tall, freely branching at the upper nodes, many-noded, internodes terete, hollow, short-pilose, nodes compressed, densely pilose with short, appressed, whitish hairs. *Sheaths* striate, sparsely or densely hirsute with short hairs, or long-pilose in the upper portion, the margins long-ciliate, more so in the upper portion. *Ligules* 0.3 mm long, membranous-ciliate. *Blades* ovate-lanceolate, 2–6 cm long, 0.6–1.5 cm wide, cordate, amplexicaulous, sparsely to densely hirsute with short, rigid hairs, or glabrescent, the margins cartilaginous, scabrous and long-ciliate with papillose-pilose hairs. *Inflorescences* terminal, exserted, peduncles to 20 cm long, cylindric, shortly hirsute; *panicles* lax, diffuse, 3–8 cm long, 2–5 cm wide; *main axis* flexuous, hirsute; pulvini densely pilose; first-order branches alternate, divergent, the axis of the branches hirsute, smooth, eglandular; pedicels hirsute, 0.6–2 mm long. *Spikelets* paired or solitary, ellipsoid, 2.2–2.6 mm long, 0.9 mm wide, sparsely hirsute with short hairs on the glumes and lower lemma, greenish or tinged with purple. *Lower glume* acute, ½ or less the length of the spikelet, occasionally larger, not embracing the upper glume at its base, 3–5-nerved, separated from the upper glume by a conspicuous stipe. *Upper glume* 1.8–2.1 mm long, occasionally a little smaller and not covering the apex of the upper anthecium, 7–9-nerved, the nerves anastomosing. *Lower lemma* glumiform, 7-nerved, the nerves anastomosing toward the apex. *Lower palea* elliptical, 1.5 mm long, 0.3 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* ellipsoid, 1.7–1.8 mm long, 0.7 mm wide, indurate, smooth, shiny, papillose with simple papillae regularly distributed all over its entire surface; lemma 5-nerved, shortly apiculate and pilose toward the apex. *Caryopsis* ellipsoid, 1.5 mm long, 0.9 mm wide; hilum punctiform, embryo ⅓ the length of the caryopsis.

*Distribution and ecology:* Bahia, Brazil, in cerrados in rocky, sandy soils, between 900 and 1,100 m, in flower between February and April.

*Additional specimens examined.* BRAZIL. BAHIA: 34 km E of Morro do Chapéu along Hwy. BA-052, Chapada da Diamantina, *Davidse et al. 11888* (K, MO, NY, SI, SP); Chapada da Diamantina, along waterfall of the Rio Ferro Doudo, ca. 21 km E of morro do Chapéu, *Davidse et al. 11950* (MO, SP); 16 km NW of Lagoinha on side road to Minas de Mimoso, 950–1,000 m, *Harley et al. 17004* (paratypes, K, NY, US); Fazenda Mundo Novo, Botafogo, *Zehntner 248, 263* (RB); Serra do Tombador, ca. 18 km E of Morro de Chapéu, *Irwin et al. 30702* (MO, UB); Serra Tinguá, *Zehntner 2017* (M); Sentacé, *Zehntner 2048* (M).

*Panicum stipiflorum* is characterized by its cordate, amplexicaulous leaves with conspicuous ciliate margins, spikelets with a stipe between the lower and upper glume, and lower glume usually less than ½ the length of the spikelet.

**32. Panicum strigosum** Muhlenb. in Elliott, Sketch Bot. S. Carolina 1: 126. 1816. *Dichanthelium strigosum* (Muhlenb.) Freckmann, Brittonia 33: 457. 1981. TYPE: United States. "Hab. in humidis. Car: & Georg:," *Elliott Herb. s.n.* (lectotype, CHARL not seen; isolectotype, US; photo and fragment, US 2808953). Figure 29.

*Panicum ciliatum* Elliott, Sketch Bot. S. Carolina 1: 126. 1816, non *Panicum ciliatum* Maercklin, 1792.

*Panicum dichotomum* L. var. *glabrescens* Griseb., Fl. Brit. W.I. 553. 1864. *Dichanthelium leucoblepharis* (Trin.) Gould & Clark var. *glabrescens* (Griseb.) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1100. 1978. *Dichanthelium strigosum* (Muhlenb.) Freckmann var. *glabrescens* (Griseb.) Freckmann, Brittonia 33: 457. 1981. TYPE: Jamaica. Without locality, *Purdie s.n.* (holotype, K).

*Panicum laxiflorum* Lam. var. *pubescens* Vasey, Contr. U.S. Natl. Herb. 3: 30. 1892. *Dichanthelium leucoblepharis* (Trin.) Gould & Clark var. *pubescens* (Vasey) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1101. 1978. *Panicum ciliatum* Elliott var. *pubescens* (Vasey) Freckmann ex R. W. Pohl, Fieldiana, Bot., n.s. 4: 356. 1980. *Panicum leucoblepharis* Trin. var. *pubescens* (Vasey) Beetle, Phytologia 48: 192. 1981. TYPE: United States. Florida: Duval County, without locality, *Curtiss s.n.* (lectotype, US).

*P. polycaulon* Nash, Bull. Torrey Bot. Club 24: 200. 1897. TYPE: United States. Florida: Hillsborough County, Tampa, 20 Aug. 1895, *Nash 2420a* (holotype, NY; isotype, US).

*P. longipedunculatum* Scribner, Tennessee Agric. Exp. Sta. Bull. 7: 53. 1894. TYPE: United States. Tennessee: White Cliff Springs, July 1890, *Scribner s.n.* (lectotype, US 742594).

Short-rhizomatous perennials, caespitose and with many fasciculate culms. *Culms* erect, 3–20 cm tall, few-noded, unbranched below the inflorescence; internodes short, cylindric, hollow, short-pilose or glabrous; nodes pilose, compressed. *Sheaths* 1 cm long, longer than the internodes, striate, glabrous, one margin ciliate, the other membranous. *Ligules* 0.2–0.4 mm long, membranous-ciliate; collar glabrous. *Blades* lanceolate, 1–5(–7) cm long, 0.3–0.5(–0.7) cm wide, flat, glabrous or with long sparse hairs, the base narrowed or subcordate, the apex acute, the margins long-ciliate with rigid papillose-pilose hairs or occasionally glabrous. *Inflorescences* terminal, exserted, peduncle 1–14 cm long, flexuous, glabrous or sometimes hirsute near the junction with the panicle; *panicles* lax, diffuse, few-flowered, 2–5 cm

long, 1.5–4.5 cm wide; *main axis* flexuous, densely hirsute with long whitish hairs, occasionally glabrous, glandular, the pulvini pilose; first-order branches alternate, the axis of the branches hirsute, flexuous and glandular; pedicels glabrous, claviform, glandular; axillary inflorescences present, similar to the terminal one. *Spikelets* solitary, obovoid or ellipsoid, 1–1.7 mm long, 0.6–0.9 mm wide, puberulous or glabrous, greenish to purplish, the upper glume and lower lemma subequal. *Lower glume* ovate, 0.5–0.8 mm long, ⅓–⅔ the length of the spikelet, nerveless or 1-nerved, embracing the upper glume at its base, acute or truncate, with a small internode between the lower and upper glume. *Upper glume* obtuse, 7-nerved. *Lower lemma* 7-nerved, glumiform, obtuse. *Lower palea* 0.3–0.7 mm long, 0.1–0.2 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* ovoid, 1–1.2 mm long, 0.6–0.9 mm wide, biconvex, whitish, indurate, smooth, glabrous, papillose; lemma shortly apiculate; stamens 3, the anthers 0.5 mm long. *Caryopsis* unknown.

*Distribution and ecology:* southern United States, Mexico, Mesoamerica, and the West Indies, in South America in Colombia and Venezuela. Commonly found in wet meadows or swampy areas and savannas, between sea level and 2,100 m.

*Selected specimens cited.* BELIZE. BELIZE: 4 km W of Hattieville along the western hwy. to Belmopan, 80 m, *Davidse & Brant 32982* (MO, SI). EL CAYO: Mountain Pine Ridge, along Coona Cairn Road, *Davidse & Brant 33037A* (MO). ORANGE WALK: savanna ca. 5 km N of August Pine Ridge on the road to Trinidad, *Davidse & Brant 32810* (MO). (A–C, based on *Alvarenga & Oliveira 525*; D, E, based on *Hatschbach & Guimaraes 45170*; F, G, based on *Chase 8327.*)

*er palea* lanceolate, (1.5–)2.1 mm long, 0.6 mm wide, membranous, the margins ciliate; lower flower absent or present, male when present, with 3 anthers each 1 mm long. *Upper anthecium* ellipsoid, 1.9–2.5 mm long, 0.9–1.2 mm wide, indurate, smooth, the apex of the lemma apiculate, scaberulous; stamens 3, the anthers 0.3–1 mm long. *Caryopsis* ellipsoid, 1.7 mm long, 1 mm wide; hilum punctiform, embryo ⅓ the length of the caryopsis.

*Distribution and ecology:* Brazil, on mountain slopes from Espírito Santo to Rio Grande do Sul, 900–2,650 m.

*Additional specimens examined.* BRAZIL. ESPIRITO SANTO: Serra do Caparaó, rocky open campo, 2,650 m, *Mexía 4014* (NY, P, US); Serra do Caparaó, 2,280–2,400 m, *Chase 10084* (IAN, RB, US). MINAS GERAIS: Barbacena, Serra Mantiqueira, *Chase 8667* (F, US); Ouro Preto, Villa Rica, 1,100 m, *Chase 9350* (F, GH, MO, NY, US); cerrado on middle slopes of Pico de Itacolumí, ca. 3 km S of Ouro Preto, 1,750 m, *Irwin et al. 29483* (MO, UB); Mun. Itamonte, Parque Nacional de Itatiaia, camino para las Agulhas Negras, 1,550–1,800 m, *Zuloaga et al. 2374** (MO, RB, SI, US). PARANA: 4 km E of Guarapuava along highway BR-277 to Curitiba, 1,050 m, *Davidse et al. 11319* (MO); Bocaiuva do Sul, *Clayton 4285* (K). RIO DE JANEIRO: Alto de Itatiaia, 2,200–2,400 m, *Chase 8299* (NY, US, W); Teresópolis, Posse, morro das Antenas de Televisao, *Sucre 2317* (SI); Tijuca, in open spot at summit, *Chase 12161* (US). RIO GRANDE DO SUL: Cambará do Sul-Itaimbezinho-Bela Vista, *Valls et al. 1870, 2903* (CEN); Serra da Rocinha, prope Bom Jesus, in dumetosis, *Rambo 53841* (US). SANTA CATARINA: Mun. Caçador, 9 km W of Caçador, *Smith & Klein 10899* (NY, US); Mun. Bom Jardim da Serra, Alto, 20 km S of Bom Jardim, *Smith & Klein 15809* (HB, NY, P, US); 5 km S of Ponte Alta along highway BR-116 to Lajes, *Davidse et al. 11104* (MO, SP); Ponte Serrado, 94 km W of Joaçaba, 700–900 m, *Smith & Klein 14008* (HB, K, SI); Mun. Urubici, 19 km N of Perico, *Smith & Klein 15889* (HB, US); Mun. Lajes, Serra do Ilhéos, *Smith & Klein 15456* (K, US). SÃO PAULO: Jardin Botânico e Parque do Estado, *Sendulsky 1063* (SI); Campos do Jordão, Serra Mantiqueira, sandy campo, 1,600 m, *Chase 9822* (NY, US).

Related to *Panicum sabulorum* and *P. stigmosum*, *P. superatum* can be distinguished by its contracted panicles and appressed spikelets.

There are two indurate florets in *Chase 9403*. *Sendulsky 1063* has anthers only 0.3 mm long.

**34. Panicum surrectum** Chase ex Zuloaga & Morrone, Novon 1: 111. 1991. TYPE: Brazil. Minas Gerais: Barbacena, long and tangled in moist brushy base of higher slope, *Chase 8664* (holotype, US; isotypes, F, NY). Figures 24D, 30.

Short-rhizomatous perennial. *Culms* decumbent to geniculate, then erect, branching at the upper nodes, scandent, 45–120 cm tall; internodes compressed or cylindric, 7–13 cm long, glabrous; nodes compressed, glabrous, brownish. *Sheaths* 4–10.5 cm long, shorter than the internodes, glabrous to papillose-pilose toward the base, shiny, one margin ciliate, the other one ciliate toward the base, otherwise glabrous. *Ligules* 0.2 mm long, membranous-ciliate; collar pilose. *Blades* linear-lanceolate, 5–12 cm long, 0.6–1 cm wide, glabrous to short-hispid, attenuate at the base and apex, the margins scabrous, long-ciliate toward the base; midnerve conspicuous. *Inflorescences* terminal, exserted; *panicles* lax, diffuse, 3.5–15 cm long, 3–10 cm wide; *main axis* glandular or eglandular, flexuous, glabrous, the pulvini glabrous; first-order branches ascendent, whorled toward the base, then subopposite or alternate, the axis of the branches glabrous, flexuous, glandular or eglandular; pedicels triquetrous, glabrous, glandular or eglandular. *Spikelets* narrowly ellipsoid, 1.8–2.2 mm long, 0.8 mm wide, glabrous, greenish, nonstipitate, the upper glume and lower lemma subequal, the nerves manifest. *Lower glume* ovate, 0.9–1.3 mm long, ⅖–½(–¾) the length of the spikelet, not embracing the upper glume, (1–)3-nerved, the lateral nerves inconspicuous. *Upper glume* 1.6–2 mm long, not covering the apex of the upper anthecium, 9-nerved. *Lower lemma* glumiform, 1.8–2.1 mm long, 9-nerved. *Lower palea* lanceolate, 1.5–1.8 mm long, 0.4 mm wide, shortly pilose near the apex, otherwise glabrous, hyaline; lower flower male or sterile, stamens 3, the anthers 1 mm long. *Upper anthecium* ellipsoid, 1.6–1.8 mm long, 0.7 mm wide, pale, indurate, papillose, the apex of the lemma shortly crested and pilose; stamens 3, the anthers 1.2 mm long, purplish. *Caryopsis* ovoid, 1.3 mm long, 0.7 mm wide; hilum punctiform, embryo less than ¾ the length of the caryopsis.

*Distribution and ecology:* Brazil, occasionally present in Paraguay, found at forest edges, between 600 and 1,800 m.

*Additional specimens examined.* BRAZIL. DISTRITO FEDERAL: ca. 35 km E of Brasília, *Irwin & Soderstrom 5419* (NY, UB, US). GOIAS: Luziania, 15 km ao S da cidade, *Heringer 18124* (IBGE, RB). MATO GROSSO DO SUL: Dourados, *Chase 11023* (IAN). MINAS GERAIS: 19 km NE of the intersection of Hwys. 381 and 459, ca. 12 km SW of São Gonçalo do Sapucai, 870 m, *Davidse & Ramamoorthy 10602* (MO, SI); Itacolumy, E of Ouro Preto, 1,400 m, *Chase 9380* (NY, US), *9407* (US); Juiz de Forá, *Krieger SVD 1227* (RB, US); Poços de Caldas, 1,100–1,500 m, *Chase 10677* (NY, SP, US); Serra da Gramma, 1,700 m, slope above jungle, *Chase 9555* (F, GH, NY, US). PARANA: Mun. Gral. Carneiro, Rio Lageado, *Hatschbach et al. 13731* (K); Três Barras, *Dusén 17531* (F, G, GH, NY, US). RIO DE JANEIRO: below Macieiras, Serra de Itatiaia, 1,700–1,800 m, *Chase 8324* (GH, NY,

US). RIO GRANDE DO SUL: Taimbezinho, pântano, *Boechat s.n.* (ICN 41067). SANTA CATARINA: Rio Capinzal, *Dusén 17876* (US); Santa Cecilia, 1,100 m, *Reitz & Klein 11358* (US). SÃO PAULO: Serra Mantiqueira, Campos do Jordao, 1,580 m, open sandy campo, *Chase 9815* (F, NY, US) *9839* (NY, US), *Holway 1737* (US), *Leite 3510* (GH). PARAGUAY. CAAGUAZU: Caaguazú, *Balansa 7* (G).

*Panicum surrectum* shows affinities with *P. sabulorum*, *P. stigmosum*, and *P. superatum*. *Panicum surrectum* is characterized by its long-ellipsoid spikelets, and smaller lower glume, not embracing the upper glume. *Panicum stigmosum*, *P. sabulorum*, and *P. superatum* have a lower glume ½–¾ the length of the spikelet, covering the base of the upper glume, and ellipsoid to obovoid, globose spikelets. Additionally, in *P. superatum* the panicles are contracted, with the spikelets congested on the branches, and *P. stigmosum* has bigger spikelets, (2–)2.4–3.2 mm long, and leaves 10–22 cm long.

*Panicum surrectum* has, as other species of subgenus *Dichanthelium* (Morrone & Zuloaga, 1991), conspicuous glands on the axis and pedicels of some specimens.

Cleistogamous flowers were observed in *Chase 9815*, with anthers 0.6 mm long.

**35. Panicum telmatum** Swallen, Phytologia 14: 81. 1966. TYPE: Frontier between Roraima, Brazil and Bolívar, Venezuela, Serra do Sol, 28 Dec. 1954, 2,100 m, *Maguire & Maguire 40400* (holotype, US 2182190; isotype, NY). Figure 31.

Tufted perennial. *Culms* elongated, arching, branching, internodes cylindric, hollow, densely hispid with appressed hairs; nodes pilose. *Sheaths* papillose-pilose to short-pilose, the margins long-ciliate. *Ligules* membranous-ciliate, membranous portion 0.2 mm long, cilia 0.8–1 mm long, collar pilose with whitish hairs. *Blades* lanceolate, 3.5–5.5 cm long, 4–9 mm wide, flat, the base rounded, the apex acuminate, the adaxial surface sparingly hispid and with long, whitish hairs near the ligule, the abaxial surface scabrous, the margins long-ciliate. *Inflorescence* with base included in uppermost sheath or short-exserted, 3–5 cm long, pyramidal, few-branched, the branches divergent from the axis; *main axis*, the branches and pedicels hirsute with whitish hairs. *Spikelets* solitary, ellipsoid, 3–3.2 mm long, 1.2–1.4 mm wide, minutely appressed-puberulent; lower glume separated from the upper glume by a short internode. *Lower glume* 2–2.3 mm long, broadly ovate, blunt, 3–5-nerved, about ¾ the length of the spikelet, the nerves anastomosing. *Upper glume and lower lemma* as long as spikelet, broadly rounded on back, 7–9-nerved, the nerves anastomosing toward the apex. *Lower palea* ovate, 2 mm long, 0.6–0.8 mm wide, ca. ⅔ as long as the lemma, hyaline, glabrous, the margins short-ciliate, the lower flower absent. *Upper anthecium* ellipsoid, 2.3–2.5 mm long, 1.1 mm wide, nearly as long as spikelet, glabrous, short-pilose at the apex of the lemma; lemma 7-nerved, with simple papillae over its entire surface. *Caryopsis* unknown.

*Distribution and ecology:* endemic to Uei-tepui (Cerro del Sol), Venezuela, about 25 km SE of Mt. Roraima, where growing in "burnt part of boggy central area."

*Additional specimens examined.* VENEZUELA. BOLIVAR: Distr. Roscío, altiplanicie que rodea la cumbre del Uei-tepui (Cerro del Sol), sector occidental por encima del valle del Río Arabopo, *Huber 10008* (MO, MYF, SI).

*Panicum telmatum* is related to *P. sabulorum*; the latter species has smaller, biconvex obovoid spikelets 1.9–3 mm long and is known from central and southern Brazil, Paraguay, Uruguay, Bolivia, Chile, and Argentina.

**36. Panicum umbonulatum** Swallen, Contr. U.S. Natl. Herb. 29: 420. 1950. *Dichanthelium umbonulatum* (Swallen) Davidse, Novon 2: 105. 1992. TYPE: Guatemala. Zacapa: upper slopes of Sierra de Las Minas, along Río Repollal, 2,100–2,400 m, 12–13 Jan. 1942, *Steyermark 42469* (holotype, US 1935002; isotypes, F, NY). Figure 31.

*Panicum alcobense* Swallen, Contr. U.S. Natl. Herb. 29: 423. 1950. TYPE: Guatemala. Jalapa: collected in oak wood around top of Cerro Alcoba, just E of Jalapa, 1,700 m, 2 Dec. 1939, *Steyermark 32515* (holotype, F 1040005; fragment and photo, US 2236474).

*Panicum ramiparum* Swallen, Contr. U.S. Natl. Herb. 29: 423. 1950. TYPE: Guatemala. Quezaltenango: collected in mountains near Santa María, S of Quezaltenango, 25 Mar. 1932, *Weatherwax 160* (holotype, US 1914983).

Perennial without a basal rosette of broader leaves. *Culms* decumbent, rooting and branching at the lower nodes and trailing, to erect, 40–100 cm tall, internodes terete, hispid, greenish to purplish; nodes compressed, purplish, densely papillose-pilose with whitish retrorse hairs. *Sheaths* striate, papillose-pilose with deciduous tuberculate hairs, the margins ciliate. *Ligules* membranous-ciliate, 0.6–1 mm long; pseudoligule present, with long hairs at the adaxial surface of the blade; collar

densely pilose. *Blades* lanceolate, 5–12 cm long, 0.4–1.4 cm wide, flat, the base cordate to subcordate, the apex acuminate, short-hispid on the adaxial surface or glabrous and long-pilose toward the base, the lower margins ciliate, otherwise glabrous. *Inflorescences* terminal, exserted, peduncle terete, ca. 20 cm long, hispid, densely pilose toward the distal portion near the junction with the panicle; *panicles* lax, diffuse, multiflowered, 4–12 cm long, 3.5–10 cm wide; *main axis* flexuous, hispid, the pulvini pilose; first-order branches alternate, divergent, the axis of the branches triquetrous, greenish to purplish, scabrous and sparsely hispid, spikelets solitary on second- or third-order branches; pedicels triquetrous, scabrous. *Spikelets* ellipsoid, (2.2–)2.4–2.8 mm long, 1–1.1 mm wide, greenish to purplish, plano-convex, sparsely hispid or glabrous, the upper glume and lower lemma subequal, as long as or shorter than the upper anthecium. *Lower glume* 1.2–1.4 mm long, ⅓–½ the length of the spikelet, obtuse, 1-nerved, not embracing the upper glume. *Upper glume* 7–9-nerved. *Lower lemma* glumiform, 7-nerved. *Lower palea* lanceolate, 1.5 mm long, 0.4 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* narrowly ellipsoid, 2.4–2.5 mm long, 0.9–1.1 mm wide, whitish, smooth, shiny, indurate, papillose, apiculate and short-pilose and with a green spot on the apex of the lemma. *Caryopsis* ellipsoid, 1.6 mm long, 1 mm wide; hilum punctiform, embryo less than ½ the length of the caryopsis.

*Distribution and ecology:* Mexico to El Salvador, and Ecuador, on forest edges, in moist places, between 550 and 2,400 m.

*Additional specimens examined.* ECUADOR. LOJA: Argelia, 2,300 m, *Espinosa 547* (US). EL SALVADOR. SANTA ANA: Hacienda San José, *Rohweder 2111* (MO). GUATEMALA. EL PARAISO: 31 km S of El Zamorano, on road between Guinope and Mandasta, *Pohl & Davidse 12152* (MO); edge of bog in mixed oak-pine forest near Piedra Herrada, 1,500 m, *Williams 15983* (US). FRANCISCO MORAZAN: Universidad, Campo abierto, *Lainez 91* (MO); W slope of Cerro de Uyuca, along trail from Las Flores toward Tatumbla, 1,600 m, *Standley 22813, 23466* (US); SW of San Juancito, *Pohl & Davidse 11984* (MO); Jutiapa, ca. 7 km NE of Tegucigalpa, *Pohl & Davidse 11977* (MO); La Tigra, 35 km NE de Tegucigalpa, *Ordoñez 42* (MO). OCOTEPEQUE: alrededores de Belén Gualcho, *Nelson et al. 4026* (MO). MEXICO. CHIAPAS: Mun. Siltepec, on the ridge above Siltepec on the road to Huixtla, *Breedlove & Almeda 58273* (MO). OAXACA: 56 km de Tlaxiaco rumbo a Putla, *Beetle M-4807* (MO).

This species is related to *P. viscidellum*, differing in its larger spikelets (2.2–)2.4–2.8 mm long. It is also related to *P. divergens*; the latter species lacks a conspicuous pseudoligule and usually has sparsely hispid spikelets.

**37. Panicum viscidellum** Scribner, U.S.D.A. Div. Agrost. Circ. 19: 2. 1900. *Dichanthelium viscidellum* (Scribner) Gould, Brittonia 32(3): 357. 1980. TYPE: Mexico. Veracruz: near Jalapa, 1,250 m, 1899, *Pringle 8089* (lectotype, US 354526; isolectotypes, M, MO, P). Figures 18, 19, 20, 30.

*Panicum tremulosum* Mez, Notizbl. Bot. Gart. Berlin-Dahlem 7: 76. 1917. TYPE: Venezuela. Distrito Federal: prope Caracas, *Moritz s.n.* (holotype, B; fragment, US).

*Panicum longiculme* Swallen, J. Wash. Acad. Sci. 21: 15. 1931. TYPE: Colombia. Antioquia: Quebrada del Alto, in mountains above Bello, 17 June 1930, *Archer 160* (holotype, US 1445529).

*Panicum blakei* Swallen, Contr. U.S. Natl. Herb. 29: 422. 1950. TYPE: Guatemala. Izabal: along trail from Los Amates to Izabal, Cerro de Las Minas, 31 May 1919, *Blake 7817* (holotype, US 1163068).

*Panicum furtivum* Swallen, Contr. U.S. Natl. Herb. 29: 421. 1950. TYPE: Guatemala. Huehuetenango: between Quetzal and Barillas, Sierra de los Cuchumatanes, 1,600–2,000 m, 18 July 1942, *Steyermark 49123* (holotype, US 1935043).

Short-rhizomatous perennial. *Culms* decumbent, rooting and branching at the lower nodes, then erect, branching at the upper nodes, 15–100 cm tall; internodes 3.5–18 cm long, hollow, striate, compressed, hispid, with long, rigid hairs; nodes compressed, densely pilose with whitish, retrorse hairs. *Sheaths* 2.5–13.5 cm long, papillose-pilose with tuberculate, caducous hairs, the margins ciliate. *Ligules* short-membranous at the base, then long-ciliate, 0.3–1(–2) mm long, with a conspicuous pseudoligule with hairs 2–3 mm long; collar pilose. *Blades* ovate-lanceolate to lanceolate, 3–14 cm long, 0.4–2 cm wide, glabrous or short-pilose on both surfaces, the base cordate and clasping, the apex acute, the margins long-ciliate and scabrous. *Inflorescences* terminal, exserted or partially included within the upper leaves, peduncle flexuous, 10–23 cm long, glabrous or sparsely or densely hispid; *panicles* diffuse, 3–12 cm long, 2–

10 cm wide; *main axis* glabrous or densely hirsute; pulvini pilose and scaberulous, first-order branches alternate to subopposite, ascendent and divergent, the axis of the branches glabrous or hispid, eglandular. *Spikelets* solitary, ellipsoid, (1.5–)1.8–2(–2.2) mm long, 0.7 mm wide, sparsely pilose, occasionally glabrous, the upper glume and lower lemma subequal, the stipe absent. *Lower glume* ovate, 0.6–1 mm long, ⅓–½ the length of the spikelet, sparsely pilose, acute, nerveless to 1–3-nerved, not embracing the upper glume. *Upper glume* 1.4–1.8 mm long, 7–9-nerved. *Lower lemma* glumiform, 7-nerved. *Lower palea* 0.7 mm long, 0.2 mm wide, hyaline, glabrous; lower flower absent. *Upper anthecium* ellipsoid, 1.5–1.8 mm long, 0.6 mm wide, indurate, papillose, shortly apiculate, apicule puberulous; stamens 3, the anthers 0.8 mm long. *Caryopsis* ellipsoid, 1.2 mm long, 0.6 mm wide, hilum punctiform, embryo ½ the length of the caryopsis.

*Distribution and ecology:* from Mexico and the West Indies to northern South America, in Colombia, Ecuador, and Venezuela. Commonly found on forest edges, roadsides, and riverbanks, in moist places among shrubs, between 100 and 2,800 m.

MERIDA: Capellanía (Bailadores), 1,600 m, *Tamayo 2362* (VEN). MIRANDA: 34 km NW of Santa Lucía by road, *Davidse 2912* (MO). TACHIRA: between Las Delicias and Paraguita, bordering Río Táchira, *Steyermark 57148* (US).

*Panicum viscidellum* is a common species with some degree of variation in the size of leaves and pilosity, characters that were used for describing *P. tremulosum*, *P. blakei*, and *P. furtivum*. *Panicum viscidellum* is related to *P. sciurotoides* and *P. umbonulatum*, differing from the first species by the presence of a conspicuous pseudoligule and its usually larger spikelets, and from *P. umbonulatum* by its smaller spikelets.

Pohl (1980) noted that the correct name for this species might be *Panicum reflexopilum* Steudel, Syn. Pl. Glumac. 1: 84. 1853 (described from Oaxaca, Mexico). However, neither he nor we could find the type specimen of *P. reflexopilum*, so the name remains dubious.

All specimens examined for anatomical purposes have a leaf anatomy typical of section *Dichanthelium*, including numerous macrohairs, either cushion-based (Fig. 18D) or with few modified epidermal cells associated with the hair bases (Fig. 19A–D). Several of the specimens exhibit an unusual silicification of the basal cells associated with the macrohairs (Fig. 20). The hairs themselves may be lost but the modified, swollen basal cells are then clearly seen to contain opaline silica deposits (Fig. 20F).

# A REVISION OF *MONNINA* SUBG. *PTEROCARYA* (POLYGALACEAE) IN NORTHWESTERN SOUTH AMERICA[1]

*Bente Eriksen*[2]

ABSTRACT

Three subgenera are currently recognized in the genus *Monnina*, which consists of approximately 175 species. This paper treats the systematics of *Monnina* subg. *Pterocarya* in northwestern South America. The subgenus is a naturally coherent taxon characterized by dry, samaroid fruits. It consists of ca. 25 species, 11 of which occur in the area concerned.

The genus *Monnina* was established by Ruíz & Pavón (1798) and was dedicated to José Moñino, the count of Floridablanca. It comprises fruticose species with drupaceous fruits, as well as herbaceous ones with more or less winged samaras. De Candolle (1824) described the section *Pterocarya* to accommodate the species that have the fruit margin expanded into a membranaceous wing. This division, however, is artificial because it neglects a number of species with samaras, where the wing is small or completely lacking. Chodat (1896) realized this and emended section *Pterocarya* DC. to comprise all annual or perennial herbs with samaras and gave the taxon subgeneric rank. The genus *Monnina* comprises ca. 175 species, ca. 25 of which belong to the subgenus *Pterocarya*.

Species of *Monnina* subg. *Pterocarya* have never been revised as a group. The works of Chodat (1894, 1896, 1909, 1915, 1934), Chodat & Wilczek (1902), and Ferreyra (1990) mostly included various descriptions of new species, and those of Ferreyra (1946, 1953) and Grondona (1945) were entirely floristic. The aim of the present paper is to give an extensive treatment of the subgenus in the northern Andes. Here, the southern limit of the northern Andes is defined as the Peruvian border with Chile and Bolivia. This geographical boundary coincides with a natural phytogeographical boundary (Molau, 1988). A revision of the remainder of the species is in preparation.

## ECOLOGY AND GEOGRAPHICAL DISTRIBUTION

Plants of *Monnina* subg. *Pterocarya* are confined to semiarid habitats. The distribution is disjunct, with a western and eastern territory in South America and an exclave in Mexico and the southwestern United States. The western territory is found along the coast of the Pacific Ocean and in the mountains from southern Ecuador to central Chile, extending into western Bolivia and Argentina. The eastern territory covers northeastern Argentina, southern Paraguay, Uruguay, and the dry parts of southeastern Brazil, principally east of Río Paraná (Fig. 1). The map shows the narrow gap in the South American distribution area directed north-south through Argentina. The gap coincides with the extensive plain occupied by the Larrea Desert of Gran Chaco and adjacent areas (Walter, 1979) and is probably too dry to be favorable for *Monnina*. Grondona (1945) noticed the absence of *Monnina* in this particular area and established, as a consequence, their preference for mountainous habitats. He did not exclude the possibility that specimens might be collected there in the future. Since Grondona wrote the Flora, however, no spec-

[1] This paper is based upon research supported by Anna Ahrenbergs Fond, Kungl. och Hvitfeldtska stipendieninrättningen, and Adlerbertska forskningsfonden, which are gratefully acknowledged. I deeply appreciate the comments and criticisms of Ulf Molau, Lennart Andersson, and Gunnar Harling. I thank the curators of the following herbaria for allowing me to examine material under their care: AAU, B, F, G, GB, GH, GOET, K, L, LE, LY, M, MA (photos of types), MO, MOL, NY, P, PH, QCA, S, UC, US, USM, W, and WIS. I also thank Torkel Hagström at the Museum of Natural History in Göteborg for determining the insect found in the flowers of *M. pterocarpa*. South American maps are the Flora Neotropica base map no. 1 prepared by H. R. Rypkema, Institute for Systematic Botany, State University of Utrecht.

FIGURE 1. Distribution of *Monnina* subg. *Pterocarya*.

imen has been found in that area. The fact that different species occur on either side of the gap supports the assumption that the plain serves as a barrier. To the north, the two territories are delimited by areas with higher humidity or, in the Planalto do Mato Grosso, by periodical flooding. The coastal desert of Peru is, like the Gran Chaco, very dry and should be unsuitable for *Monnina* species, but here the "garua," or fog blanket, caused by the cold sea current off the Peruvian coast, plays an important role. Even though the precipitation is not measurable, a considerable amount of water is yielded through fog (Walter, 1979).

Only one species occurs north of the equator, viz *M. wrightii* in Mexico and the southwestern United States, but the same species is abundant in Bolivia and Argentina and has probably been introduced to Mexico.

The semiarid habitats to which the species are confined are usually devoid of dense and tall vegetation. In some areas of southern Ecuador the natural vegetation is mainly dense shrubland, and competition for light does seem to be a limiting factor. The *Monnina* species here are always confined to open grassland, natural or artificial.

Flowering begins near the end of the rainy season and continues 3–9 months. In habitats with sporadic rainfall, the flowering season is variable and flowering occurs whenever humidity allows it.

The altitudinal range of *Monnina* is rather wide, sometimes even within species. In most cases, however, two species sharing latitude are usually separated altitudinally with little or no overlap.

As the different species are rarely sympatric, it is not surprising that no specimens have been found that could be interpreted as hybrids. Besides, the pollination mechanism in *Monnina* is likely to prevent interspecific pollination. The flowers are pollinated by bumblebees. On landing, the insect presses the released pollen through an opening near the

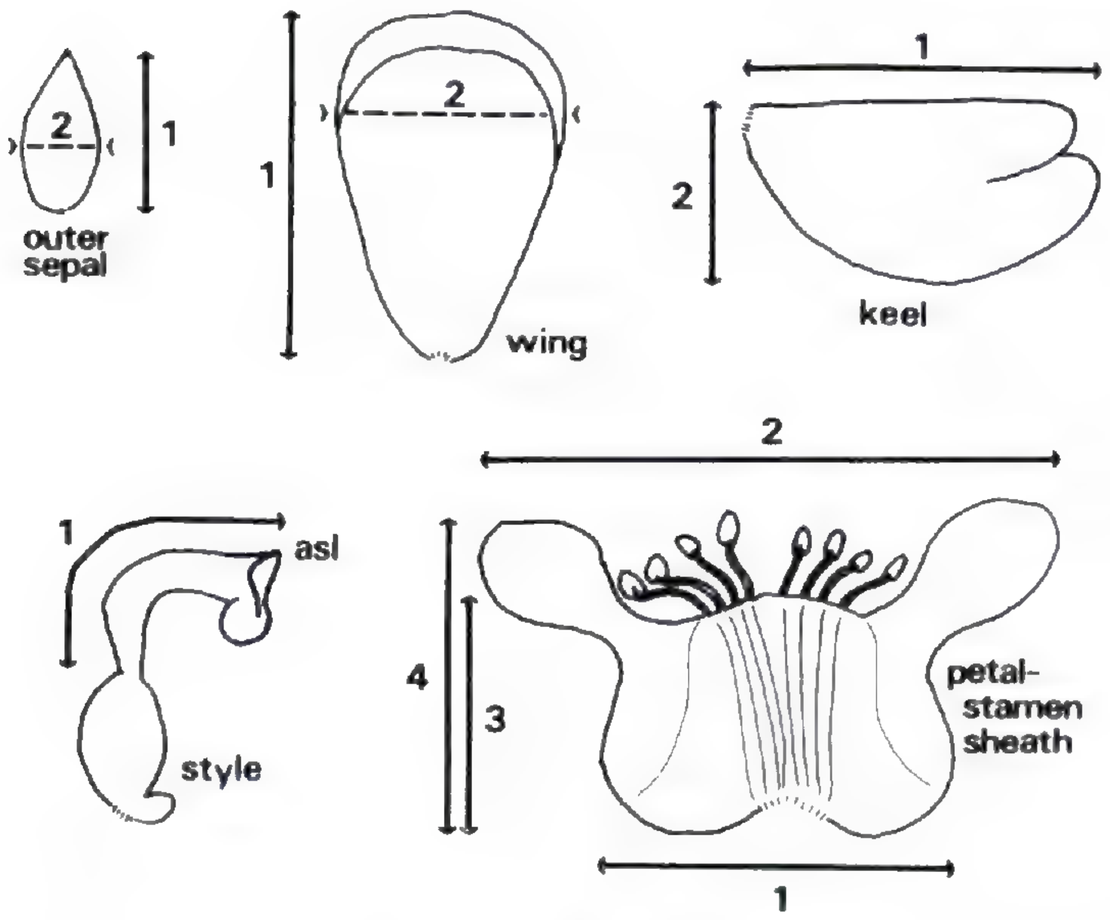

FIGURE 2. Floral structures showing the way in which the various parts were measured. Outer sepal, wing, and keel given as *1* × *2*. Style length *1*. Petal-stamen sheath given as *1/2* wide, *3/4* high. asl = anterior stylar lobe.

apex of the keel and at the same time foreign pollen is deposited on the stigma. Because the species differ greatly in flower size and stigma position, only a flower of the same species gets pollinated, even if the insect visits another species during a foraging bout.

## MATERIALS AND METHODS

This study is based on herbarium specimens, pickled material, and fieldwork. Field studies were carried out in 1987–1988 in Ecuador and northern Peru. Five species of *Monnina* subg. *Pterocarya* were seen in the field.

### MEASUREMENTS

Measurements were taken on the leaves of the main axis (leaves on the branches are generally smaller). The measurements are given in the descriptions as length × width. For the inflorescence, the main one was measured (inflorescences on the branches are shorter). Inflorescences that have started to fruit were selected, since the inflorescence axis elongates during flowering.

The pedicel was measured when carrying an open flower.

The flower parts measured were taken from the bud just above the youngest unfolded flower. This choice ensures intact flower parts and still gives a relatively good picture of the flower size. The way in which the various flower parts were measured is shown in Figure 2. In the descriptions, measurements for the petal-stamen sheath are given as "width at base"/"width across petal lobes" and "length of filament sheath"/"total length including petal lobes."

Fruit size is given for mature fruits.

Vegetative parts of dry material were measured. My experiments have shown that leaves of *Monnina* shrink approximately 10% in the drying process. The descriptions have not been corrected for shrinkage. Flowers are measured on rehydrated material, except for a few specimens of which I have pickled material.

### TERMS

The nodal glands present in some species of *Monnina* are traditionally, and so also here, called stipules, although they are not homologous with stipules.

The construction of the flower in *Monnina* is quite extraordinary, and this type of papilionaceous flower is unique for the Polygalaceae. Figure 2 shows the floral parts and the terms used for each.

## SYSTEMATICS

**Monnina** subg. **Pterocarya** (DC.) Chodat, Bull. Herb. Boissier 4: 251. 1896. *Monnina* sect. *Pterocarya* DC., Prodr. 1: 340. 1824. TYPE: *Monnina pterocarpa* Ruíz & Pavón, lecto-type here designated.

Annual or perennial herbs. Leaves alternate, short-petiolate to subsessile, with or without stipules. Stems and branches terete, covered by unicellular hairs, either white, conical and curved or compressed and straight, or yellowish with knoblike thickenings on their outer side and ± straight. Laminae simple, pinnately veined, entire or rarely undulate. Flowers arranged in simple racemes, each subtended by a bract and two bracteoles, irregular; outer sepals 3, small, herbaceous, free or rarely the lower two shortly connate at base; inner sepals (wings) 2, large, lateral, petaloid; petals 3, the lower (keel) carinate, the upper two united in their lower part with the filament sheath (see below), but free from each other, forming a conduplicate petal-stamen sheath; stamens diadelphous, (4–)6–8, the filaments fused for most or all of their length into a filament sheath to which lateral margins the upper petals are adnate; style compressed, geniculate to gently curved, apically unequally cleft, the posterior lobe with a sessile or ± stalked capitate or discoid stigma, the anterior lobe sterile, often forming a tooth. Ovary 1- or 2-locular, subtended by a glandular disc enlarged toward the adaxial side into a knoblike process. Fruit a regularly or irregularly winged, or occasionally wingless samara.

KEY TO THE SPECIES OF *MONNINA* SUBG. *PTEROCARYA* IN NORTHWESTERN SOUTH AMERICA

1a. Stipules absent.
2a. Stamens 8, the filaments free in the upper part, or anthers seemingly sessile.
3a. Fruit villous.
4a. Perennial, the leaves linear, ericoid ..... 1. *M. fosbergii*
4b. Annual, most leaves rhomboid, not ericoid.
5a. Stem and branches erect, wings and keel bright blue, the keel yellow apically, anterior stylar lobe a blunt tooth ..... 2. *M. leptostachya*
5b. Stem and branches ascending, wings pale blue, the keel pale yellow throughout, anterior stylar lobe a pointed tooth ..... 3. *M. polygonoides*
3b. Fruit glabrous or pubescent.
6a. Filaments free in the upper part ..... 4. *M. ramosa*
6b. Filaments adnate throughout, the anthers seemingly sessile on the petal-stamen sheath.
7a. Leaves linear, style straight or bent 30°, posterior stylar lobe with a spherical stigma apically ..... 5. *M. macbridei*
7b. Leaves narrowly obovate to narrowly rhomboid, the upper leaves sometimes linear, style bent 80–90°, posterior stylar lobe carrying a bilobed, discoid stigma at base ..... 6. *M. macrostachya*
2b. Stamens 6, sometimes 4 in flowers on branches; in each fascicle some or all filaments fused throughout.
8a. The filaments of the two outer stamens of each fascicle connate throughout, the third free in the upper part or reduced (Fig. 8B), the fruits crescent-shaped ..... 9. *M. wrightii*
8b. The filaments of the three (two) stamens of each fascicle all connate throughout (Fig. 8F), the fruits rotund.
9a. Upper leaves narrowly lanceolate to linear, 0.8–3.7 cm long, obtuse, the inflorescence few-flowered, "torpedo"-shaped in outline ..... 7. *M. amarella*
9b. Upper leaves linear, 2.5–7.0 cm long, acute, the inflorescence many-flowered, very narrowly triangular in outline ..... 8. *M. filifolia*
1b. Stipules present.
10a. Tall plant, usually > 0.5 m, the older parts of stem and branches glaucous, the flowers robust, the stigma a sessile or short-stalked, bilobed disc, the fruit always with a broad, entire wing ..... 10. *M. pterocarpa*
10b. Small plant, usually < 0.5 m, the older parts of stem and branches green or straw yellow, flowers delicate, the stigma resembling a hammer-head (Figs. 9K, 10J), the fruit usually irregularly winged, occasionally wingless or with a narrow, entire wing ..... 11. *M. herbacea*

*Distribution.* Dry lowland and mountainous areas from central Ecuador to central Chile, and from central Brazil to Uruguay; Mexico and the southwestern United States (Fig. 1).

**1. Monnina fosbergii** Ferreyra, Phytologia 69: 356. 1990. TYPE: Ecuador. Loja: S of Oña, above Tablón de Oña, 2,740 m, 21 Feb. 1945, *Fosberg 23204* (holotype, US; isotypes, NY, P). Figure 3.

Perennial herb, decumbent, to 70 cm across, 18–28(–50 fide Barclay & Juajibioy) cm tall, the ascendent branches to 40 cm long crowning the short, woody stem. Branches rooting at nodes, terete, 1 mm diam., furrowed by decurrent leaves, white-pubescent, the hairs curved. Leaves exstipulate; petiole very short or absent; blade narrowly lanceolate to linear, ericoid, coriaceous, 4–13 × 1–1.5 mm, acute at apex, cuneate at base, white-pubescent throughout. Inflorescence few-flowered, narrowly triangular in outline, 11–24 cm long; pedicel 0.5 mm, hirsute; bracts lanceolate, acute, 2.0–3.0 × 0.7–0.8 mm, abaxially hirsute, blue with a green, ciliate margin. Flowers all chasmogamous; outer sepals slightly unequal, the upper one ovate, 1.8–2.0 × 0.8–1.0 mm, arched, the lower narrowly ovate, 1.2–2.0 × 0.7–0.8 mm, all ciliate and blue; wings obovate, 3 × 2 mm, truncate at base, the upper margin ciliate, blue; keel 3 × 2 mm, truncate at base, glabrous, blue with a yellow, emarginate and 2-lobed apex; petal-stamen sheath 2–3/4 mm wide, 1.5–2/2–3 mm high, the petals hirsute adaxially and abaxially on the lower half, the lobes blue, otherwise greenish as the filament sheath; stamens 8, the upper part of the filaments free, glabrous, 1.2–1.5 mm long including the anther, the anther to filament ratio 0.3–0.5; style 1.5–2 mm long, glabrous, bent 45° approximately ⅓ from base; anterior stylar lobe a blunt tooth not exceeding 0.1–0.2 mm in length, the posterior lobe with a sessile or very short-stalked, spherical stigma (Fig. 10A). Fruit 2-locular, narrowly obpyriform with a basal tooth dorsally, 2 × 4 mm when mature, villous, wingless, probably green.

*Distribution.* Probably endemic to the Oña area in Ecuador, ca. 2,800 m (Fig. 6B).

*Specimens examined.* ECUADOR. AZUAY/LOJA: between Oña and Rancho Ovejero, 2,800 m, 1–2 Aug. 1959, *Barclay & Juajibioy 8437* (MO). LOJA: road Oña–

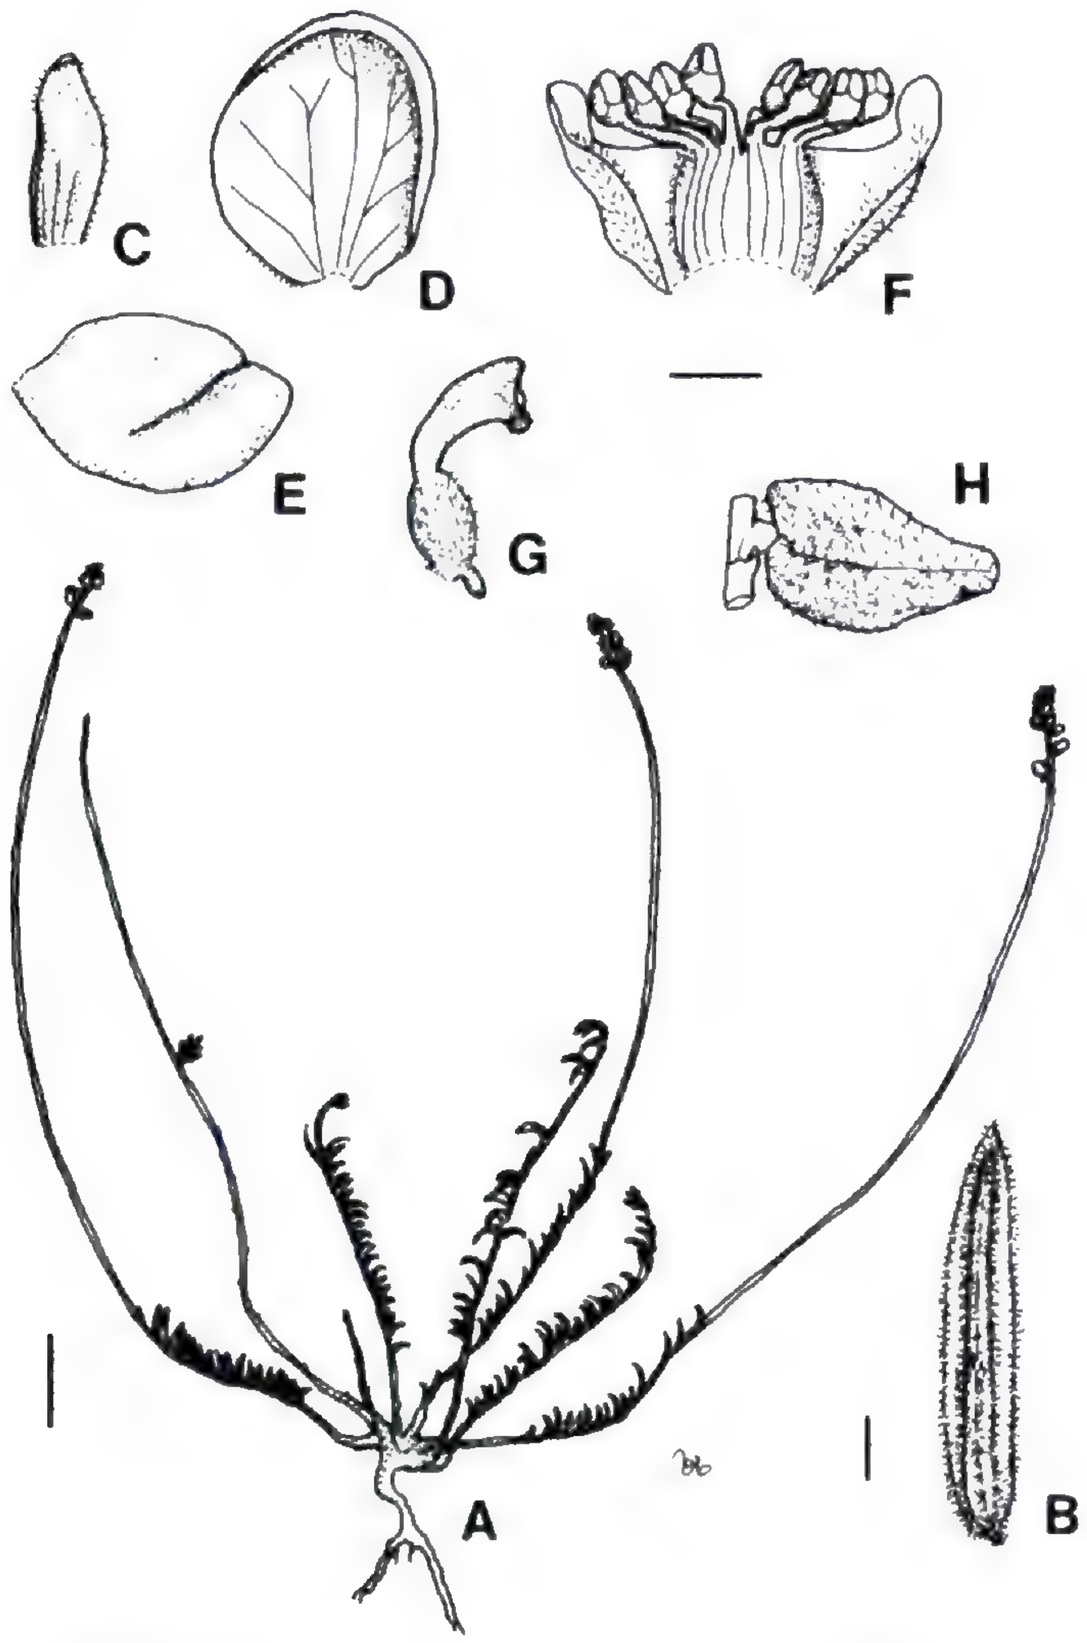

FIGURE 3. *Monnina fosbergii.* —A. Flowering individual. —B. Leaf. —C. Outer sepal. —D. Wing. —E. Keel. —F. Petal-stamen sheath. —G. Gynoecium. —H. Fruit. A–G, *Fosberg 23204* (isotype, NY). H, *Barclay & Juajibioy 8437* (MO). Scales: A = 2 cm. B = 1 mm. C–H = 1 mm.

Saraguro, ca. km 9, 2,800 m, 13 Feb. 1991, *Øllgaard 98803* (AAU, GB, QCA, QCNE).

*Monnina fosbergii* closely resembles the Chilean species *M. linearifolia*, but the floral parts are different. *Monnina fosbergii* has eight stamens, a sessile stigma, and a 2-locular, villous, wingless samara, whereas *M. linearifolia* has six stamens, the stigma at the tip of a very long stalk, and a 1-locular, glabrous, winged samara. Ferreyra (1990), in the original description, compared *M. fosbergii* with *M. filifolia*, to which species it is only distantly related. *Monnina filifolia* has, as the epithet suggests, very narrow leaves, but they are not of the ericoid type. The two species differ in habit and in all essential characters.

Ferreyra (1990) characterized *M. fosbergii* as an erect herb. It is actually decumbent and woody at the base. Perennial species of subgenus *Pterocarya* are common from southern Peru (*M. ramosa*) and southward and in the eastern distribution area, whereas in the north the only perennial representative is *M. fosbergii.* Ferreyra also stated that the ovary is pubescent, which is true only in the broad sense of the word. More precisely, the ovary, and later the fruit, is villous.

**2. Monnina leptostachya** Benth., Pl. Hartw. 125. 1845. TYPE: Ecuador, Loja: near Loja, *Hartweg 713* (lectotype, selected here, K; isolectotypes, NY, P, W). Figure 4.

Annual herb, 15–50 cm, rarely taller. Stem erect, 0.5–3(–4) mm diam., terete or slightly furrowed, unbranched or branched distally, white-pubescent, the hairs curved. Leaves exstipulate; petiole 1–2(–3) mm long, pubescent; laminae on the main axis changing in shape and size from base to apex of the stem; lowermost blades obovate to narrowly obovate, 0.4–4.0 × 0.2–2.0 cm, acute at apex, middle ones rhomboid to narrowly rhomboid, 1.5–6.5 × 0.5–2.5 cm, acute to acuminate at apex, and uppermost blades lanceolate to narrowly lanceolate, 0.8–5.0 × 0.2–1.0 cm, acuminate at apex; all laminae chartaceous, cuneate at base, glabrous except on veins and margin where they are pubescent (in young leaves pubescent throughout). Inflorescence many-flowered, very narrowly triangular in outline, 8–40 cm long; pedicel 0.5 mm long; bracts lanceolate, acute, 1.0–2.0 × 0.3–0.5 mm, less than twice the length of the bud, green, blue, or both colors, ciliate. Flowers all chasmogamous; outer sepals ovate, equal in size or the upper one slightly larger, 1.0–2.0 mm long, ciliate, blue along the margin, otherwise green; wings obovate, 2.5–4 × 2–3 mm, truncate and ciliate at base, bright blue; keel 2.5–4 × 1.5–2 mm, truncate at base, glabrous, bright blue with a yellow, 3-dentate apex; petal-stamen sheath 2–4/4–6 mm wide, 1.5–3/1.5–3 mm tall, the petals hirsute adaxially and at the base abaxially, the lobes bright blue, otherwise greenish as the filament sheath; stamens 8, the upper part of filaments free, glabrous, 0.75–1.25 mm long including the anther, the anther to filament ratio 0:3–0:5; style 2–3 mm long, glabrous, bent 60–90° just above the middle; anterior stylar lobe a blunt tooth, not exceeding 0.1 mm in length, the posterior lobe with a sessile, elongated stigma (Fig. 10B). Fruit 2-locular, ovoid or obpyriform, 1.5–2.5 × 2–3.5 mm, villous, wingless, green, often with purple spots at base or a purple line dorsally.

*Distribution.* Central Ecuador to the Eastern Cordillera of northern Peru. Scattered to locally frequent as a weed in dry scrub, on roadbanks, and among grass in cultivated areas, 1,200–3,000 m (Fig. 6A). It appears after the rainy season and flowers from January to September.

In Peru, *M. leptostachya* has only been collected in Amazonas in the Eastern Cordillera. A similar distribution is shown by *Calceolaria comosa* Pennell subsp. *comosa* (Molau, 1988). The area between the Peruvian and Ecuadorean localities is poorly collected, and it is uncertain whether the distribution is continuous or whether the Peruvian population constitutes an exclave of a disjunct distribution.

*Specimens examined.* ECUADOR. AZUAY: along the Río Tarqui, 4–18 km S of Cuenca, 2,500–2,700 m, 26 Feb. 1945, *Camp E-1836* (NY); near the village of Girón, 2,100 m, 10 Mar. 1945, *Camp E-2199* (F, GH, MO, NY, US); between El Pan and Guachapala, 2,250–2,950 m, 4 Sep. 1945, *Camp E-5263* (NY); Baños, 2,700 m, 17 Sep. 1983, Larsen & Eriksen 45187 (AAU), 2,600 m, 18 July 1939, *Penland & Summers 1058* (GH, NY); Cuenca–Machala road, between Girón and Santa Isabel, km 17 from Girón, 1,800 m, 7 June 1979, *Løjtnant & Molau 14174* (AAU); 10 km S of Gualaceo on road to Sígsig, 2,350 m, 5 Feb. 1988, *Molau, Eriksen et al. 2943* (GB); between Río Molleturo at Huigra and Cruz Pamba, crossing Río Mihuir, N of Molleturo, 1,650–2,300 m, 11 June 1943, *Steyermark 52924* (NY). Calla, 27 km E of Balsas on road to Leimebamba, 2,250 m, 23 Mar. 1988, *Molau & Eriksen 3385* (GB); Taquia E of Chachapoyas, 2,400–2,500 m, 21 June 1948, *Pennell 15582* (PH); Utcubamba S of Chachapoyas, 1,700–1,750 m, 26 June 1948, *Pennell 15590* (PH); 1 km SW of Chachapoyas, 2,300 m, 22 May 1962, *Wurdack 473* (F, GH, UC, US).

*Monnina leptostachya* is closely allied to *M. polygonoides* but is easily distinguished by its erect habit and blunt anterior stylar lobe (see Fig. 10B and C and discussion under *M. polygonoides*).

Ferreyra (1953) synonymized *M. leptostachya* under *M. herbacea*, based on type photographs and fragments. The two species have, in fact, very little in common, and the mistake would not have been made with the original material at hand.

One record states that the vernacular name is "Guarmiiguila," which means small (female) "Iguila." In Quechua, "Iguila" is the common name for all species of *Monnina*.

**3. Monnina polygonoides** Chodat, Bull. Soc. Bot. Genève sér. 2, 25: 200. 1934. TYPE: Peru. Huánuco: Prov. Huánuco, Ambo, 2,100 m, 5 Apr. 1923, *Macbride 3181* (lectotype,

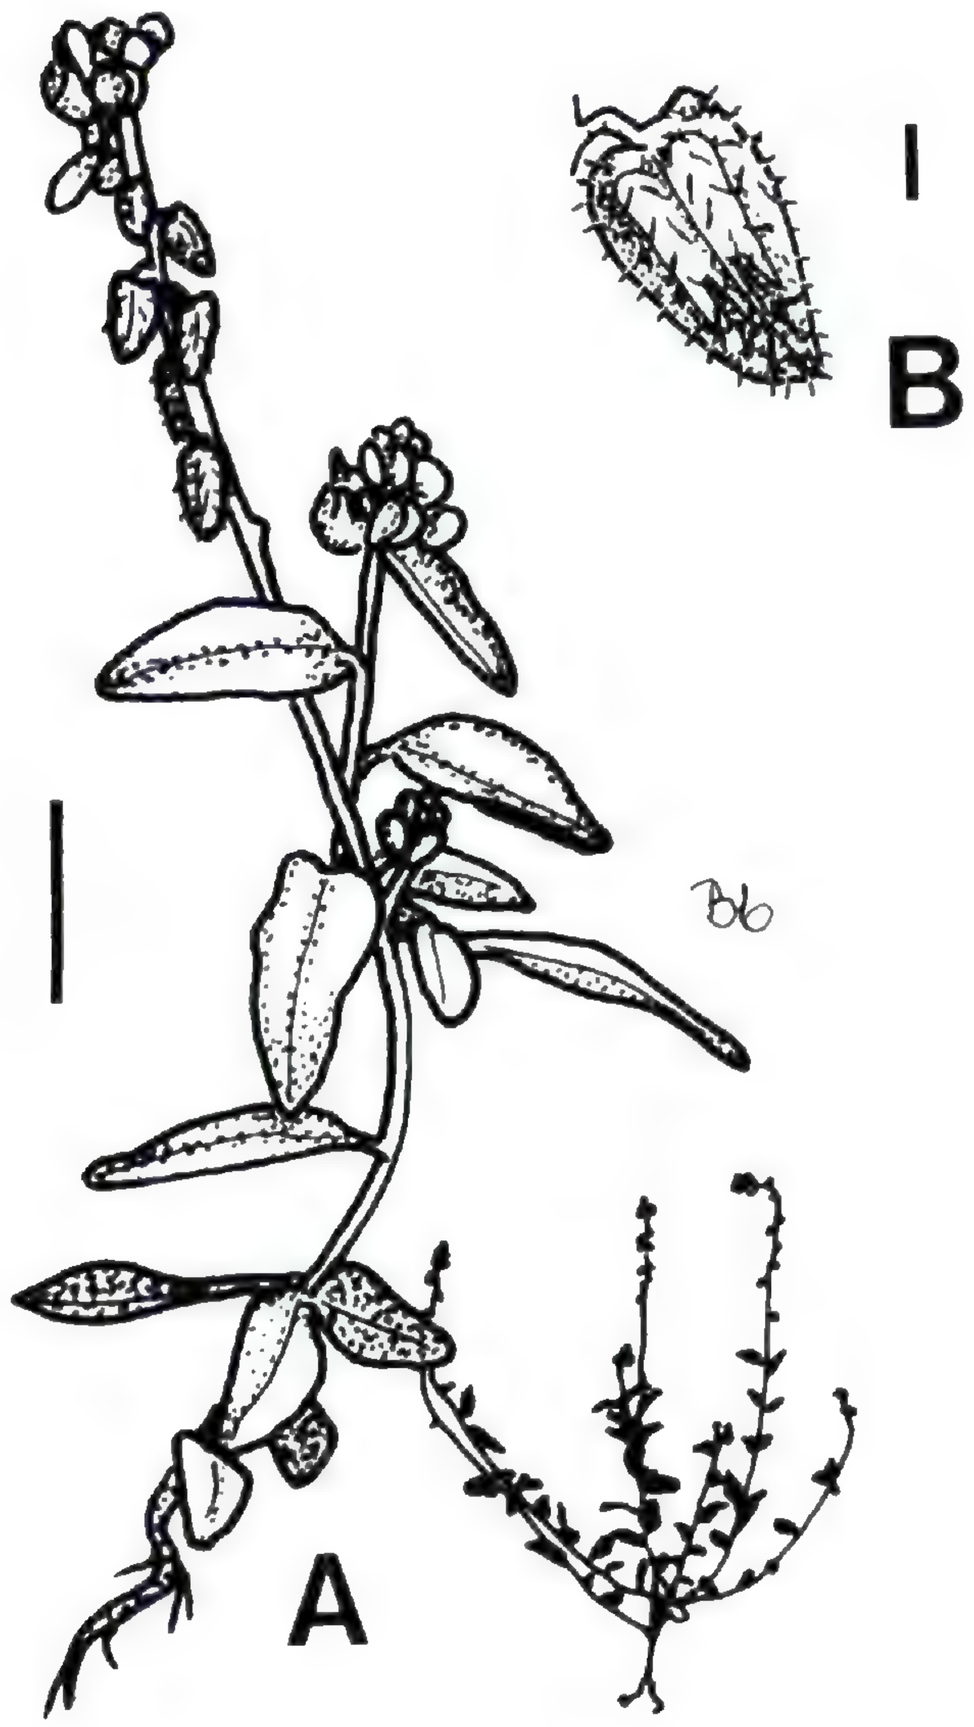

FIGURE 5. *Monnina polygonoides*. —A. Habit and flowering individual. —B. Fruit. A, B, *Molau & Eriksen 3379* (GB). Scales: A = 1 cm. B = 1 mm.

selected by Ferreyra (1946), F; isolectotypes, GH, US). Figure 5.

Annual herb, ascendent, 5–30 cm tall, the branches to 40 cm or more. Stem 0.5–3 mm diam., usually much branched from the base, the stem and branches terete, furrowed by decurrent leaves, white-pubescent, the hairs curved. Leaves exstipulate; petiole 1–1.5 mm long, pubescent; laminae changing in shape and size from base to apex of the branches; lowermost blades narrowly obovate, 0.3–1.5 × 0.1–0.5 cm, obtuse at apex, cuneate at base, middle ones narrowly rhomboid, 0.7–3.2 × 0.3–1.4 cm, acute at apex, cuneate at base, the uppermost leaves lanceolate to linear, 0.9–2.3 × 0.1–0.7 cm, acute at apex, shortly attenuate at base; all laminae chartaceous, minutely mucronate, pubescent on veins and margin, otherwise glabrous (in young leaves pubescent throughout). Inflorescence few-flowered, triangular in outline, 1.5–20(–30) cm; pedicel 0.5 mm; bracts narrowly lanceolate to linear, 1.5 × 0.1–0.2 mm, acute, never exceeding twice the length of the bud, bluish green, ciliate, deciduous. Flowers all chasmogamous; outer sepals usually slightly unequal, the upper one narrowly ovate to lanceolate, 1.5 mm long, 3-nerved, the lower ones ovate, 1.0–1.5 mm long, 1-nerved, all of them ciliate, greenish blue to pale blue; wings obovate, 2.5–3.5 × 2–2.5 mm, truncate at base, glabrous, pale blue; keel 2.5–3.5 × 2 mm, truncate at base, glabrous, pale yellow, 3-dentate at apex; petal-stamen sheath 2.5–3/4–5 mm wide, 1.5–2/2–3 mm long, the petals hirsute adaxially and at base abaxially, the lobes pale blue, otherwise yellowish as the filament sheath; stamens 8, the upper part of filaments free, glabrous, 1–1.5 mm long including the anther, the anther to filament ratio 0.3–0.5; style 1.5–2 mm long, glabrous, bent 45° just above the middle; anterior stylar lobe a pointed tooth, 0.2–0.25 mm long, the posterior lobe with a sessile, rounded stigma (Fig. 10C). Fruit 2-locular, narrowly obpyriform with a dorsal gibba, 2 × 4 mm, villous, wingless, green, the gibba purple.

*Distribution.* Northern to central Peru. Steep, rocky slopes in dry, mountainous areas, 2,000–2,850 m (Fig. 6C). It has been collected flowering from February to May, i.e., from the end of the rainy season and a couple of months onward.

*Specimens examined.* PERU. AMAZONAS: Prov. Bongara, road Moyobamba–Chachapoyas, 2,250 m, 13 Apr. 1984, *Croat 58232* (MO); Prov. Chachapoyas, 9 km below and W of Chachapoyas on road to Caclic, 2,000 m, 25 Mar. 1964, *Hutchison & Bennett 4516* (F, UC). ANCASH: Prov. Bolognesi, Conay, 6 km below Chiquián, 2,600 m, 12 May 1950, *Ferreyra 7381* (UC, mixed coll.); Prov. Huaylas, dry hillsides above Río Santo across from Mancos, 10 Apr. 1970, *Earle Smith & Blas 4922* (US). CAJAMARCA: Prov. Cajamarca, Quebrada de San Vicente SW of Cajamarca, 2,800–2,850 m, 4 Apr. 1948, *Pennell & Reichlin 14999* (PH); Prov. Celendín, Celendín, 2,700 m, 18 May 1964, *Hutchison & Wright 5144* (F, GH, MICH, MO, UC); 4–5 km E of Celendín on road to Balsas, 2,750 m, 23 Mar. 1988, *Molau & Eriksen 3379* (GB); Limón E of Celendín, 2,000 m, 15 Apr. 1948, *Pennell 15181* (GH, PH). Huánuco, Acomayo, 2,100 m, 10 Feb. 1946, *Woytkowski 34014* (F, MO, UC), 2,300 m, 22 Apr. 1946, *Woytkowski 34234* (F, MO, UC). LA LIBERTAD: Prov. Santiago de Chuco, near Santiago de Chuco, 2,800 m, 13 June 1984, *Sagástegui et al. 11773* (MO). PASCO: Prov. Pasco, Huariaca, 2,900 m, 3 Apr. 1923, *Macbride 3116* (syntypes, GH, MICH, US). Department unknown: sine loco, *Weberbauer 6235* (F).

*Monnina polygonoides* is closely related to *M. leptostachya*. These two species are primarily characterized by 2-locular, villous fruits. However, *Monnina polygonoides* is ascendent, has pale blue flowers, and a pointed anterior stylar lobe (Fig.

10C), whereas *M. leptostachya* is erect, has dark blue flowers, and a blunt anterior stylar lobe. The two species may be confused when dried, but they are easily distinguished in the field because of habit and flower color.

Ferreyra (1946) synonymized *M. polygonoides* under *M. herbacea* and thereby also related it to *M. leptostachya* (see above under this species). *Monnina polygonoides* is, as mentioned above, closely related to *M. leptostachya*, but it has little in common with *M. herbacea*.

**4. Monnina ramosa** I. M. Johnston, Contr. Gray Herb. 70: 77. 1924. TYPE: Peru. Arequipa: Prov. Arequipa, S slope of Chachani Mountain N of Arequipa, 3,355 m, Mar. 1920, *Hinkley & Hinkley 13* (holotype, GH; isotype, US).

Perennial herb, 15–25 cm tall. Stem 1.5–2.5 mm diam., terete, much branched from the base, the branches spreading, white-pubescent, the hairs curved. Leaves exstipulate; petiole 0.5–1 mm long, pubescent; blade lorate to linear, 8–30 × 1–2 mm, chartaceous, acute at apex, cuneate at base, white-pubescent throughout. Inflorescence many-flowered, narrowly triangular to very narrowly triangular in outline, 5–18 cm long; pedicel 0.5 mm; bracts narrowly ovate to ovate, acute 1.2–2 × 0.7–1 mm, bluish, pilose. Flowers all chasmogamous; outer sepals ± equal, narrowly to broadly ovate, 1.2–2.0 × 0.6–1.0 mm, bluish, ciliate; wings obovate, 3.5 × 2 mm, cuneate at base, blue, glabrous; keel 3 × 1.5–2.5 mm, truncate at base, yellow at least apically, glabrous, 3-lobed at apex, the central lobe emarginate; petal-stamen sheath 1.5–2/3.5 mm wide, 2/3 mm tall, hirsute adaxially at sinus between the petal lobe and the staminal sheath and sparsely on the lower half of the petal; stamens 8, the upper part of the filaments free, glabrous, 1 mm long including the anther, the anther to filament ratio 1.0; style 1.5 mm long, glabrous, bent 80° ⅔ from base; anterior stylar lobe a long (0.2 mm), pointed tooth, the posterior lobe a 0.5-mm-long stalk with a rounded stigma at the tip (Fig. 10D). Fruit unilocular, compresed, ± elliptic, 4 × 3 mm, densely strigose with a glabrous wing.

*Distribution.* Only known from southernmost Peru, where it occurs in sandy habitats above 2,300 m (Fig. 6E). It may be endemic to the Arequipa area or it may be present further south reaching into the adjacent mountains of northern Chile (although it has not yet been collected there).

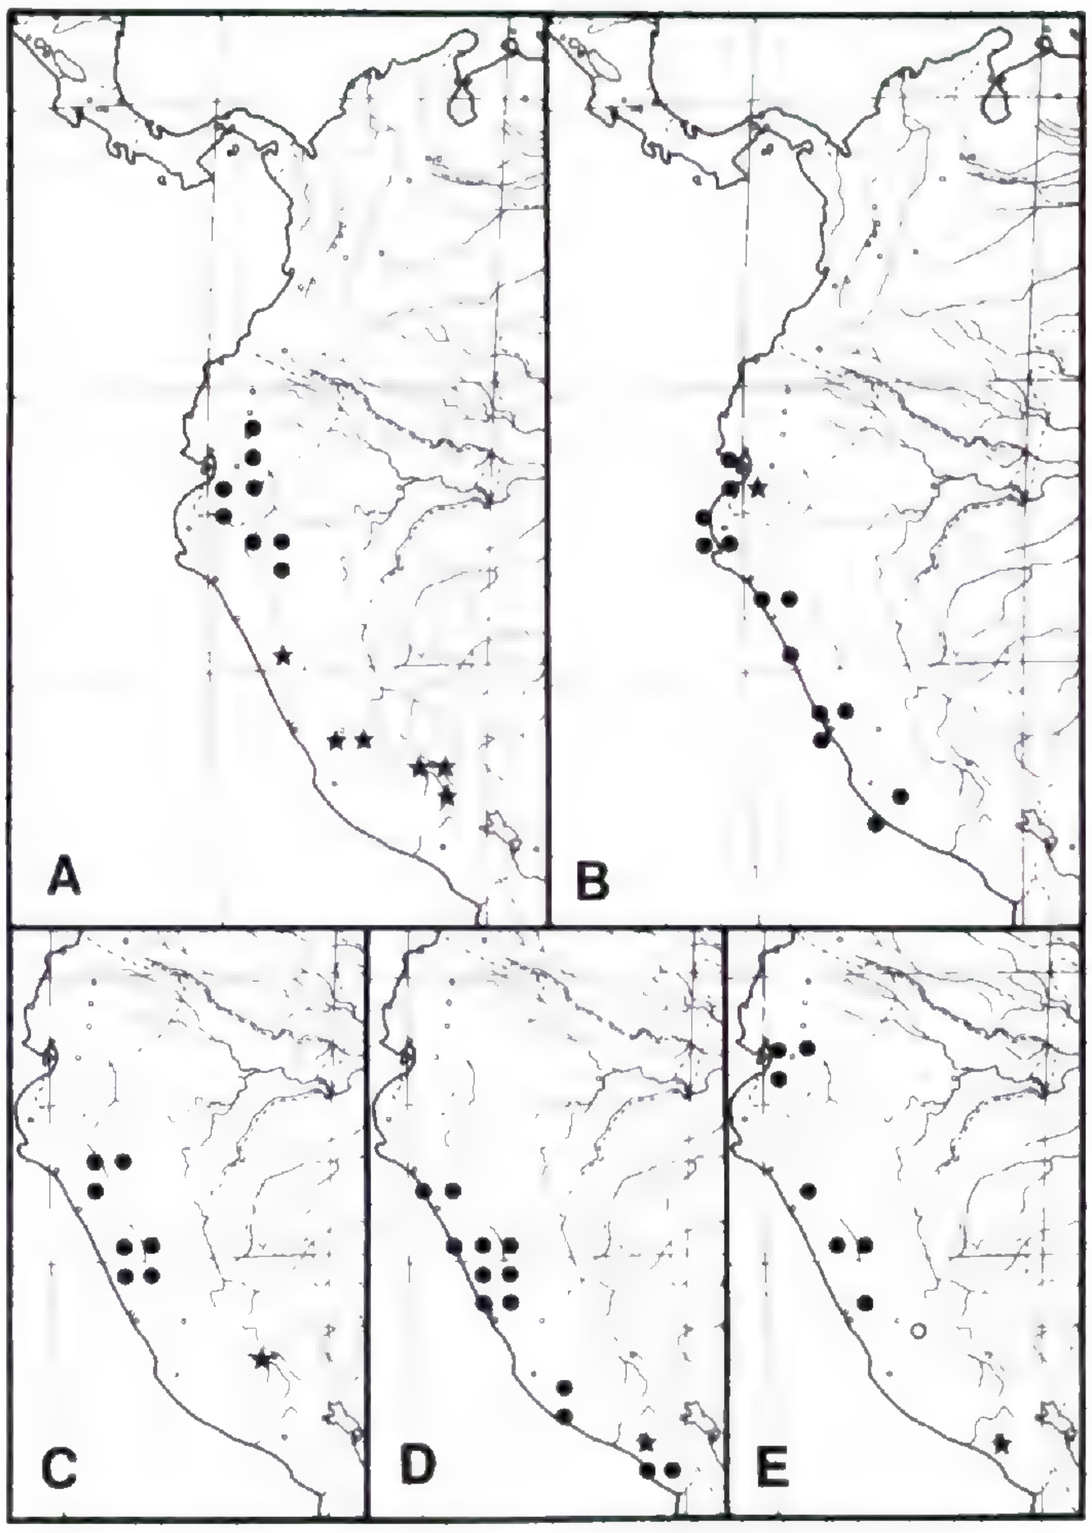

FIGURE 6. Distributions of the species of *Monnina* subg. *Pterocarya* in northwestern South America. —A. *Monnina leptostachya* (dots) and *M. amarella* (stars). —B. *Monnina fosbergii* (star) and *M. pterocarpa* (dots). —C. *Monnina polygonoides* (dots) and *M. wrightii* (star). —D. *Monnina macrostachya* (dots) and *M. macbridei* (star). —E. *Monnina herbacea* (dots), *M. ramosa* (star), and *M. filifolia* (circle).

*Specimen examined.* PERU. AREQUIPA: Prov. Arequipa, Volcán Misti, 2,300 m, July–Aug. 1921, *Rutten 1019* (U).

*Monnina ramosa* has, like *M. fosbergii* from Ecuador, a general appearance similar to that of *M. linearifolia* from Chile, i.e., a decumbent, woody perennial with small, linear leaves. The most obvious distinction between *M. linearifolia* and *M. ramosa* is that the former has six stamens not eight. *Monnina fosbergii*, like *M. ramosa*, has eight stamens with the upper part of the filaments free, but all other flower parts are different. The fruit of *M. fosbergii* is 2-locular while that of *M. ramosa* is 1-locular. *Monnina ramosa* grows sympatrically with *M. macbridei*, but the latter species is easily recognized because it is annual and has seemingly sessile anthers.

The exact colors of the flower parts are uncertain. The colors fade in the drying process, and the label data are imperfect.

**5. Monnina macbridei** Chodat, Bull. Soc. Bot. Genève sér. 2, 25: 199. 1934. TYPE: Peru. Arequipa: Prov. Arequipa, Arequipa, 2,500–2,600 m, 7–16 Apr. 1925, *Pennell 13167* (lectotype, selected by Ferreyra (1946), F; fragments, USM; isolectotypes, GH, LE, NY, PH, S, US).

Annual herb, 5–35 cm tall. Stem erect, 0.5–2 mm diam., terete or slightly furrowed by decurrent leaves, unbranched or sparsely branched distally, white-pubescent, the hairs curved. Leaves exstipulate; petiole 0.5–1 mm long, pubescent; laminae on the main axis changing in shape and size from base to apex of the stem; lowermost blades spathulate, 1.4–3.0 × 0.2–0.5 cm, upper ones lorate to linear, 1.7–4.2 × <0.1–0.4 mm, acute at apex, cuneate at base; all laminae chartaceous, white-pubescent throughout. Inflorescence many-flowered, very narrowly triangular in outline, 2–25 cm long; pedicel 0.5 mm long; bracts lanceolate, 1.5–2.0 × 0.5 mm, acuminate, probably green with bluish tinge, glabrous. Flowers all chasmogamous; outer sepals unequal in shape and size, pale blue, glabrous; the upper sepal narrowly ovate, 1.5 × 0.7 mm, the lower ones narrowly ovate to lanceolate, 1.0–1.5 × 0.5 mm, all acute at apex; wings obovate to narrowly obovate, 1.5–2 × 3 mm, cuneate at base, pale blue, glabrous; keel 1.5 × 2.5–3.5 mm, cuneate at base, glabrous, profoundly emarginate and 2-lobed at apex, probably yellow throughout; petal-stamen sheath 1–2/2–3 mm wide, 2–2.5 × 2.5–4 mm tall, the petal sheath hirsute adaxially, the lobes probably pale blue, otherwise greenish yellow as the filament sheath; stamens 8, the anther 0.1–0.2 mm long, seemingly sessile or the two central anthers occasionally with a 0.1-mm-long free filament; style 1–1.5 mm long, glabrous, straight or bent 30° ⅔ up; anterior stylar lobe an upright pointed tooth, 0.1 mm long, the posterior lobe a 0.4–0.6-mm-long stalk, bent 90° in relation to the style, with a rounded stigma at the tip (Fig. 10E). Fruit unilocular, broadly elliptic to circular in outline, 3–4 × 3–4 mm, glabrous or pubescent, winged, green, possibly purple-spotted.

*Distribution.* From the present collections, *M. macbridei* seems endemic to the Arequipa area in southern Peru, where it inhabits sandy sites on dry slopes, ca. 2,000–3,400 m (Fig. 6D). As argued earlier under *M. ramosa*, which occurs sympatrically with this species, it is plausible that the distribution extends into the mountains of northern Chile.

*Specimens examined.* PERU. AREQUIPA: Prov. Arequipa, Arequipa, 21 Aug. 1925, *Cockerell s.n.* (US); Chachani mountains N of Arequipa, 3,355 m, Mar. 1920, *Hinkley & Hinkley 18* (GH); Tingo, 2,100–2,300 m, 8 Apr. 1925, *Pennell 13110* (syntypes of *M. macbridei*, GH, LE, US); SW side of Río Chili, 4 km N of Arequipa, 2,500 m, 8 May 1977, *Solomon 2780* (MO).

*Monnina macbridei* is close to *M. macrostachya* in some aspects. Both have a petal-stamen sheath with eight seemingly sessile anthers, a character that is unique for these two species. The habit of *M. macbridei* is very similar to that of *M. macrostachya*. The two species differ in other characters, e.g., the posterior stylar lobe, the stigma, and the apex of the keel.

**6. Monnina macrostachya** Ruíz & Pavón, Syst. Veg. Fl. Peruv. Chil. 1: 173. 1798. TYPE: Peru. Lima: Provinces of Cercado (Lima) and Chancay, *Ruíz & Pavón s.n.* (lectotype, selected here, MA). Figure 7.

*Monnina arenicola* Ferreyra, J. Arnold Arbor. 27: 137. 1946. TYPE: Peru. Arequipa: Prov. Islay, S of Mollendo, 17 Nov. 1935, *Mexia 4175* (holotype, GH; fragments, USM; isotypes, M, UC).

Annual herb, 3.5–46 cm tall. Stem erect, 0.5–3 mm diam., terete, slightly furrowed by decurrent leaves, unbranched to much branched all along the main axis, the branches erect or ascending, white-pubescent, the hairs curved. Leaves exstipulate; petiole 1–2 mm long, pubescent; laminae on the main axis changing in shape from base to apex of the stem; lowermost blades narrowly obovate, 0.4–3.6 × 0.2–1.8 cm, obtuse to acute at apex, middle ones narrowly rhomboid, 1.0–4.2 × 0.4–2.1 cm, acute at apex, and uppermost blades lanceolate to linear, 0.8–4.2 × 0.1–1.2 cm, acute at apex; all laminae chartaceous, minutely mucronate, cuneate at base, pubescent on veins, margin, and sometimes the upper surface, otherwise glabrous (in young leaves pubescent throughout). Inflorescence many-flowered, 1.5–31 cm long, dense at apex, rather abruptly becoming looser and more expanded; pedicel 1 mm long; bracts lanceolate, acuminate, 1.0–2.0 mm long, ciliate, blue. Flowers all chasmogamous; outer sepals usually unequal in shape and size, blue; upper sepal ovate to narrowly ovate, 1.5–3 mm long, boat-shaped, acuminate, glabrous or ciliate along margin and midrib abaxially, lower sepals narrowly ovate to lanceolate, 1–2.5 mm long, acuminate, glabrous or ciliate along the margin; wings obovate, 1.5–3 × 3–4.5 mm, cuneate at base, glabrous or ciliate basally along the abaxial margin, blue; keel 1.5–2 × 3–5 mm, 3-dentate at apex, cuneate and ciliate at base, usually sparsely pilose along the midrib adaxially, blue, the apex or only the central tooth yellow; petal-stamen sheath 1.5–3/3–5 mm wide, 2–4.5/2.5–5 mm long, the petals hirsute adaxially and at least at base abaxially, the lobes blue, otherwise greenish as the filament sheath; stamens 8, the anther 0.2–0.7 mm long, seemingly sessile; style 1.5–3 mm long, glabrous, bent 80–90°, rarely less, ca. ⅓ from apex; anterior stylar lobe a short (ca. 0.1 mm) pointed tooth, the posterior lobe 0.5–0.8 mm long, at base carrying a bilobed, discoid stigma, the apex a pointed, hirsute tooth (Fig. 10F). Fruit unilocular, 2 × 2 mm, glabrous or pubescent, in dry condition lacunate, usually winged but often irregularly so, green, often suffused with purple.

Reddish flowers occur in some specimens. In the population I saw, ca. 10% of the individuals had red flowers.

*Distribution.* Peru. In sand dunes and in Lomas near the coast or on rocky slopes in the mountains, 0–3,500 m (Fig. 6D).

*Specimens examined.* PERU. ANCASH: Prov. Bolognesi, Chacchash, near Chiquián, 3,220 m, 12 Apr. 1949, *Ferreyra 5681* (US); Casca, below Chiquián, 3,100–3,200 m, 28 Apr. 1950, *Ferreyra 7316* (US); Conay, 6 km below Chiquián, 2,600 m, 12 May 1950, *Ferreyra 7381* (UC, mixed coll.); below Chiquián, 3,200–3,300 m, 22 May 1948, *Pennell 15412, 15413* (PH); Prov. Department and Province unknown: sine loco, *Fischer s.n.* (LE).

In his systematic overview of the genus *Monnina*, Chodat (1896) classified *M. macrostachya* among the stipulate species. In 1909, he described the taxon *M. weberbaueri* and its three varieties to accommodate some exstipulate specimens from central and southern Peru, otherwise essentially like *M. macrostachya*. The type of *M. macrostachya* is, however, exstipulate, and thus I have here synonymized *M. weberbaueri* and its varieties under *M. macrostachya*.

*Monnina macrostachya* is a very variable species. In Lomas and sand dunes, the plants are often lower than they are when growing in the mountains, but the leaves are not proportionally smaller, which results in a very peculiar appearance (Fig. 7B). *Monnina arenicola* and *M. macrostachya* var. *pumila* were described mainly on the basis of smaller plant size, but I have found no evidence in other characters supporting the exclusion of small plants into a separate taxon. The degree of reduction of the fruit wing varies considerably. There is a continuous series of forms—from fruits with entire wings through very irregularly winged ones to completely wingless fruits. Furthermore, the fruits range from glabrous to densely pubescent.

**7. Monnina amarella** Chodat, Bull. Soc. Bot. Genève sér. 2, 25: 200. 1934. TYPE: Peru. Cuzco: Prov. Cuzco, San Sebastián, 3,300–3,400 m, 25 Apr. 1925, *Pennell 13629* (lectotype, selected by Ferreyra (1946), F; isolectotypes, GH, NY, PH, US). Figure 8D–F.

Annual herb, 3–27 cm tall. Stem erect, 0.5–2 mm diam., terete, furrowed by decurrent leaves, usually branched all along the main axis, the branches erect, white-pubescent, the hairs curved. Leaves exstipulate; petiole 0.5–1 mm long; laminae on the main axis changing in shape and size from base to apex of the stem, the basal ones oblanceolate, 0.5–1.6 × 0.2–0.6 cm, obtuse and emarginate at apex, the upper ones narrowly lanceolate to linear, 0.8–3.7 × 0.1–0.9 cm, obtuse and either minutely mucronate or rarely emarginate or acute at apex; all laminae chartaceous, cuneate to attenuate at base, glabrous except on the midrib. Inflorescence few-flowered, "torpedo"-shaped in outline, 1.5–18 cm long; pedicel 0.5 mm long; bracts lanceolate to narrowly lanceolate, acuminate, ca. 0.5–1.5 mm long, dark blue, glabrous. Flowers of the main inflorescence chasmogamous, those of the branches usually cleistogamous (measurements for these given in parentheses); outer sepals unequal in shape and size, dark blue, glabrous; upper sepal ovate to narrowly ovate, 1.3–1.5 × 0.6–1.0 mm (0.8–1.5 × 0.6–1.0 mm), boat-shaped, acute, lower sepals narrowly ovate to lanceolate, 1.0–1.2 × 0.3–0.5 mm (0.8–1.0 × 0.3 mm); wings narrowly obovate, 2–2.5 × 1–1.5 mm (2–2.5 × 1–1.5 mm), cuneate at base, glabrous, dark blue; keel 2.5 × 1.5 mm (2–2.5 × 1–1.5 mm), 3-lobed at apex, the central lobe emarginate, truncate at base, glabrous, yellow; petal-stamen sheath 1.5–2.5/4–4.5 mm (1–2/3–4 mm) wide, 1–2/1–2.5 mm (1–2 × 1–2 mm) long, the petals pilose to hirsute adaxially on sheath, the lobes dark blue, otherwise greenish like the filament sheath; stamens 6, in flowers on branches often 4, the filaments of the 3 (2) anthers of each fascicle fused throughout (Fig. 8F), glabrous, 0.8–1 mm (0.8–1.0 mm) including the anthers, the anther to filament ratio 0.25–0.5 (0.3); style 1.5–2.0 mm (1–1.5 mm) long, glabrous, evenly curved, the central part dorsiventrally expanded building a cavity, to 0.8 mm wide; anterior stylar lobe a short pointed tooth, 0.1–0.2 mm long, the posterior lobe with a sessile, rounded stigma (Fig. 10G). Fruit 1-locular, compressed, rotund in outline, 2.5–4.5 × 3.5–5 mm when mature, glabrous or puberulent, green, often partly covered by the remaining, withered keel, the wing ca. 0.8 mm wide, bluish-tinged.

*Distribution.* Central and southeastern Peru. Open slopes among grass and rocks in the mountains, ca. 2,000–4,000 m (Fig. 6A).

*Specimens examined.* PERU. ANCASH: Prov. Huaraz, Cerro Shaurema SE of Huaraz, 3,250 m, 9–13 May 1948, *Pennell 15357* (PH). AYACUCHO: sine loco, ca. 2,400 m, 1951, *Soukup 4018* (F). CUZCO: Prov. *Monnina amarella* possesses two kinds of flowers: normal chasmogamous flowers with six stamens on the main inflorescence, and smaller, cleistogamous flowers with four stamens and more or less reduced petal-stamen sheath on the branches. Cleistogamous flowers are found in *M. wrightii* as well.

Vernacular name: "bolsa bolsa."

**8. Monnina filifolia** Chodat, Bull. Soc. Bot. Genève sér. 2, 25: 198. 1934. TYPE: Peru. Huancavelica: Prov. Tayacaja, valley of the Mantaro River, below Colcabamba, 1,900 m, Mar. 1913, *Weberbauer 6454* (holotype, F: isotypes, GH, NY, S, US, USM).

Annual herb, 43–65 cm tall. Stem erect, 1.5–3 mm diam., terete, furrowed by decurrent leaves, unbranched or branched distally, the branches erect, white-pubescent, the hairs curved. Leaves exstipulate; petiole 1–2 mm long; laminae changing in shape and size from base to apex of the stem, the basal ones oblanceolate, 1.3–1.9 × 0.2–0.3 cm, obtuse or sometimes obtuse with a point at apex, the upper ones linear, 2.5–7.0 × 0.1–0.3 cm, acute at apex; all laminae chartaceous, cuneate at base, glabrous. Inflorescence many-flowered, very narrowly triangular in outline, 21–46 cm long; pedicel 1 mm long; bracts linear, acute, ca. 2 mm long, glabrous. Flowers all chasmogamous; outer sepals unequal in size, narrowly ovate, ciliate; upper sepal 1.5 × 0.8 mm, boat-shaped, the lower ones 1.0 × 0.5 mm; wings obovate, 2.5 × 1.5 mm, cuneate at base, glabrous, lilac (fide Weberbauer); keel 2.5 × 1 mm, 3-lobed at apex, the central lobe deeply emarginate, truncate at base, glabrous, yellow (fide Weberbauer); petal-stamen sheath 1.5/3 mm wide, 1/1.5 mm long, the petals hirsute adaxially at base, the lobes lilac (fide Weberbauer); stamens 6, the filaments of the three stamens in each fascicle fused throughout, glabrous, 0.8 mm long, the anther to filament ratio 1.0; style 1 mm long, glabrous, evenly curved, the central part diventrally expanded building a cavity; anterior stylar lobe a short blunt tooth, the posterior lobe with a sessile, elongate stigma (Fig. 10G). Fruit 1-locular compressed, rotund in outline, 5 × 4 mm when mature, densely pubescent, the wing ca. 0.8 mm wide.

*Distribution.* Central Peru, ca. 2,000 m (Fig. 6E). Known only from the type collection.

*Monnina filifolia* is very similar to *M. amarella*. Both lack stipules and have six anthers with the three filaments of each fascicle united throughout. The most striking differences between the two species are the growth habit (branches only developed distally vs. all along the main axis), the leaf size and shape (upper leaves very long, narrow, and acute vs. shorter, wider, and obtuse), the number of flowers (many vs. few), and the outline of the inflorescence (very narrowly triangular vs. "torpedo"-shaped). The leaf size and shape vary within many other species, whereas growth habit, flower number, and inflorescence outline are generally constant characters within a species. The collection of *M. filifolia* comes from a lower altitude (1,900 m) than the majority of the *M. amarella* collections (2,900–3,900 m). That fact indicates either that *M. filifolia* is a separate taxon with a distinct habitat preference, or that *M. filifolia* should be lumped into *M. amarella* as a lowland ecotype. It is important to note that *M. amarella* collections from approximately the same geographical area and comparatively low altitude as *M. filifolia* (*Stork & Horton 10909* and *Soukup 4018*, both 2,400 m) have a tendency toward longer and more narrow leaves. However, more ample material is needed to determine whether *M. filifolia* should be considered a separate taxon, as done here, or whether it should be included in *M. amarella*.

**9. Monnina wrightii** A. Gray, Pl. Wright. 2: 31. 1853. TYPE: U.S.A. New Mexico: near the copper mines, 1851, *Wright 938* (lectotype, selected here, GH; isolectotypes, GH, NY, PH, US). Figure 8A–C.

*Monnina brachystachya* Griseb., Abh. Königl. Ges. Wiss. Göttingen 19: 75. 1874. TYPE: Argentina. Tucu-

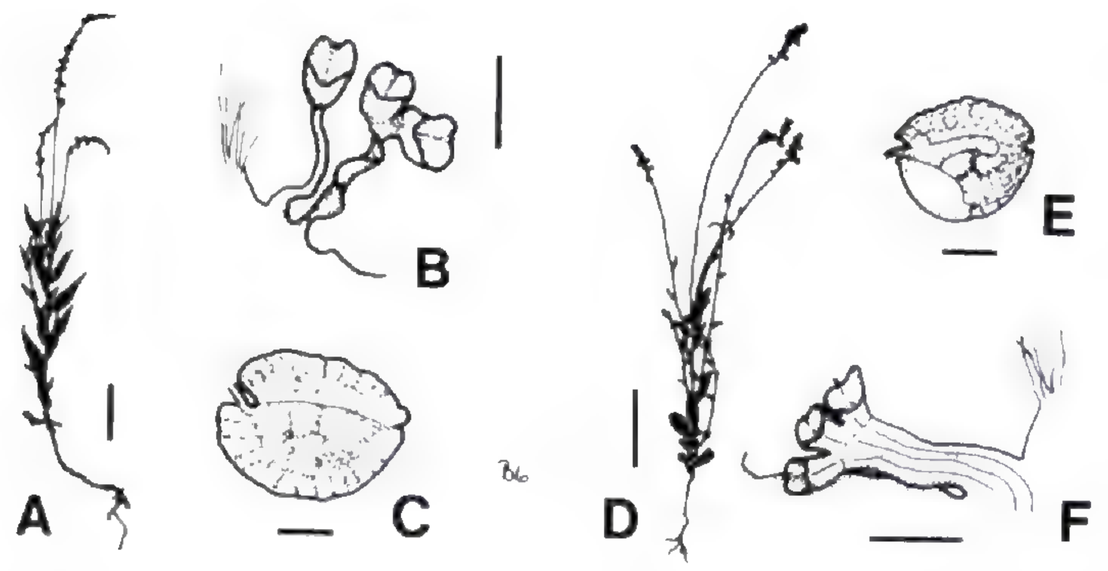

FIGURE 8. *Monnina wrightii* (A–C) and *M. amarella* (D–F). —A, D. Habit. —B, F. Detail of petal-stamen sheath showing a fascicle of stamens with connate filaments. —C, E. Fruits. mán: Catamarca, Mar.–Apr. 1872, *Lorentz 105* (lectotype, selected here, GOET).

*Monnina macrostachya* var. *stenophylla* Kuntze, Revis. Gen. Pl. 3(2): 10. 1898. TYPE: Bolivia. Larecaja (La Seja?), 1892, *Kuntze s.n.* (lectotype, selected here NY).

*Monnina eriocarpa* Chodat, Meded. Rijks-Herb. 27: 29. 1915. TYPE: Bolivia. Santa Cruz: Prov. Florida, Achirastal, 1,300 m, Mar. 1911, *Herzog 1726* (lectotype, selected here, G; isolectotypes, L, S, W).

Nomenclatural note: *Monnina brachystachya* was based on two incongruent elements, viz *Lorentz 105* and *Lorentz 414*. The original description seems to be based on the flowers of #414 and the fruits of #105. *Lorentz 414*, however, belongs to a species different from *M. wrightii*, probably *M. dictyocarpa* Griseb. *Monnina brachystachya* is here typified on *Lorentz 105*, because this collection is the most complete, showing both fruits and flowers (cleistogamous) as well as the habit of the plant. The name *M. brachystachya* has traditionally been applied to the species represented by #105. It was probably the confused original description of *M. brachystachya* that caused Chodat to describe *M. eriocarpa*.

Annual herb, 14–86 cm tall. Stem erect, 1–5 mm diam., terete, usually branched distally, white-pubescent, the hairs curved. Leaves exstipulate; petiole 1–3 mm long, pubescent; laminae on the main axis changing from narrowly ovate at base to very narrowly lanceolate or linear near inflorescence, 1.4–8.5 × 0.2–4.2 cm, chartaceous, acute to acuminate at apex, cuneate at base, the margin and midrib pubescent, otherwise glabrous, the young leaves pubescent throughout. Inflorescence many-flowered, narrowly to very narrowly triangular in outline, 3.5–54 cm long, sometimes very densely pubescent; pedicel 0.5 mm in open flower; bracts very narrowly lanceolate, acuminate to caudate, 1.5–2 mm long, ciliate, undulate, yellowish green mixed with blue. Flowers of the main inflorescence chasmogamous, those of the branches usually cleistogamous (measurements for these given in parentheses); outer sepals unequal, the upper sepal ovate to narrowly ovate, 1–1.5 × 0.5–1 mm (1–1.5 × 0.4–0.6 mm), boat-shaped, the lower ones lanceolate, 1–1.5 × 0.3–0.5 mm (1–1.5 × 0.2–0.5 mm), all acute at apex, ciliate, yellowish mixed with blue; wings obovate to narrowly obovate, 1.5–3 × 1–2 mm (1.5–2.5 × 0.8–1.5 mm), cuneate to attenuate at base, glabrous, blue; keel 1.5–3 × 0.7–1.5 mm (1.5–2 × 0.4–1.2 mm), emarginate at apex, truncate at base, glabrous, possibly yellow throughout; petal-stamen sheath 1–3/1.5–4.5 mm (0.3–1.5/2.5–3 mm) wide, 1–2/1–2.5 mm (1–1.5/1.2–2 mm) tall, a tuft of hairs present at the upper margin between the two filament fascicles, the petals hirsute adaxially, the lobes blue, otherwise greenish as the filament sheath; stamens 6, or two of them ± reduced or totally absent, the upper part of the filaments of the outer two stamens of each fascicle fused throughout, the third stamen, when present, single, glabrous, 0.7–1.2 mm (0.5–1 mm) long including the anther, the anther to filament ratio 0.3–1 (0.5–1); style 0.8–2 mm (0.5–1.2 mm) long, glabrous, bent 45–90° ⅓ to ⅔ from the base, with or without a cavity at the middle; anterior stylar lobe absent or a very short, blunt tooth, the posterior lobe with a sessile, crested stigma (Fig. 10H). Fruit 1-locular, crescent-shaped in outline, 2–5 × 3–6 mm when mature, pubescent, some fruits rarely uni- or bilaterally glabrous, green, narrowly winged (ca. 1 mm), the margin occasionally erose.

*Distribution.* Southern Peru to central Argentina; Uruguay; Mexico and the southwestern United States. Gravelly slopes in the mountains, 1,000–3,000 m (Fig. 6C). In the north it flowers in September–October, in the south between November and April.

*Monnina wrightii* shows an extreme disjunction in its distribution. The type, in appearance, belongs to the homogeneous Mexican–North American population, while the main population of the species, in which variation among individuals is extensive, is found in Bolivia and Argentina. Since the rest of subgenus *Pterocarya* occurs south of the equator, and the largest variation within the species is found there as well, I presume that *M. wrightii* has been introduced to Mexico and the southwestern United States from the Bolivian–Argentinian population. Grondona (1945) was aware of the wide distribution of this species, considered by him to be *M. brachystachya*, and wrote: "Se extiende desde México por la Región Cordillerana

hasta La Rioja, en el noroeste de la Argentina." He did not realize that an earlier, valid name, *Monnina wrightii*, had been published based on a type from New Mexico.

The species seems rather uncommon in Peru and Uruguay; only a single collection is known from each of these countries.

*Specimen examined.* PERU. CUZCO: Prov. Urubamba, Ollantaytambo, 2,850 m, 26 Apr. 1925, *Pennell 13683* (PH).

*Additional material studied (representative collections).* ARGENTINA. CATAMARCA: *Rodriguez 3344* (GH). JUJUY: *Cabrera et al. 17038* (GH). SALTA: *Meyer 3779* (GH). TUCUMAN: *Schreiter 3317* (GH); *Bailetti 150* (GH). BOLIVIA. COCHABAMBA: *Eyerdam 24954* (UC). LA PAZ: *Mandon 836* (GH). PANDO: *Buchtien 259* (GH). TARIJA: *Fiebrig 2054* (LY). MEXICO. CHIHUAHUA: *Pringle 302* (B). MORELIA: *Arsène s.n.* (LY). URUGUAY. SACUAREMBO: *Osten 6537* (GH).

This species possesses two kinds of flowers, a fact already noted by Grondona (1945). Normal chasmogamous flowers occur on the main inflorescence axis, while small and very reduced cleistogamous flowers occur on the branches. In the cleistogamous flowers the petal-stamen sheath is usually reduced to the filament sheath carrying two fascicles each with two anthers, which in turn are adherent to the stigma. The reduction is not always complete, however. The style is usually C-shaped and very short.

The lectotype of *M. brachystachya* (*Lorentz 105*) lacks the main inflorescence axis and consequently has only cleistogamous flowers. Grondona's illustration is slightly misleading because chasmogamous and cleistogamous flowers are shown on different individuals.

The field notes on colors of the flower are rather sparse. I have not seen this species alive, so the description of the colors is given with reservation.

Annual (or perennial?) herb, ca. 0.5–2.5 m tall. Stem erect, ca. 3–10 mm diam., terete, simple below, loosely branched above, the stem and older branches often glabrous, glaucous, the younger branches sparsely white-pubescent, the hairs curved. Leaves stipulate; petiole 1–3 mm long, pubescent; laminae on the main axis lanceolate to narrowly lanceolate in some plants, narrowly ovate to lanceolate in others, 2–6.5 × 0.2–3.2 cm, chartaceous, acute at apex, cuneate at base, ± pubescent throughout, the branches always with gradually shorter and more narrow laminae toward the inflorescence. Inflorescence many-flowered, very narrowly triangular in outline, ca. 15–40 cm long; pedicel 1 mm; bracts lanceolate, acuminate, 1–3 mm long, ± densely white-hirsute. Flowers all chasmogamous; outer sepals equal in size or the upper

sepal slightly larger, narrowly ovate to lanceolate, 1.2–2.2 mm long, glabrous or rarely sparsely pilose abaxially; wings obovate to broadly obovate, 2–3.5 × 1.5–3 mm, cuneate to truncate at base, glabrous, pink to violet; keel 2.5–4 × 2–2.5 mm, truncate at base, glabrous, emarginate with two lateral lobes at apex, yellow, at least the tip and two lateral spots; petal-stamen sheath 1–2.5/3–7 mm wide, 0.7–3/1–3.5 mm tall, the petals pubescent at the basal margin, the staminal sheath pilose along the midline abaxially (a tuft of these hairs is seen between the filament bundles), the fold marking the line between the petal and filament sheath fringed by long hairs, the petal lobes pink to violet, otherwise greenish as the filament sheath; stamens 8, the upper part of the filaments free, glabrous, 1–1.5 mm long including the anther, the anther to filament ratio 1.0; style 1.5–3.5 mm long, glabrous, ± sigmoid; anterior stylar lobe absent or a very short blunt tooth, the stigma a bilobed disc, sessile or at the tip of a short posterior lobe (Fig. 10I). Fruit 1-locular, compressed, orbicular to rotund, 5–7 × 4–7 mm when mature, glabrous or pubescent, sometimes varying on the same individual, green, occasionally purple-spotted, broad-winged, the wing purple.

*Distribution.* Ecuador, Peru, and Chile. In sand and gravel in dry areas along the coast, or on steep, rocky slopes in the coastal mountains, 0–2,200 m (Fig. 6B).

*Specimens examined.* ECUADOR. GUAYAS: near La Libertad, 23 Feb. 1972, *Beck Breuninger 156* (GB); 11 km N of Sta. Because of the size of the plant, the basal parts are usually not present in herbarium specimens. It is therefore difficult to see whether the plant is annual or perennial. It is hard to believe that a 2.5-m-tall plant with a more or less woody base could possibly sprout and mature in one short season in a dry area. On the other hand, I have seen several withering plants devoid of leaves in a natural population, and the root system seems too tiny for a perennial. Collectors disagree on the subject; some noted "annual," others "perennial" on the labels.

It seems as if there is a gradient from very broad-leaved specimens in the north to almost linear-leaved ones in the south of the distribution area. That is, however, an artifact. The Ecuadorean specimens are generally smaller than the Peruvian ones, and the whole plant, instead of a branch, is usually collected. Since the leaves on the main axis are the largest of the plant, the specimens from the north seem extraordinarily broad-leaved.

Bracts vary in length from 1 to 3 mm and tend to be longest in specimens from the north. The transition is gradual, however.

Ferreyra (1990) described the species *M. piurensis* on the basis of larger leaves and longer bracts relative to *M. pterocarpa*. *Monnina piurensis* is, for the reasons mentioned above, included here in *M. pterocarpa*.

The color of the flowers fades after drying and is mostly very poorly described on the labels. According to the notes I have seen, pink flowers with a brownish yellow keel are common. It is, however, my experience that the brownish tinge of the yellow keel is due to post-pollination color change. The plants I saw had more violet flowers, the keel with a yellow tip and two lateral, yellow spots. Variation in flower color is also seen in *M. macrostachya*.

In a few specimens, unhatched insects (Hymenoptera–Chalcidoidea, determined by T. Hagström) were found inside the flowers. This group of insects is richly represented in the tropics and, according to Hagström, taxonomically very difficult. As it is known to contain both parasitizing and pollinating species, it is not known whether the presence of the insects is a matter of pure parasitism or part of the pollination syndrome.

*Monnina spruceana* Chodat, Bull. Herb. Boissier 2: 167. 1894. TYPE: Ecuador. Ecuadorean Andes, 1857–1859, *Spruce 5977* (holotype, G; isotypes, E, GH, GOET, LE, NY, S, US, W).

*Monnina graminea* Chodat, Bot. Jahrb. Syst 42: 103. 1909. TYPE: Peru. Cajamarca: Prov. Hualgayoc, San Miguel, 2,200 m, *Weberbauer 3919* (lectotype, selected here, MOL; isolectotype, USM).

Annual herb, ca. 20–100 cm. Stem erect, 1–4 mm diam., terete, slightly furrowed by decurrent leaves, unbranched or branched distally, white-pubescent, the hairs curved. Leaves stipulate; petiole usually 2 mm long, pubescent; laminae lanceolate to narrowly lanceolate, 0.1–2.0 × 1.2–5.2 cm, chartaceous, acute to acuminate at apex, cuneate at base, glabrous except at the margin and the midrib below, the young leaves pubescent throughout. Inflorescence many-flowered, narrowly triangular in outline, ca. 15–50 cm long; pedicel 1 mm long; bracts narrowly lanceolate, 1–2 mm long, acuminate, dark bluish-tinged, ciliate and often sparsely pilose abaxially. Flowers all chasmogamous; outer sepals narrowly ovate to lanceolate, slightly unequal in size, the upper sepal 1.5 × 0.5–0.7 mm, the lower ones 1–1.5 × 0.5 mm, glabrous or rarely sparsely ciliate, dark purplish blue; wings obovate, 2.5–3 × 1.5–2 mm, cuneate to attenuate at base, glabrous, dark purplish blue; keel 2.5–3 × 1.5–2 mm, cuneate at base, glabrous, 3-lobed at apex, the central lobe emarginate, bright yellow, the keel otherwise dark purplish blue; petal-stamen sheath 2–2.5/3–4 mm wide, 2/2–3 mm tall, the petals pubescent at lower margin, the lobes hirsute adaxially, dark purplish blue, otherwise yellowish green as the filament sheath, the fold marking the line between the petal and filament sheath fringed by long hairs, the upper margin of the filament sheath provided with long, curled hairs; stamens 8, the upper part of the filaments free, glabrous, 0.8–1.0 mm long including the anther, the anther to filament ratio 0.3–0.5; style 1.5–2 mm long, glabrous, bent 90° at the middle; anterior stylar lobe absent or a very short blunt tooth, the posterior lobe resembling a hammer-head, i.e., a short stalk with a shorter and narrower stalk perpendicular to it, at the tips of which the stigma is found (Fig. 10J). Fruit 1-locular, ± crescent-shaped in outline, 3–5 × 2–4 mm when mature, glabrous or pubescent, sometimes so on the same inflorescence, wingless, or irregularly or regularly winged, green with purple lines or spots, the wing, when entire, purple-margined.

*Distribution.* Central Ecuador to central Peru. Gravelly slopes in the mountains, ca. 1,200–2,800 m (Fig. 6E).

*Monnina herbacea* is, together with *M. pterocarpa*, unique among the species of subgenus *Pterocarya* in northwestern South America because of having stipulate leaves. Stipulate leaves are more common among the species in the eastern distribution area.

The main difference between the two species mentioned is the construction of the anterior stylar lobe and the position of the stigma. In *M. herbacea* the anterior stylar lobe resembles a hammer-head with rounded stigmas at the tips, while the stigma of *M. pterocarpa* is a sessile or short-stalked, bilobed disc (Fig. 10I, J). Furthermore, *M. herbacea* is in all parts smaller, the flowers are of more delicate texture with differences in proportion and shape of many details, and the stipules tend to be longer. They are also separated altitudinally, with *P. pterocarpa* primarily occurring from the coast up to 1,500 m (rarely higher) and *M. herbacea* above 1,500 m (occasionally lower). Overlap exists, and the two species are even sympatric in some areas.

The name *M. herbacea* has, since the species was described by de Candolle in 1824, been assigned to almost every small, annual species in the subgenus except the taxon of the type. Chodat (1896) placed it among the species lacking stipules, but my studies of the type at G-DC revealed that stipules are present. In 1894, Chodat described *M. spruceana* from Ecuador, and later (1909) *M. graminea* on material from northern Peru, both stipulate. Together with the type of *M. herbacea* from the Lima area they constitute a single, uniform taxon. Ferreyra (1946, 1953), based on Chodat's erroneous note on lack of stipules, and the wingless fruits mentioned in the diagnosis, applied the name mostly to specimens of *M. leptostachya* and *M. polygonoides*.

Vernacular name: "palomilla."

# THE MISCONSTRUED AND RARE SPECIES OF *COMMELINA* (COMMELINACEAE) IN THE EASTERN UNITED STATES[1]

*Robert B. Faden*[2]

## Abstract

Five species of *Commelina* (Commelinaceae), all introduced in the eastern United States, are reviewed and discussed. The widespread but overlooked *C. caroliniana* is contrasted with the more common *C. diffusa*, and the species are found to be distinguished best by their seeds. *Commelina gigas* is determined to be a polyploid of *C. diffusa*, and the new combination *C. diffusa* var. *gigas* is made. Variety *gigas* is considered likely to have been separately introduced. *Commelina benghalensis* probably became naturalized in Florida early this century. Of the two recently discovered species, *C. forskaolii* is known from a single Florida population that may have been eradicated, and *C. nigritana* var. *gambiae* is becoming well established along roadsides in Florida. Maps of the eastern North American distributions of *C. caroliniana*, *C. diffusa* var. *gigas*, *C. benghalensis*, *C. forskaolii*, and *C. nigritana* var. *gambiae* are provided. Chromosome counts are reported for *C. caroliniana* ($2n$ = ca. 86), *C. diffusa* var. *diffusa* ($2n$ = 30), *C. diffusa* var. *gigas* ($2n$ = 90), *C. benghalensis* ($2n$ = 22), *C. forskaolii* ($2n$ = 30), and *C. nigritana* var. *gambiae* ($2n$ = 56), all first reports from the United States.

The purpose of this paper is to supply background information about five misunderstood or rare species of *Commelina* in the eastern United States. All of them will be fully described in my treatment for the *Flora of North America*, so detailed descriptions have not been included. Instead, data are provided and discussed that cannot be contained in the flora because of format and length restrictions. All five species treated here were introduced in the eastern United States. Among other naturalized species, only *C. communis* L. is not considered, because it is widespread and well known. *Commelina diffusa* Burm. f., the second most common and widespread introduction, is discussed only in the context of its separation from the often overlooked *C. caroliniana* Walter and its relationship with the enigmatic Florida plant *C. gigas* Small. Among the five taxa dealt with in detail herein, three were either misinterpreted (*C. caroliniana*), or ignored (*C. gigas*), or overlooked (*C. benghalensis* L.) in the most recent monograph of the U.S. species (Brashier, 1966). The other two, *C. forskaolii* M. Vahl and *C. nigritana* Benth., had not yet been collected by 1966.

## Distinctions Between *Commelina caroliniana* and *C. diffusa*

*Commelina caroliniana* was recently shown to be a distinct species in the eastern United States and an old introduction from India (Faden, 1989). It is a widespread weedy plant (Fig. 1), yet it remains poorly understood. Undoubtedly this is because of its close resemblance to the even more widespread *C. diffusa*. Both species are usually annual, diffusely spreading plants that root at the nodes. Both have spathes that are solitary (not clustered), simply folded (i.e., margins not fused), and usually acuminate at the apex; small flowers with three blue petals (as contrasted with *C. communis* L., which has a white lower petal); and typically five-seeded capsules with the dorsal locule one-seeded and indehiscent and ventral locules two-

[1] I thank R. P. Wunderlin, J. Beckner, and J. Popenoe for assistance with the fieldwork in Florida in 1983; R. D. Thomas and R. P. Wunderlin for supplying living material of *C. caroliniana* and *C. diffusa* var. *gigas*, respectively; A. R. Tangerini for the maps and line drawings; R. Oliver for technical assistance with the chromosome counts; the curators of the following herbaria for assistance during visits to their institutions or for supplying loans of specimens: CHARL, CLEMS, DUKE, F, FLAS, FSU, FTG, GH, LSU, LTU, MO, NCU, NLU, NY, PH, TENN, UARK, USF, and VPI; and A. J. Faden for heroically caring for the living plants for many years.

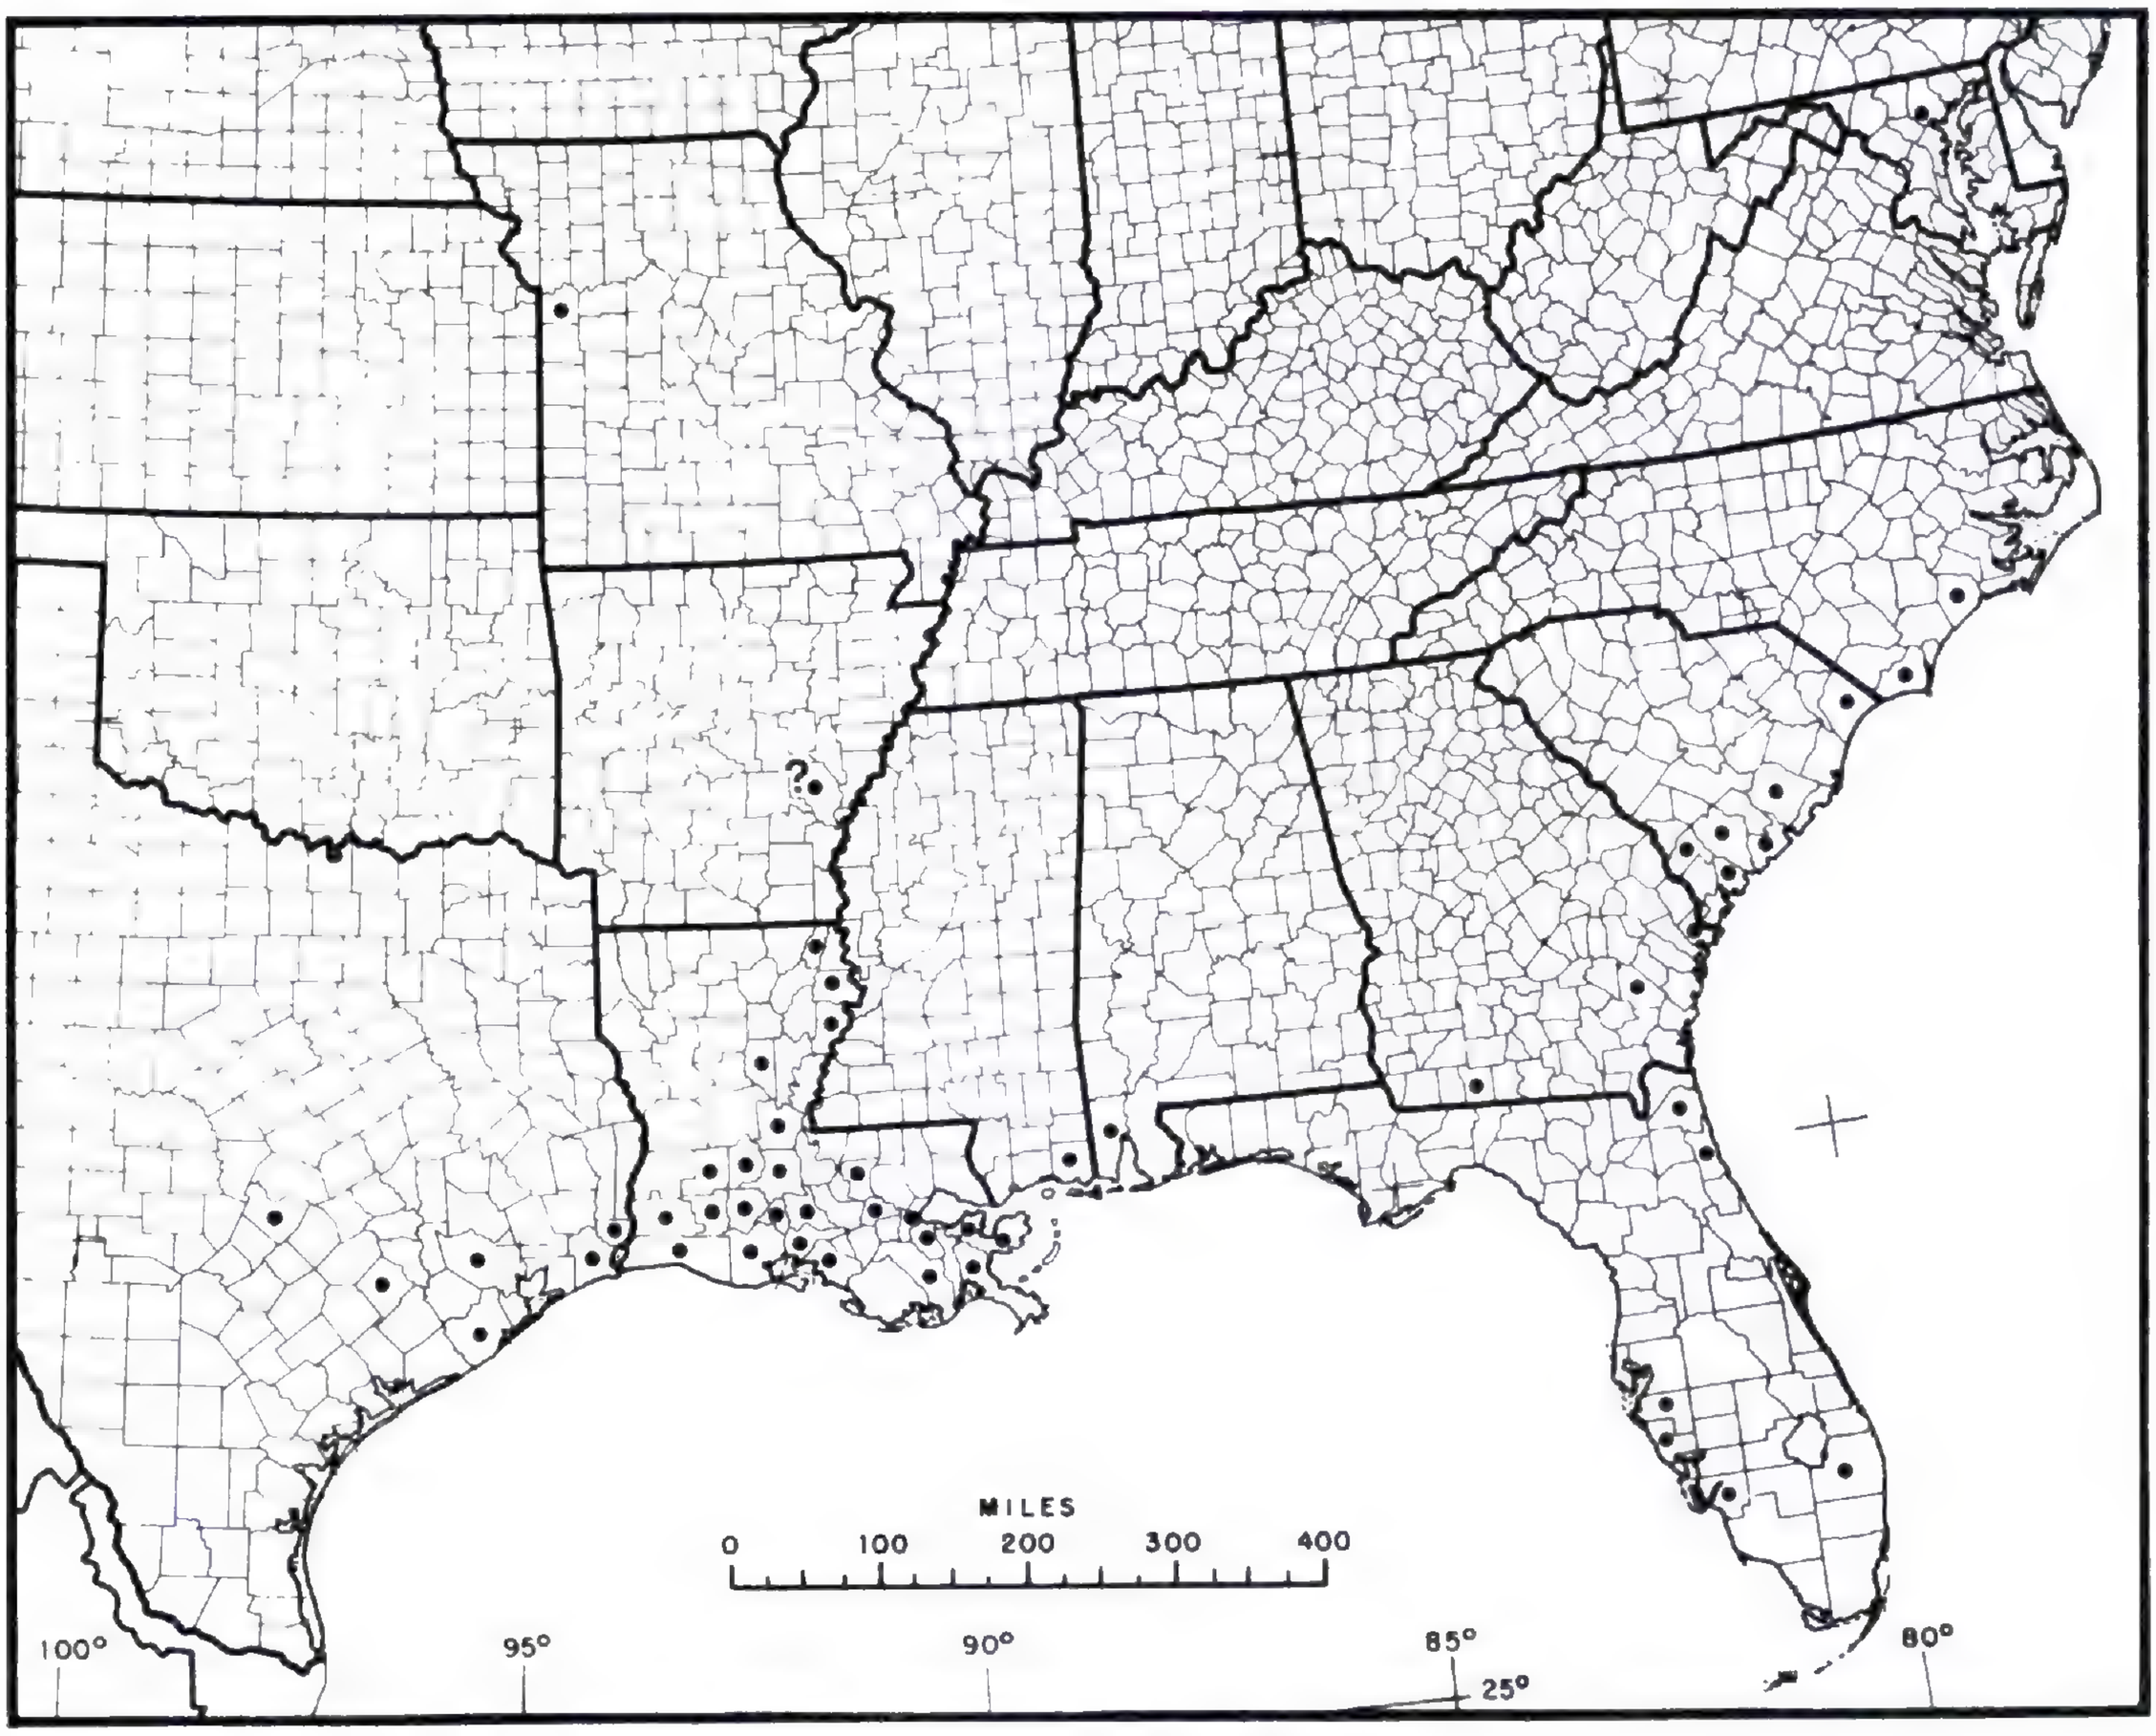

FIGURE 1. Distribution of *Commelina caroliniana* in the United States.

seeded and dehiscent. Because authors have been concerned mainly with separating *C. diffusa* from *C. communis*, it is hardly surprising that cryptic *C. caroliniana* has been overlooked.

It may be noted that reviewer Austin questioned whether *C. diffusa* truly is annual in southern Florida. In my experience, this species is usually perennial in the tropics, so potentially it could persist year-round in the deep South. To determine whether it does indeed survive mild winters in this region, one would need to make long-term observations of populations. Further north, both *C. diffusa* and *C. caroliniana* clearly are annual because they lack subterranean, perenniating organs.

The only modern floras in which *C. caroliniana* has been correctly circumscribed are Gleason (1952, 1963), Gleason & Cronquist (1991), and Steyermark (1963). Radford (1968) considered it a doubtful species. In all of these works, except Gleason & Cronquist (1991), *C. caroliniana* and *C. diffusa* were distinguished by supposed differences in habit and spathe length, characters that do not work. Brashier (1966) considered *C. caroliniana* to be a synonym of *C. diffusa*.

The distinguishing features that may be used to separate *C. caroliniana* from *C. diffusa* are summarized in Table 1. The most absolute difference between them is the testa (Fig. 2). In addition to being nearly smooth (vs. reticulate), the seeds of *C. caroliniana* are also larger and darker brown than those of *C. diffusa*.

The spathes of both species are distinctive, and thus flowering specimens almost always can be identified. The spathes of *C. caroliniana* characteristically lack an exserted upper cincinnus (helicoid cyme) and have a lower edge (i.e., the spathe midrib) that is nearly straight to only slightly curved (Fig. 3A–C). The spathes are not strongly falcate. In contrast, the spathes of *C. diffusa* typically have an exserted upper cincinnus bearing one to several flowers. The lower edge of the spathe is moderately curved, making the spathes distinctly falcate (Fig. 3D–F). Specimens of *C. diffusa* with very small spathes that lack an exserted upper cincinnus normally also bear larger, more typical spathes.

The spathe margin is commonly ciliate basally in *C. caroliniana* (at least a few long hairs present) and usually ciliolate to glabrous (rarely ciliate) in

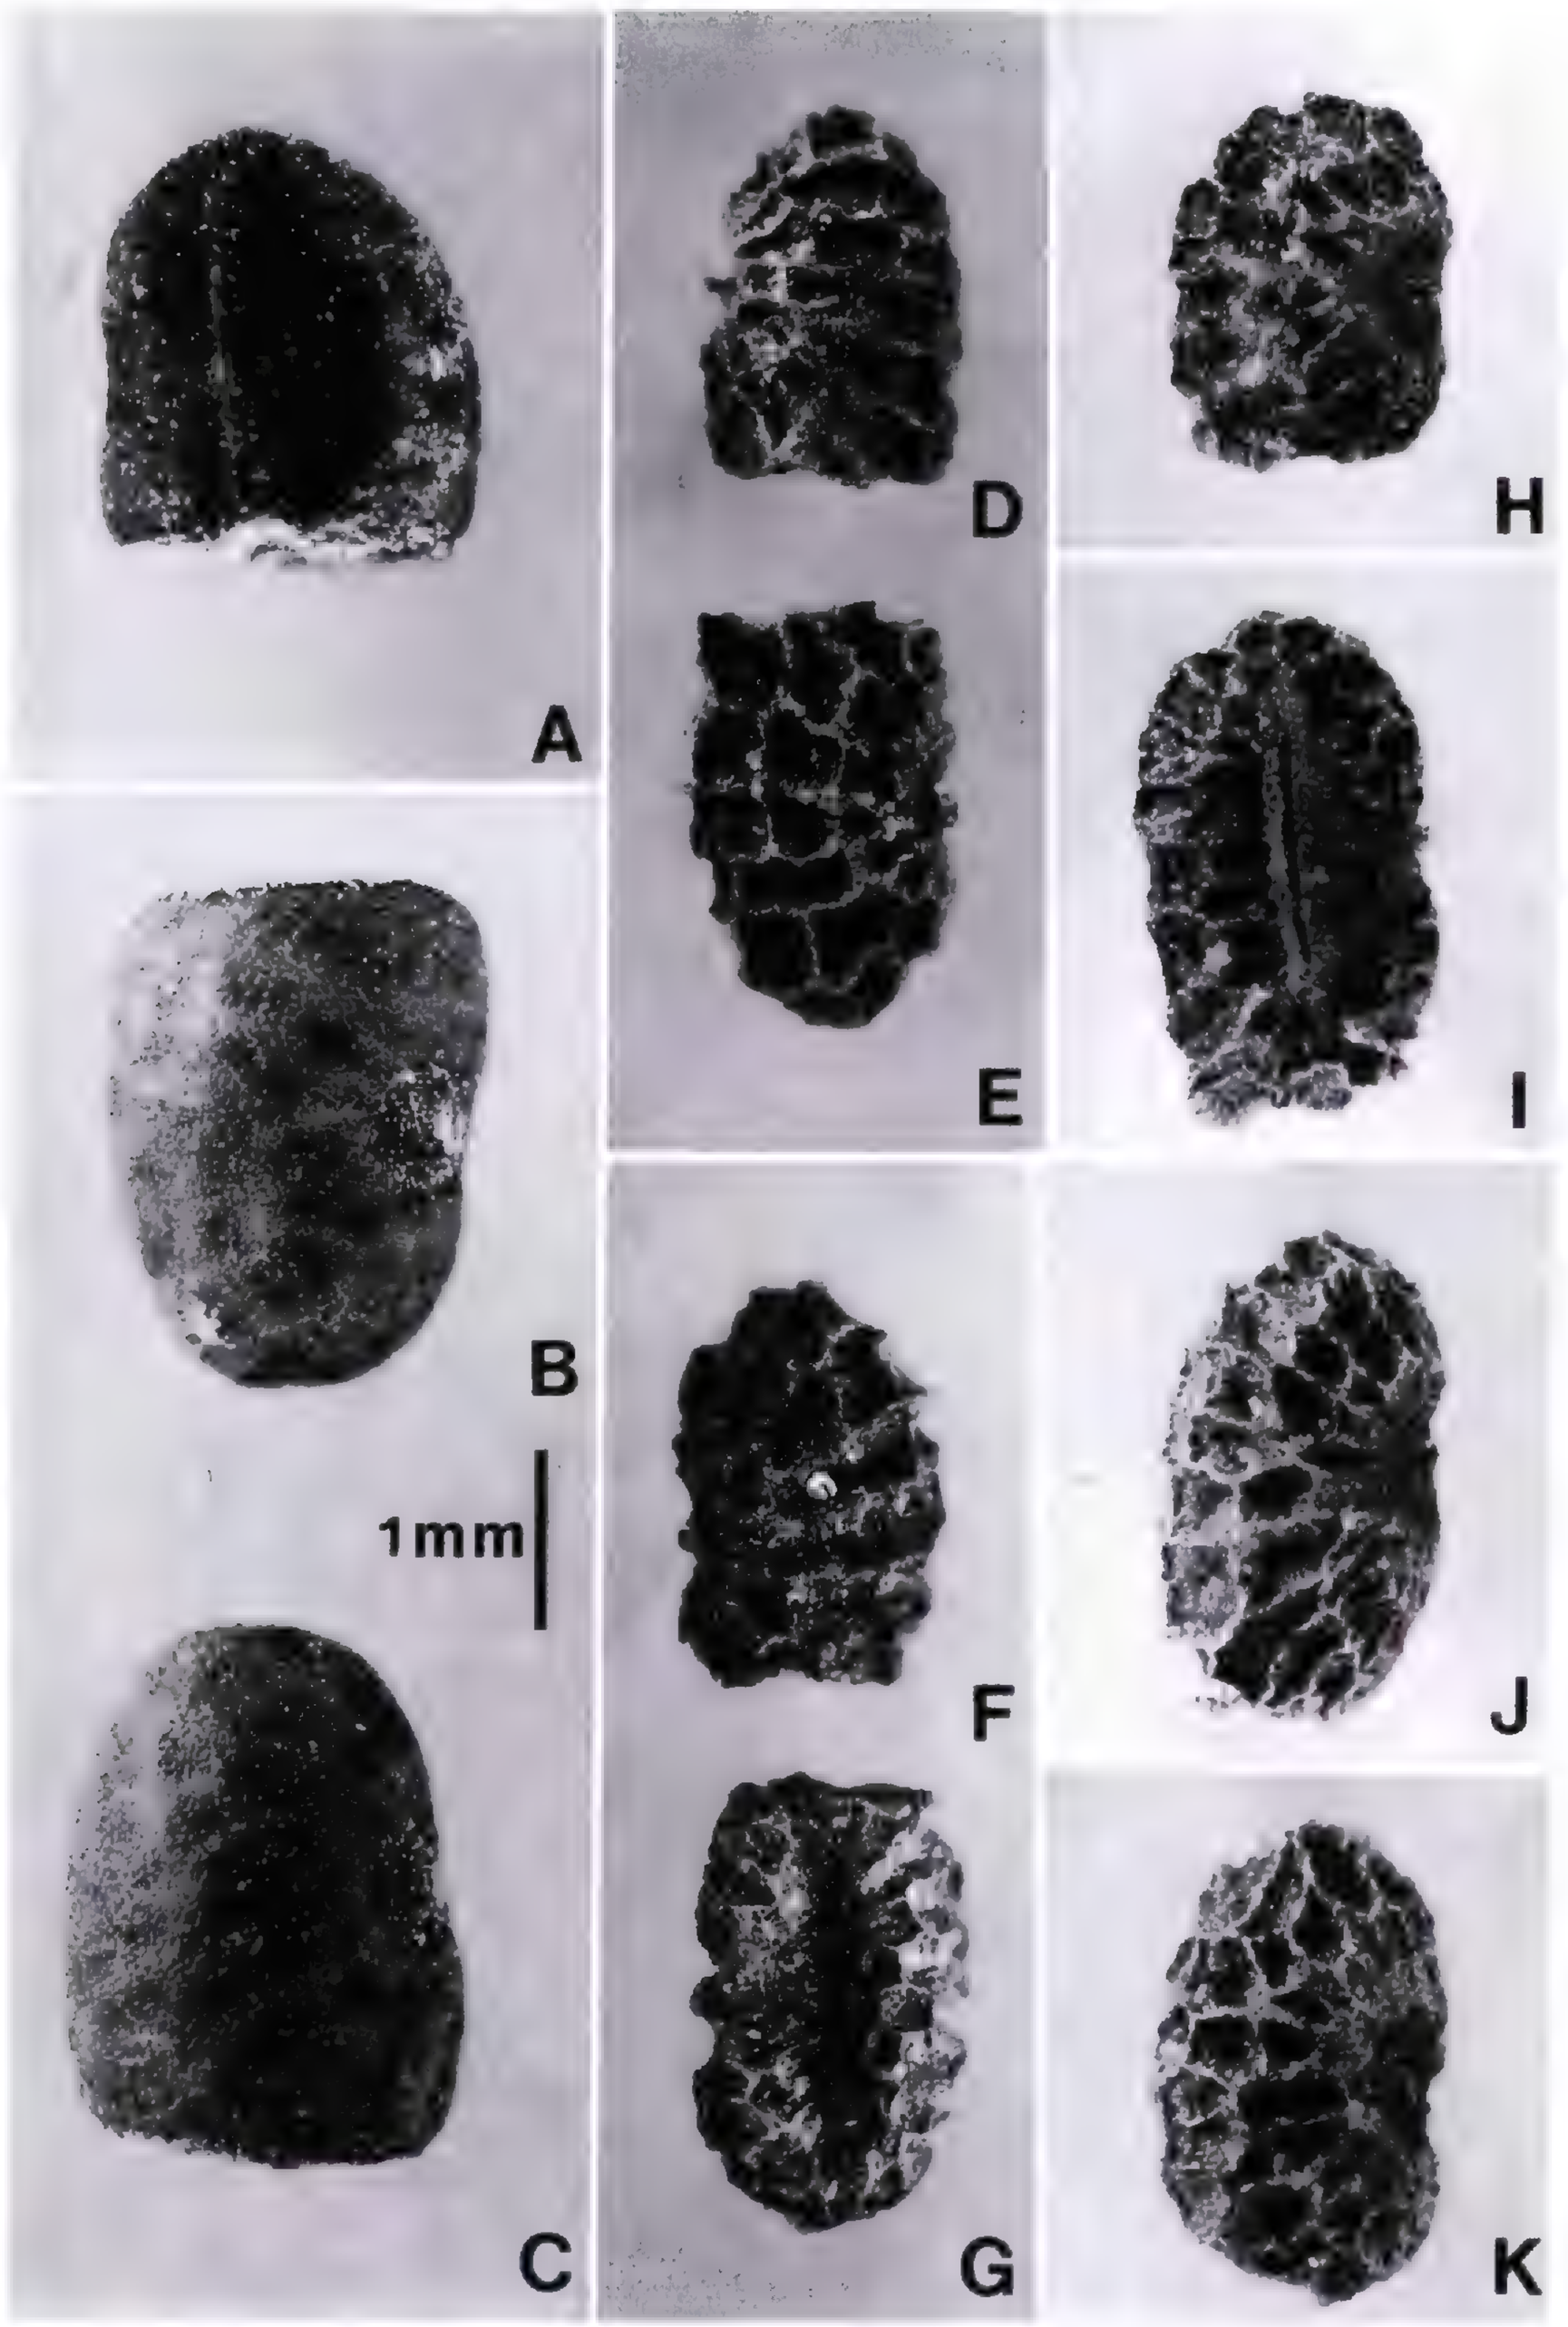

FIGURE 2. Seeds of *Commelina* species in the United States.—A–C. *Commelina caroliniana* (*Thomas et al. 86831*, US).—D–G. *Commelina diffusa* var. *diffusa* (*Faden & Faden 76/1*, US).—H–K. *Commelina diffusa* var. *gigas* (*Faden et al. 83/35*, US). All to the same scale.

*C. diffusa*. The hairs on the peduncles of the spathes are longer in *C. caroliniana* (to 0.5 mm long) than in *C. diffusa* (to ca. 0.1 mm).

The floral differences between the two species, listed in Table 1, need further verification. Although the floral morphology of *C. diffusa* has been recorded from numerous populations in the Paleotropics, it has been observed in only a few, scattered populations in the United States. Similarly, living material from only three populations of *C. caroliniana* (all from Louisiana, supplied by R. Dale Thomas) has been studied. Populations of *C. diffusa* typically have some or all flowers with the medial staminode vestigial or lacking. The antherodes (staminode anthers) in this species never have a central maroon spot. The medial stamen anther normally has a violet to maroon connective (but see *C. gigas* below).

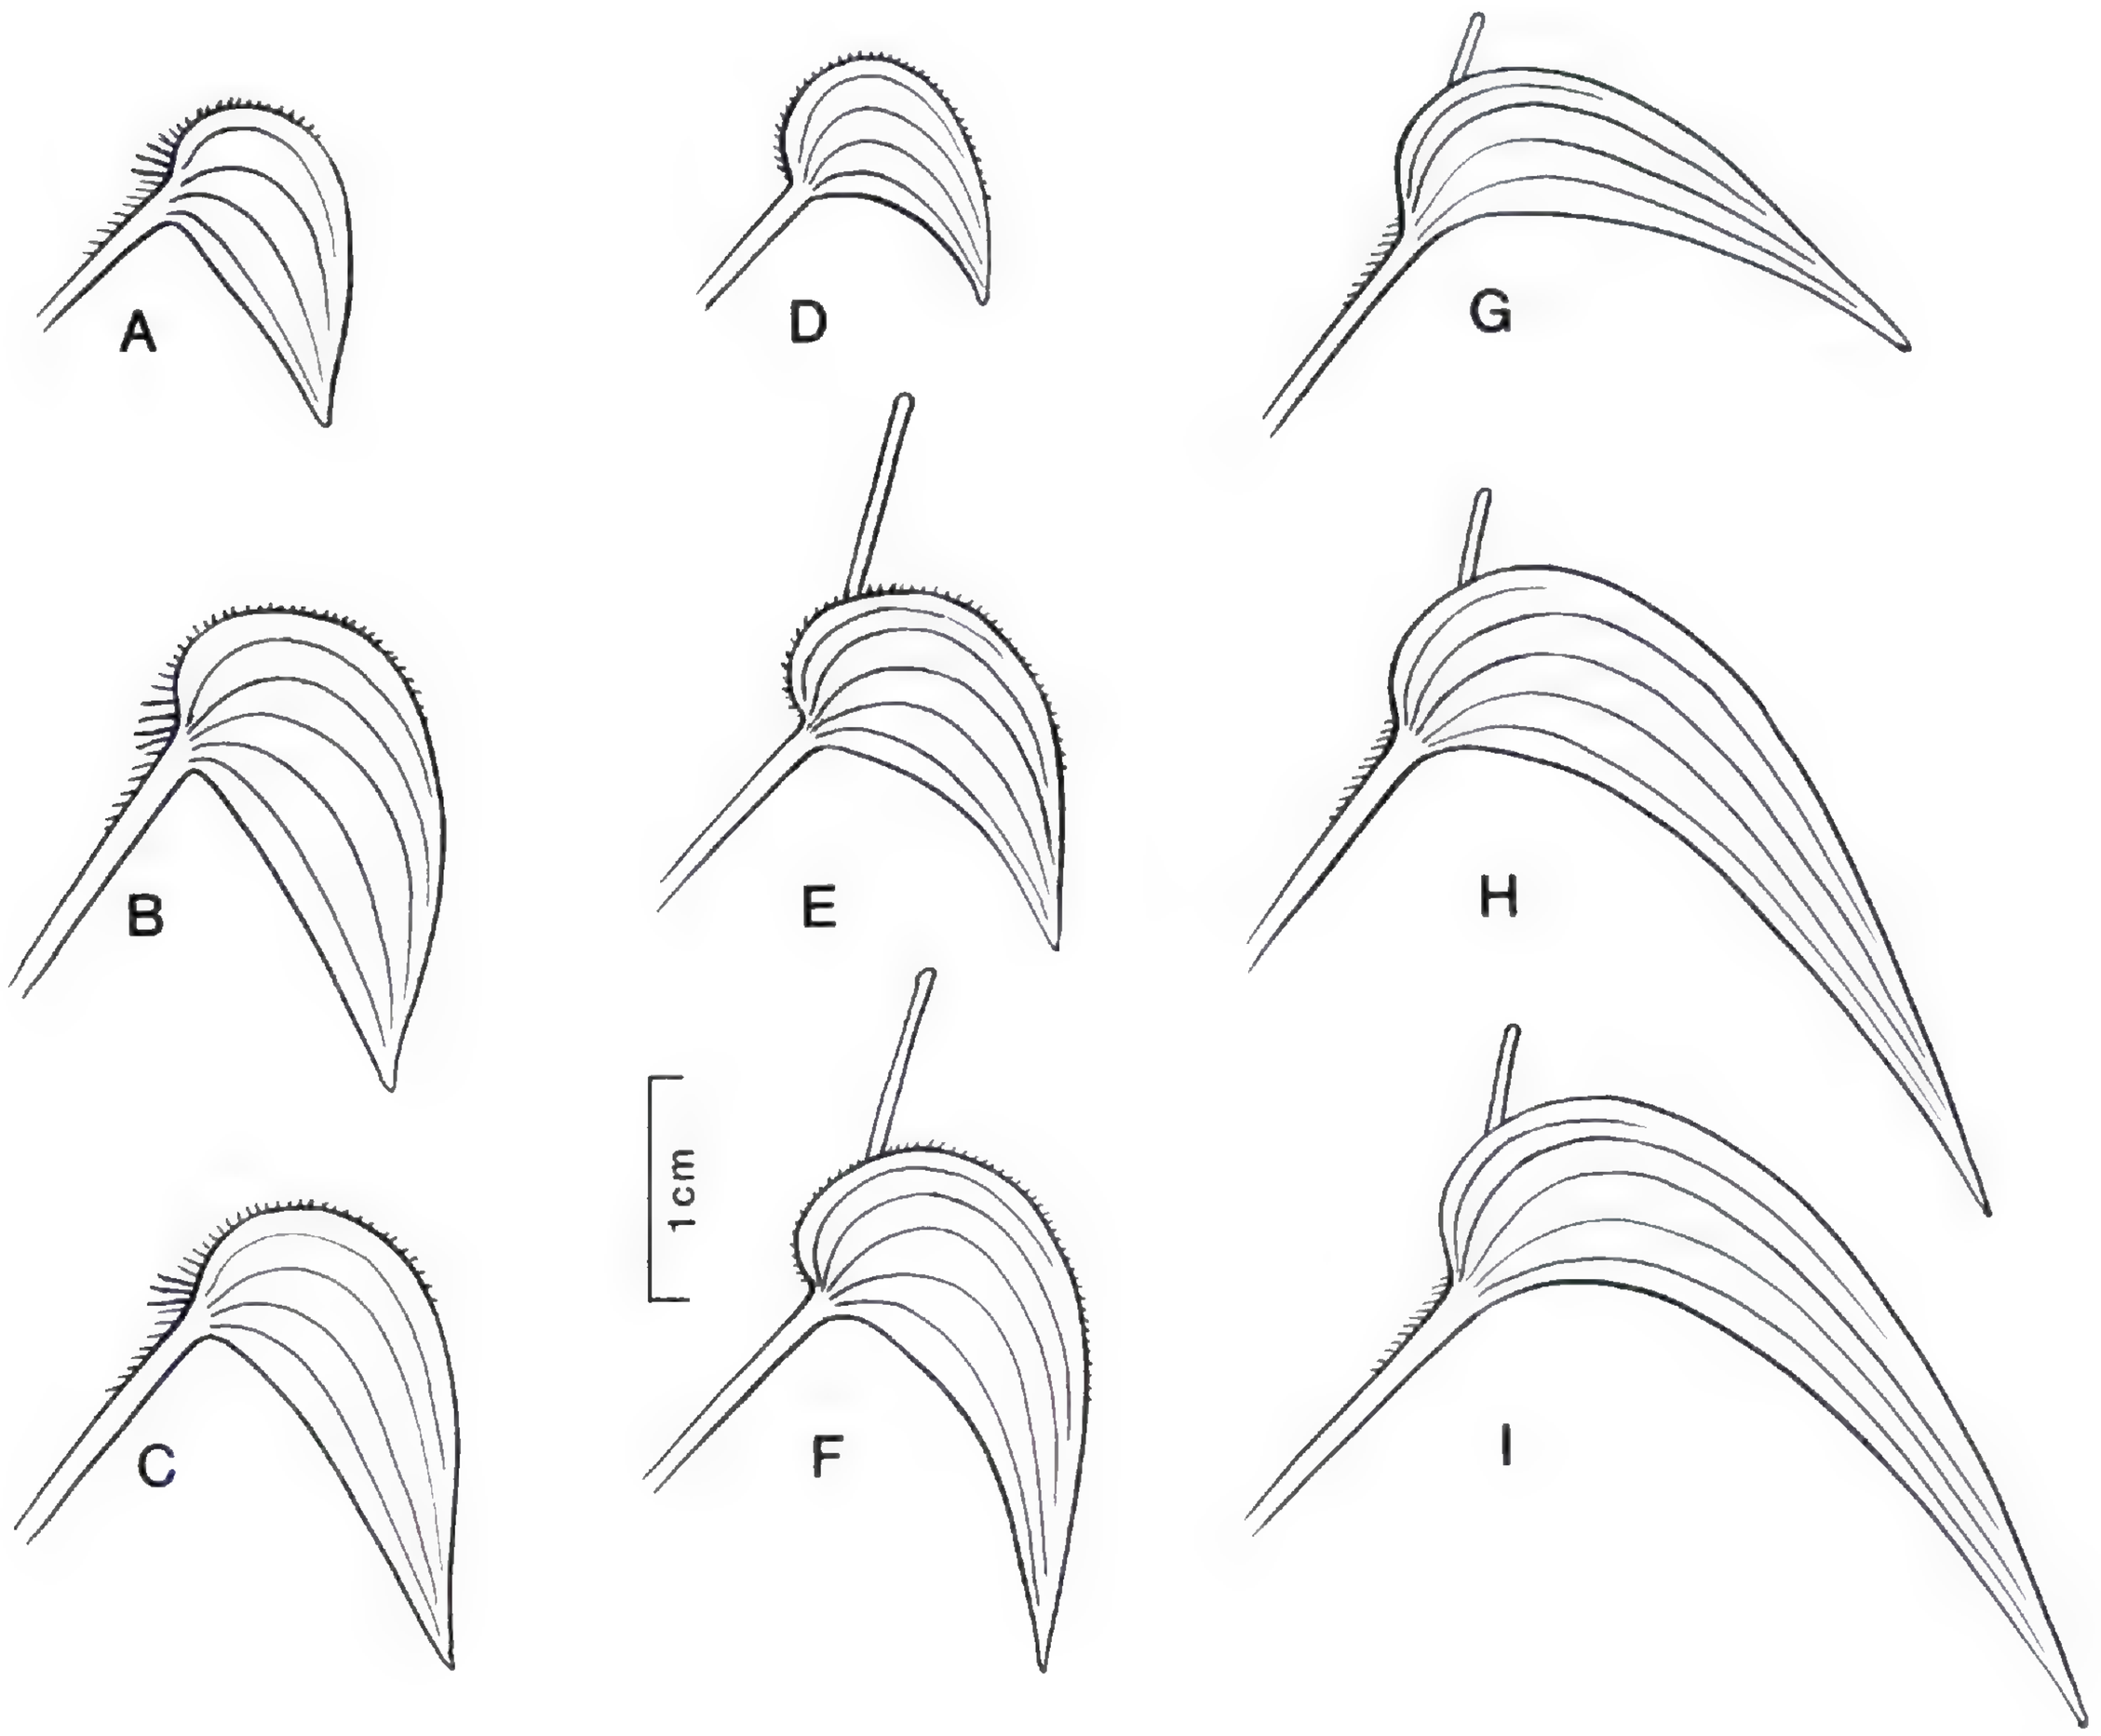

FIGURE 3. Spathes of *Commelina* species in the United States.—A–C. *Commelina caroliniana* (A, *Garber s.n.*, US; B, *Mellichamp s.n.*, US; C, *Curtiss 5177*, US).—D–F. *Commelina diffusa* var. *diffusa* (D, *Smith 486*, US; E, *Plowman 13267*, US; F, *Anderson 10893*, US).—G–I. *Commelina diffusa* var. *gigas* (*Faden et al. 83/35*, US). All to the same scale.

In *C. caroliniana* the flowers from all three populations observed had three equal staminodes with fully developed, 4–6-lobed antherodes. In two of the populations the antherodes had a central maroon spot; in the third population the antherode lobes were entirely yellow. In *Garber s.n.* (US) from Florida, the yellow antherodes of pressed flowers show a central blue spot. In all three living collections, the medial stamen anther consistently had a white connective. It is probable that at least some floral differences noted between the two species will be confirmed from further observations.

Cytological differences between the two species have also been found. Although *C. diffusa* has been reported to have many different chromosome numbers in various parts of its pantropical and warm temperate range (see Faden & Suda, 1980, for summary), the only count for typical material from the United States is $2n = 30$ (two populations from Florida: *Faden et al. 83/32*, *J. Thomas s.n.*, vouchers at US). An exact count was not obtained for *C. caroliniana*, but $2n =$ ca. 86 was secured for all three Louisiana populations (*R. D. Thomas 86722*, *R. D. Thomas et al. 86830*, *R. D. Thomas et al. 86831*, all US). This agrees in ploidy (but not exact number) with two reports from India of $n = 45$ for this species (as *C. hasskarlii*) (see Rao et al., 1968, for summary). Based on preliminary data, typical *C. diffusa* is diploid in the United States while *C. caroliniana* is hexaploid and probably also aneuploid.

Only one specimen that is probably *C. caroliniana* cannot be identified with certainty. Unfortunately, *Toler 45* (UARK) would represent the sole record from Arkansas (see Fig. 1). The single spathe of this flowering specimen is typical for *C. caroliniana*, but the spathe base is broken, and the marginal hairs cannot be checked. Better material

TABLE 1. Differences between *Commelina diffusa* and *C. caroliniana*.

| *COMMELINA CAROLINIANA* | *COMMELINA DIFFUSA* |
|---|---|
| Spathes not at all to slightly falcate, margins usually ciliate basally | Spathes usually distinctly falcate, margins glabrous or ciliolate (rarely ciliate) |
| Upper cyme usually vestigial (rarely well developed and 1-flowered) | Upper cyme in larger spathes well developed and 1–several-flowered |
| All 3 staminodes with well-developed antherodes, antherodes yellow, usually with a central maroon spot | Middle staminode commonly lacking or without antherode, antherodes entirely yellow |
| Middle anther connective white | Middle anther connective maroon to violet |
| Capsules (5–)6–8 mm long | Capsules 4–6.3 mm long |
| Ventral locule seeds smooth to faintly alveolate, 2.4–4.3(–4.6) mm long | Ventral locule seeds deeply reticulate, 2–2.8(–3.2) mm long |

is needed to confirm this species from the state, which would appear to be a reasonable extension of its confirmed range.

The record from Jackson County, Missouri, is based on two collections (one sterile and thus uncertain) from Sheffield (*Bush 3307*, *3332*, both GH, NY), which the collector (in 1905) noted as introduced. In *Flora of Missouri*, Steyermark (1963) treated this as an introduced species. It has not been re-collected in the state. Curiously, there is a very old specimen (*Nuttall s.n.*, PH) of *C. caroliniana* labeled "Missouri" but without further locality information. The state of Missouri would seem to be a very unlikely location for such an early collection of this species.

The specimen *Tracy 5122* (NY) is annotated as having been used for the illustration of *C. caroliniana* in Gleason (1952, 1963). This is the only previously published illustration of this species based on North American material.

*Commelina caroliniana* shows a limited amount of morphological variation throughout its North American range (in comparison with that shown in India). This suggests a single introduction. If the highly unusual chromosome number $2n = 86$, which would be a unique number in the genus, can be confirmed and is found to be general among American populations of this species, that would provide further evidence for a single introduction.

Plants of *C. caroliniana* occur in many different habitats, such as fields, roadsides, yards, waste places, especially in moist situations, and as a weed in crops, partcularly rice, sugarcane, and corn. Flowering occurs mainly from July to November.

## THE STATUS OF *COMMELINA GIGAS*

*Commelina gigas* was described by Small (1933) from hammocks of the Lake Okeechobee region of Florida. The plant, which has never been reported outside of Florida, has remained shrouded in obscurity since its description, being either ignored entirely (e.g., Brashier, 1966; Shetler & Skog, 1978) or listed without comment (e.g., Faden, 1982; Kartesz & Kartesz, 1980; Wunderlin, 1982). When I began work on the Commelinaceae of the southeastern United States, I recognized that Small's species required a critical reevaluation.

Surveys of endangered species of Florida had called attention to *C. gigas* as possibly endangered (Austin et al., 1980; Ward, 1978). This culminated in a brief paper by Austin (1985) in which *C. gigas* was claimed to be no more than a giant form of the introduced weed *C. diffusa*. While I agree with Austin that *C. gigas* is conspecific with *C. diffusa*, I find it more distinctive than he did. This is particularly true when specimens of *C. caroliniana*, which Austin did not recognize, are removed from consideration, and only those belonging to *C. diffusa* and *C. gigas* are compared.

*Commelina gigas* is a robust, spreading, apparently perennial herb that sometimes scrambles in shrubs. Its spathes are solitary, simply folded, falcate and very long and narrow (Fig. 3G–I). The upper cincinnus is usually exserted and one- to three-flowered. The flowers have three blue petals. The medial staminode may be lacking, or present and represented only by a filament, or with a reduced antherode (relative to the other two), or fully developed and similar to the lateral antherodes. The medial stamen anther connective is white. The ovaries are 5-ovulate, but the capsules typically have only one or two seeds in them. The testa has a strongly raised reticulum (Fig. 2). The descriptions of the floral parts in *C. gigas* are based on a small number of flowers from two collections of the same population (*Faden et al. 83/35* and

TABLE 2. Differences between *Commelina gigas* and typical *C. diffusa*.

| *COMMELINA GIGAS* | *COMMELINA DIFFUSA* (TYPICAL) |
|---|---|
| Plants sometimes scrambling in shrubs | Plants diffusely spreading, not scrambling in shrubs |
| Leaves 6–14 cm long, 1–3.3 cm wide | Leaves 1.5–5(–8) cm long, 0.5–1(–2.2) cm wide |
| Spathes 2.3–4 cm long, 2.5–6× as long as high | Spathes (0.5–)0.8–2.5(–3.7) cm long, 1.6–2.7(–3.3)× as long as high |
| Middle anther connective white | Middle anther connective maroon to violet |
| Capsules typically 1–2-seeded (through abortion) | Capsules 5-seeded (occasionally less, by abortion) |

*Wunderlin & Beckner 9118*), so the account of the stamens and staminodes should be considered provisional.

The morphological differences between *C. gigas* and typical *C. diffusa* are summarized in Table 2. To these may be added ploidy. A plant of *C. gigas* (*Faden et al. 83/35*, voucher US) has been found to be a euploid hexaploid, with $2n = 90$ chromosomes, while Florida plants of *C. diffusa*, as noted above, were found to be diploid ($2n = 30$).

Except for the color of the middle anther connective, all of the differences between *C. gigas* and *C. diffusa* are quantitative, and all can be explained by the difference in ploidy. The hexaploid is more robust and has larger leaves and spathes. The small number of seeds in the capsules of *C. gigas* could be due to reduced pollen fertility. Pollen from two Florida populations of *C. diffusa* was found to average 94% fertile (range 72–100%, N = 8); pollen from one population of *C. gigas* averaged 64% fertile (range 53–78%, N = 8). In cultivated plants of *C. gigas* few capsules are produced, and those show the same low seed numbers as field-collected specimens.

The seeds of *C. gigas* and *C. diffusa* are indistinguishable (Fig. 2), although Small (1933: 264) had erroneously described those of the former as smooth. Typically, seeds of related species of *Commelina* differ in size or testa pattern, or both. This identity of *C. gigas* and *C. diffusa* seeds, and the types of magnitude of the differences between these plants demonstrate that *C. gigas* cannot stand as a species. However, it does have a distinct range and it is recognizable, both in the field and in the herbarium. I think that *C. gigas* is best treated as a variety of *C. diffusa*.

**Commelina diffusa** Burm. f. var. **gigas** (Small) Faden, comb. nov. *Commelina gigas* Small, Manual Southeastern Flora, 264. 1933. TYPE (cited on p. 1503 of the same book): Florida. Palm Beach Co.: E shore of Lake Okeechobee, 9–10 May 1917, *Small 8247* (holotype, NY).

*Commelina diffusa* var. *gigas* is restricted to south-central peninsular Florida (Fig. 4). A map of its distribution was published by Ward (1978), showing it in all counties surrounding Lake Okeechobee and extending southeastward into Broward County. Ward's map shows a number of county records that I was unable to confirm from specimens present in 1983 in the three largest Florida herbaria (FLAS, FSU, USF). *Commelina diffusa* var. *diffusa* is distributed from Virginia to eastern Kansas south to Texas, the Gulf Coast and southern Florida.

*Commelina diffusa* var. *gigas* was first collected in 1913 and has been collected rarely since. Only 13 collections have been seen. Its undercollection may be due in part to its apparently sparse flowering—even the type specimen is sterile—as well as to its preference for wet habitats, such as cypress swamps, riverbanks and lakeshores. John Beckner (pers. comm.) stated that *C. diffusa* var. *gigas* easily could have achieved its present distribution by dispersal along waterways. Flowering specimens have been seen from March to May, August, November, and December.

The origins of *C. diffusa* var. *gigas* have not been determined. Either it arose in situ through polyploidy, or else it was introduced and thus not derived from local *C. diffusa*. I believe that it is more likely to have been introduced, because direct origin of a hexaploid from a diploid is implausible, and neither tetraploids nor plants of intermediate morphology are known. However, I have not been able to find any specimens from elsewhere that exactly match the Florida plants. This is why I have recognized variety *gigas* as distinct. Austin (1985) wrote that he observed plants in Hawaii that were identical to *C. gigas*, but Wagner et al. (1990) recorded the spathes of Hawaiian *C. diffusa*

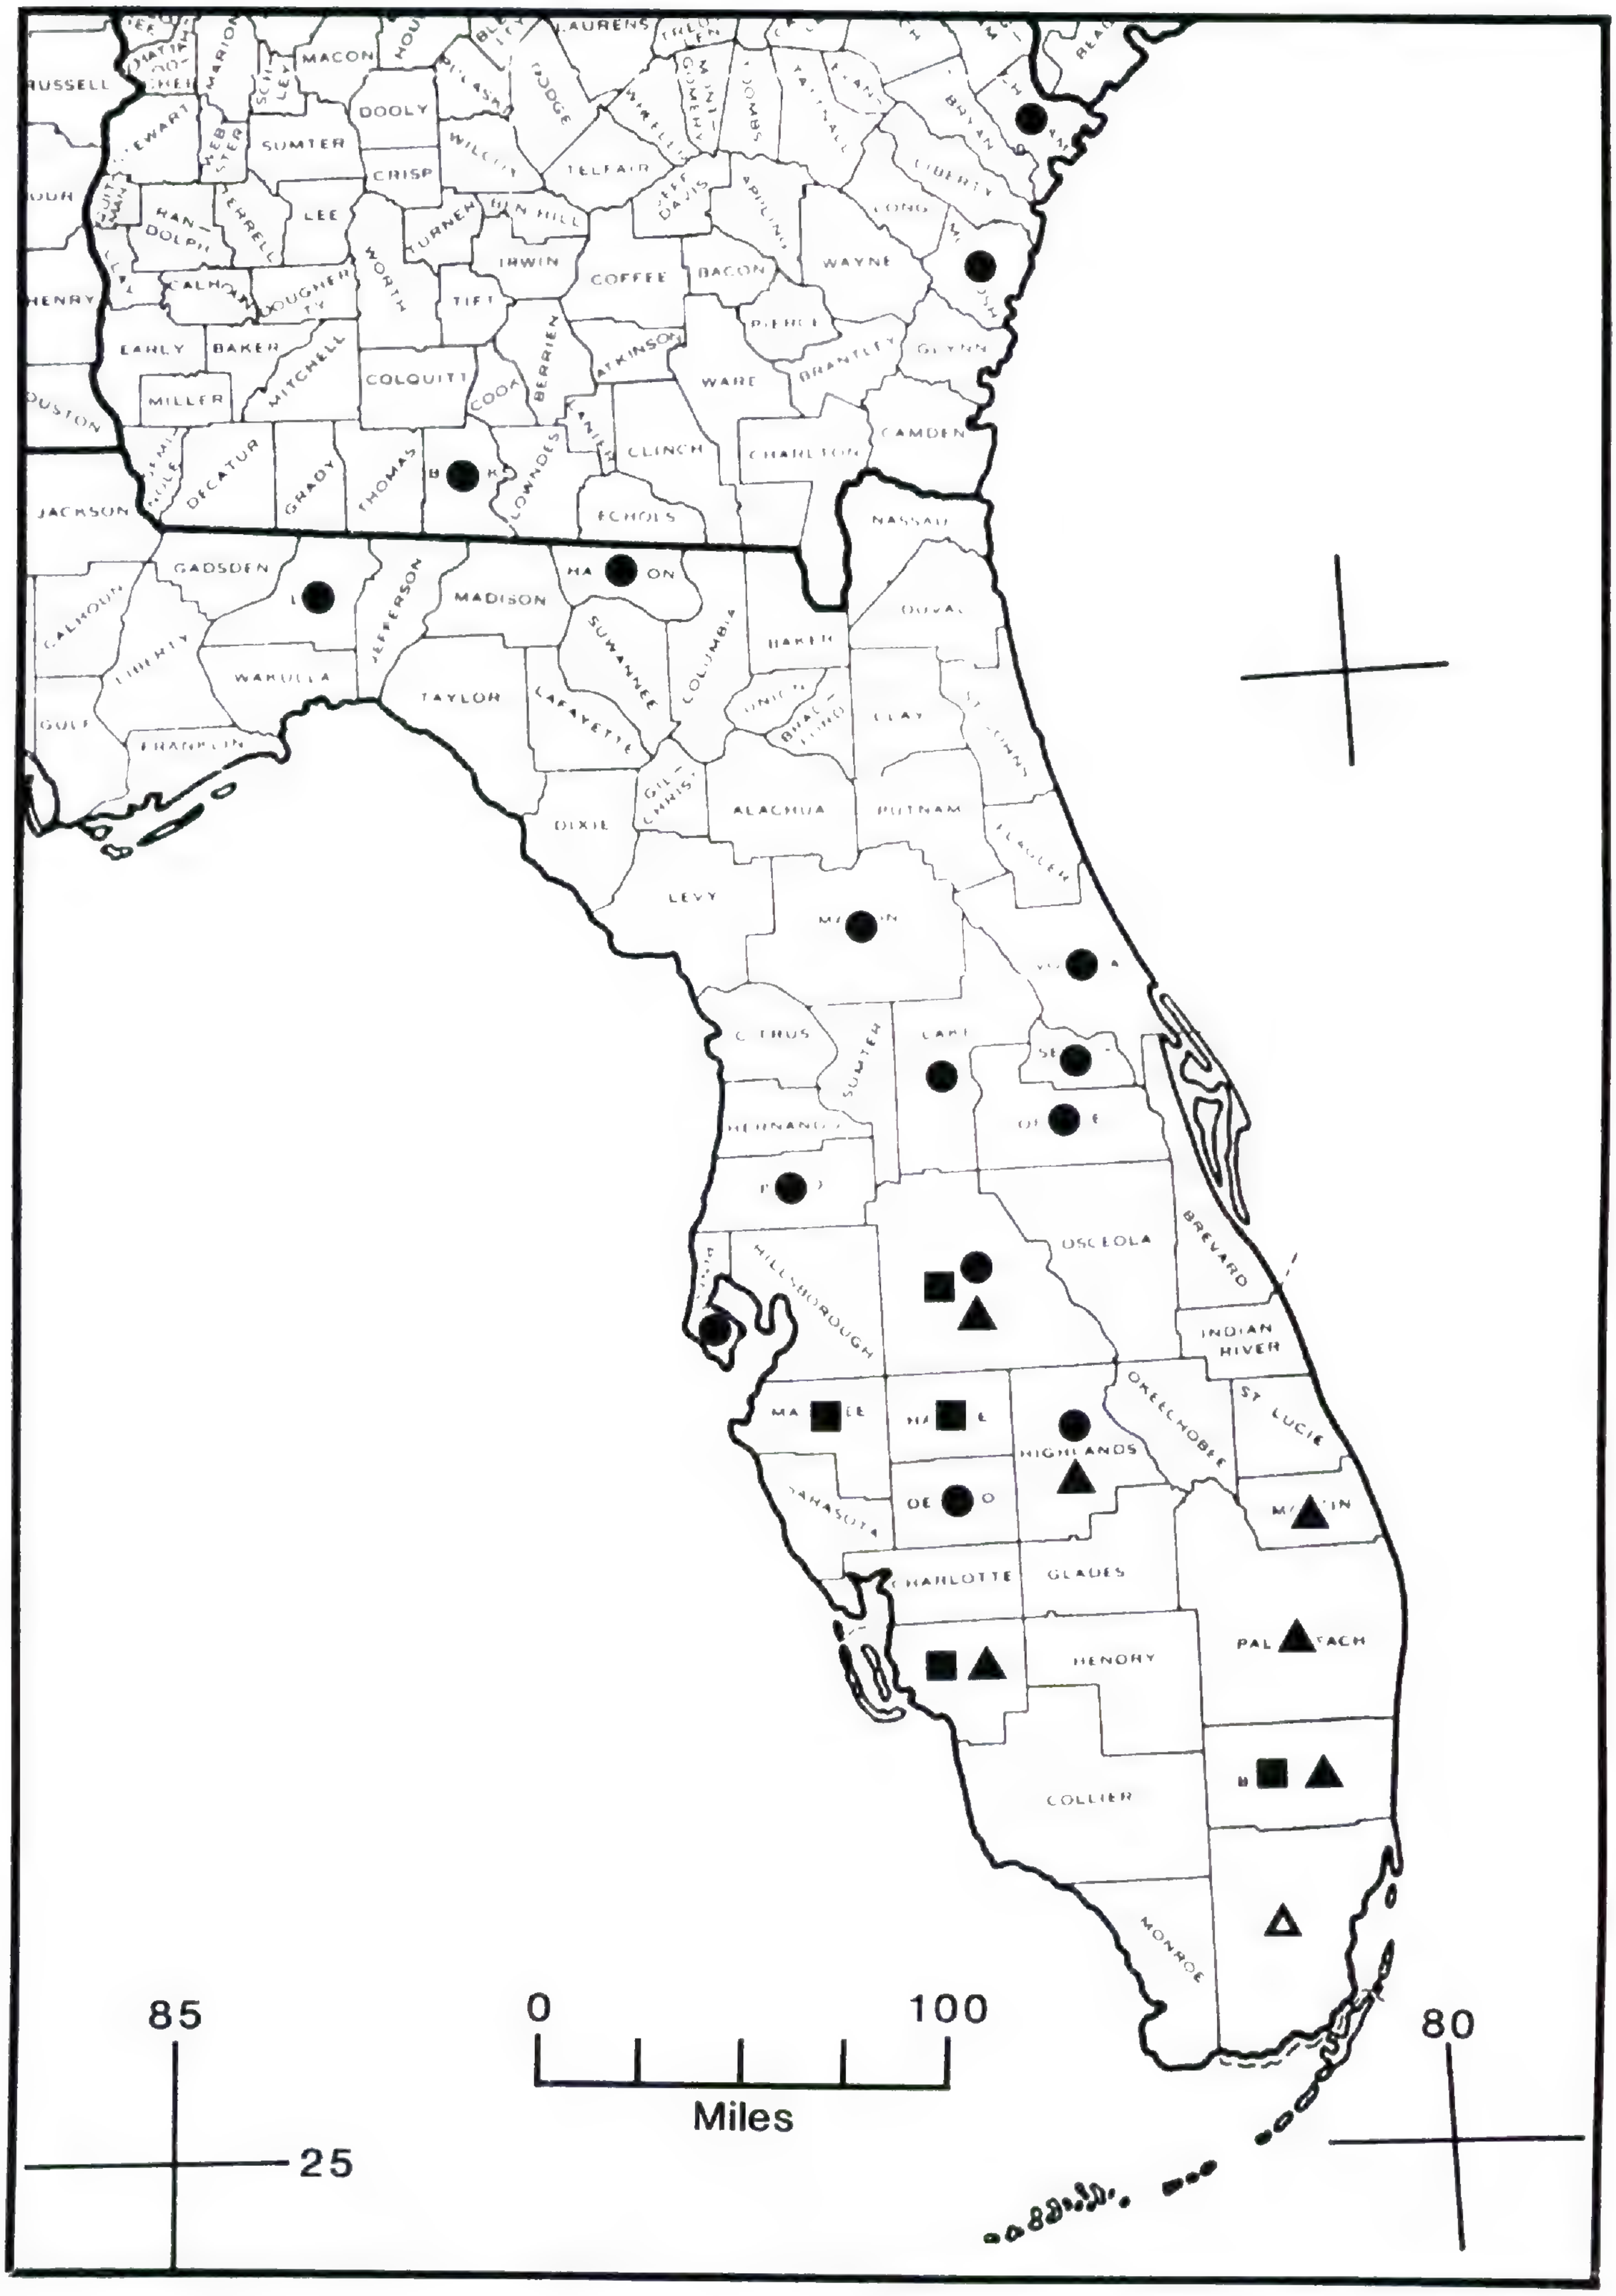

FIGURE 4. Distributions of *Commelina* species in the southeastern United States. *Commelina diffusa* var. *gigas* (solid triangles). *Commelina benghalensis* (circles), *Commelina forskaolii* (open triangle), and *Commelina nigritana* var. *gambiae* (squares).

as 1.5–2 cm long, which is too small for variety *gigas*. The origin of variety *gigas* is likely to have been the Paleotropics, but it cannot be localized further.

## *Commelina benghalensis*: A Well-established Weed in the Southeast

*Commelina benghalensis*, a common paleotropical weed, was reported by Duncan (1967) as a new species for the United States. In 1983 it was designated a "noxious weed," subject to stringent import regulations, by the U.S. Department of Agriculture (Lasseigne, 1983). Despite this fanfare and concern, *C. benghalensis* was first collected in the continental United States in 1928 (*Ruprecht s.n.*, FLAS), and by the mid 1930s it appears already to have become established in Florida. It was first cited from Florida in an unpublished manuscript (McFarlin, 1935), and its floral morphology and floral biology were studied by Uphof (1934), although the plant was misidentified as *C. virginica* L. The earliest record of *C. benghalensis* from the present United States was a pre-statehood, 1909 collection from Hawaii (Wagner et al., 1990).

*Commelina benghalensis* has been collected in at least 12 counties in Florida and three in Georgia (Fig. 4). It grows in fields, yards, other cultivated areas and disturbed sites, and especially in orange groves. This annual species can be recognized by: its funnelform spathes that are often clustered; relatively broad leaves that frequently have red hairs at the summit of the sheath; and cleistogamous flowers that are borne at the base of the plant and are usually subterranean (in addition to normal, aerial, chasmogamous flowers). The plants show a great deal of variation in leaf and spathe size and presence or absence of red hairs on the summit of the sheath and of an exserted upper cincinnus in the spathe. John Beckner (pers. comm.) stated that he thought there were two forms of *C. benghalensis* in Florida, differing in robustness and leaf size.

A study of 25 collections of *C. benghalensis* from Florida and Georgia revealed two extremes of variation: plants with small, obtuse leaves, red hairs on the sheaths, and small spathes lacking an exserted cincinnus; and plants with larger leaves (at least some acute), no red hairs, and larger spathes that frequently contain an exserted cincinnus. Although plants exhibiting these extremes are quite different in aspect, most plants are intermediate. The small-leaved type occurs only at the northern limits of distribution of the species; the larger-leaved type and intermediates are more randomly distributed but are confined to Florida.

It is possible that the extremes of morphological variation represent two separate introductions from the Old World that have since interbred, losing much of their distinctness. However, the morphological plasticity of this weed growing under different conditions has not been investigated, and it is possible that all of the variation observed may be due to environmental factors.

A chromosome count has been obtained for a plant of *Faden et al. 83/33* (US) from De Soto County, Florida, $2n = 22$. This agrees with other published counts for diploids of this species (see Faden & Suda, 1980, for summary).

*Commelina benghalensis* was recently found to be adventive in southern California (Faden & Sanders, in prep.). It is the only introduced species of *Commelina* in the western United States.

## Two Recently Introduced Species: *Commelina forskaolii* and *C. nigritana*

*Commelina forskaolii* is a common species of the drier parts of Africa and southwestern Asia. It is characterized by: small, solitary spathes with fused margins; blue flowers with lyrate, winged, lateral stamen filaments; and capsules in which usually only the dorsal locule seed develops and is shed with the dorsal capsule valve. Many populations also produce subterranean, cleistogamous flowers from the nodes of decumbent shoots.

*Commelina forskaolii* was first collected in the United States from a Dade County (Florida) Sanitary Department landfill in 1980. I first learned of its existence when I was sent a specimen of *Correll & Popenoe 51166*, the first collection, for determination. In November 1983, Popenoe showed us the single known population, from which we obtained specimens and living material. The population was quite extensive. It appeared to have been derived mainly through vegetative reproduction by diffusely spreading stems, although some seeds were present. The plants were very typical of the species, which I know well from Africa. Cleistogamous flowers could not be found. Because this species is considered a significant weed in many parts of its range, I reported it to the U.S. Department of Agriculture. In 1984, it was sprayed with herbicide. Whether it is still extant in the United States is unknown.

A chromosome count was obtained from cultivated material from this population (*Faden et al. 83/26*, US), $2n = 30$, which is usual for this species.

I first became aware of another unusual species of *Commelina* in Florida in 1978 when I was asked what an orange-flowered species in Florida might

be. No specimens were forthcoming, and it was not until several years later that I was reminded of this incident when I received a draft of the Commelinaceae for Wunderlin (1982). The name *Commelina umbellata* Thonn., a synonym of *C. nigritana* Benth., caught my attention. In 1983, accompanied by Wunderlin and John Beckner, I collected three populations of *C. nigritana* from roadsides in Hardee and Polk counties, Florida.

*Commelina nigritana* is a widespread African savanna species and occasional weed. It belongs to a group of annual species with fused spathes and buff- to orange- or apricot-colored flowers. These species also share the unusual basic chromosome number $x = 14$. Two varieties of *C. nigritiana* are recognized by Brenan (1968), variety *nigritana*, with one-seeded capsule locules and pitted seeds, and variety *gambiae* (C. B. Clarke) Brenan, with two-seeded ventral locules and reticulate seeds. All Florida plants belong to variety *gambiae*, the more narrowly distributed form, which occurs in west Africa from Senegal to northern Cameroon.

*Commelina nigritana* var. *gambiae* was first collected in Florida near Bradenton, Manatee County in 1976 (*Wunderlin 5721*, FLAS, TENN, USF). Two years later it was collected in Broward County, on the opposite side of the peninsula. It is now known from at least six counties (Fig. 4) and appears to be spreading rapidly. It has been collected almost exclusively along roadsides, and it is likely to be dispersed by mowing. So far it has not been collected in crops, so its potential to become an important weed is unknown. *Commelina nigritana* var. *gambiae* flowers from September to December.

A Florida plant of *C. nigritana* var. *gambiae* (*Faden et al. 83/27*, US) was found to be tetraploid, with $2n = 56$ chromosomes. The only previous counts for this variety, based on African material, were $2n = 28$, with occasional root tip cells in one population having 56 chromosomes (Morton, 1967).

## Discussion

Among the nine species of *Commelina* in the United States, six are not indigenous: *C. benghalensis*, *C. caroliniana*, *C. communis*, *C. diffusa*, *C. forskaolii*, and *C. nigritana*. Only *C. dianthifolia*, *C. erecta*, and *C. virginica* are native. The recent discoveries of *C. forskaolii* and *C. nigritana* in Florida and of *C. benghalensis* in California should alert botanists, especially in the South, to collect any unusual-looking plants of this genus.

*Commelina*, with 170 species, is the largest genus of Commelinaceae and its species are often difficult to identify. Capsules and seeds are frequently critical, so they should always be looked for when making collections of this genus. Flowers should be pressed separately between absorbent paper or cellophane. Floral features that should be particularly noted are: lateral sepal fusion (when present); paired petal color; lower petal degree of development and color; number of staminodes and color of the antherodes; and color of the anther connectives and pollen.

## Key to the United States Species of *Commelina*

1a. Spathes with margins free to the base.
  2a. Perennials with erect to ascending shoots; roots tuberous; leaves linear to linear-lanceolate ..... 1. *C. dianthifolia*
  2b. Annuals or perennials usually with decumbent to scandent shoots; leaves narrowly lanceolate to ovate-elliptic.
    3a. Spathes generally whitish or pale green towards the peduncle with contrasting, dark green veins; middle petal white or paler than the others; capsules bilocular; seeds rugose foveate-reticulate ..... 2. *C. communis*
    3b. Spathes lacking contrasting veins; middle petal ± concolorous with the others; capsules trilocular; seeds reticulate or smooth to faintly alveolate.
      4a. Spathes not at all to slightly falcate; upper cyme usually vestigial (rarely well developed and 1-flowered); seeds smooth to faintly alveolate ..... 3. *C. caroliniana*
      4b. Spathes usually distinctly falcate; upper cyme in larger spathes usually well developed and 1-several-flowered; seeds reticulate ..... 4. *C. diffusa*
1b. Spathes with margins fused basally.
  5a. Flowers apricot- or peach-colored ..... 5. *C. nigritana*
  5b. Flowers blue (rarely lilac to lavender or white).
    6a. Leaves with auricles at summits of sheaths; roots stout; middle petal white, inconspicuous; locules all 1-seeded ..... 6. *C. erecta*
    6b. Leaves not auriculate; roots thin; middle petal blue to lilac or lavender, conspicuous; some locules usually 2-seeded.
      7a. Perennials with erect to ascending shoots; sheaths with red hairs at the summit; lamina 6–20 cm long; spathes 1.5–3 cm long; underground, cleistogamous flowers lacking ..... 7. *C. virginica*

7b. Annuals or perennials with ascending to decumbent, repent or scrambling shoots; sheaths with or without red hairs at the summit; lamina 2–7(–9) cm long; spathes 0.5–2 cm long; underground, cleistogamous flowers sometimes present.

8a. Lamina ovate to lanceolate–elliptic; sheaths often with red hairs at summit; lateral stamen filaments not winged; capsules usually 5-seeded, the ventral locule seeds developed ..... 8. *C. benghalensis*

8b. Lamina oblong to lanceolate-oblong or oblong-elliptic; sheaths lacking red hairs; lateral stamen filaments winged; capsules usually 1-seeded, only the dorsal locule seed developed ..... 9. *C. forskaolii*

Appendix. Specimens of *Commelina caroliniana* seen from the United States.

Because of the difficulty in identifying *Commelina caroliniana* with certainty, all American specimens seen of this species are cited below. This is intended to be a means for checking whether particular specimens belong to this species, so only collection numbers and institutional codes are listed. Institutional sheet numbers (when available) are listed where there is no collection number. Specimens from NLU with more than one collection number on the sheet have the additional number(s) in brackets.

# *TRADESCANTIA CRASSIFOLIA* (COMMELINACEAE), AN OVERLOOKED SPECIES IN THE SOUTHWESTERN UNITED STATES[1]

*Robert B. Faden*[2]

ABSTRACT

*Tradescantia crassifolia* (Commelinaceae), a widespread species in Mexico, is reported from the United States for the first time, based on two nineteenth-century collections. The specimen from Texas is considered reliably localized; that from New Mexico is deemed questionable.

*Tradescantia crassifolia* Cav., a common species known from Mexico to Guatemala, has not been reported from the United States. In the course of preparing the *Flora of North America* treatment of Commelinaceae, I discovered two old specimens that document this species in the Southwest. I call attention to this record and encourage local botanists to seek this species in order to determine whether it is still extant in the United States. The specimens seen are:

UNITED STATES. TEXAS: Chinati [Chenate] Mountains, *V. Havard*, October 1880 (US sheet #225303) (Fig. 1). NEW MEXICO: Without specific locality, *Edwards*, 1848 (NY).

It is probable that the locality of the Texas specimen is correctly stated. Valéry (often written without the accent mark of the original French) Havard (1846–1927), an Army physician with a background in botany, collected plants in western Texas from 1880 to 1884 (Lanjouw & Stafleu, 1957; McVaugh, 1957). McVaugh, quoting monthly reports filed by Havard (originals in the National Archives), noted that in Havard's report of 30 September 1880 he mentioned a trip made to the Chinati Mountains, and that in a later report he recorded being in these mountains 20–24 December the same year. McVaugh concluded that Havard probably gained most of his knowledge of the Chinati Mountains between September and December 1880, when he was Post Surgeon at Camp Eagle Nest in Presidio. Havard's (1885) "Report on the flora of western and southern Texas" included a brief account of the flora of the Chinati Mountains, demonstrating that he clearly visited the area and could have collected plants there (publication of this in the *Proceedings of the U.S. National Museum* was a direct quid pro quo for Havard's donation of his collections to the Smithsonian Institution, according to correspondence in the Smithsonian Institution archives). There is no evidence that Havard ever collected in Mexico, the only other possible origin of this specimen.

Hunt (in litt., 4 Oct. 1990) stated that a range extension for *T. crassifolia* into Texas and New Mexico would not be unreasonable. In the U.S. National Herbarium there are two Mexican collections of *T. crassifolia* from the Sierra del Carmen, Coahuila, a mountain range very close to Big Bend National Park, Texas, and six collections from the region around Cd. Chihuahua. These Mexican localities are in the same U.S.D.A. Plant Hardiness Zone (Zone 8) (Cathey, 1990) as the Chinati Mountains, which could thereby be expected to support many of the same plant species. Johnston (in litt.) has noted that several Mexican species are known in the United States only from the Chinati Mountains, including *Calliandra coulteri* S. Watson (Fabaceae) and *Argythamnia astroplethes* J. Ingram (Euphorbiaceae).

The New Mexican collection is more problematical. The collector Edwards is Lewis Allison Edwards (fide R. Barneby via M. Nee) (1823–1877), an Army surgeon who was stationed near Monterey, Mexico, during the Mexican War, 1846–1848, and sent plant collections to John Torrey.

[1] I thank reviewer Marshall Johnston and an anonymous reviewer for helpful suggestions.

[2] Department of Botany, National Museum of Natural History, Smithsonian Institution, Washington, D.C. 20560, U.S.A.

FIGURE 1. *Tradescantia crassifolia* Cav. (*Havard s.n.*, US).

He is commemorated by *Cracca edwardsii* A. Gray (fide R. Barneby). Edwards was based in Santa Fe after the Mexican War. On 29 June 1848 he wrote to John Torrey (archives New York Botanical Garden) from Monterrey, Mexico, that "We have just received orders to proceed to California & Santa Fe. . . . We start in about 14 days, passing through Parras, the great vine growing country, Chihuahua, Paso del Norte, &c." Edwards wrote that he hoped to "make amends" during the next 10 months for not having collected many specimens recently. Edwards's actual itinerary was detailed in a 20 October 1848 report (original in National Archives) sent to Thomas Lawson, Surgeon General, U.S. Army, from Santa Fe: "The command left Monterey [sic] on the 25th of July, arriving at the village of Castañuelas on the 31st, a distance of 115 miles. On the 26th of August we reached Chihuahua, remaining at that city until the 1st ultimo. On the 30th of September we encamped at the settlement of Sa Parida, distant from Chihuahua 376 miles. On the 10th inst. we arrived at this place, making in all a distance of about 1050 miles." He was stationed at Santa Fe until September 1850 (Woodward, 1879).

Whether Edwards actually collected plants in New Mexico is uncertain (e.g., he is not included in McKelvey, 1955). Rodgers (1942: 219), stated that Edwards was one of several collectors who collected in the vicinity of Santa Fe, these collections forming the basis of *Plantae fendlerianae* (Gray, 1849), but a perusal of this work revealed that the only Edwards's collections cited are from Mexico. The only other evidence is the label on the specimen of *T. crassifolia* cited above. The problems with that information are: (1) "New Mexico" (as of February 1848) was the newly ceded New Mexico Territory, consisting of most of the present states of New Mexico and Arizona, as well as a small portion of Colorado, and some of western Texas (Wooton, 1906) (the locality is thus rather vague); and (2) the Santa Fe area, where Edwards was based and would have had time to collect plants, appears to be climatically unsuitable for this plant (R. Spellenberg, pers. comm.). The specimen most likely came from further south and was collected en route to Santa Fe. Edwards passed through appropriate habitats for this species (and at the right time of year to find it) around Cd. Chihuahua, where the plant is known to occur. Thus it could have been collected in Mexico and later mislabeled. Hence, the New Mexico record is unproven.

*Tradescantia crassifolia* Cav. (Fig. 1) is easily recognized by a number of features: tuberous roots; distichous, lanceolate to ovate leaves; cobwebby, white pubescence on the vegetative parts (especially the leaf sheaths); sessile cyme-pairs in the axils of the upper 1–5(–7) leaves; pedicels and sepals pilose with eglandular hairs. Although this species is very variable in Mexico, especially in shoot length, leaf shape, and amount of pubescence on the vegetative parts, it is unlikely to be confused with any of the five other species of *Tradescantia* that occur in Trans-Pecos Texas and/or New Mexico. All of these species have some or all of the cyme-pairs stipitate and subtended by foliaceous or spathaceous bracts. In addition, three of them, *T. wrightii* Rose & Bush (Texas and New Mexico), *T. pinetorum* Greene (New Mexico), and *T. occidentalis* (Britton) Smyth (Texas and New Mexico), have linear-lanceolate, glabrous (to scabridulous) leaves, and glabrous to glandular-puberulent sepals. The other two west Texas species, both formerly placed in *Setcreasea* (see Hunt, 1975), *T. brevifolia* (Torrey) Rose and *T. leiandra* Torrey, have terminal or leaf-opposed inflorescences, clawed petals that are gamepetalous basally, and glabrous filaments. In addition, *T. leiandra* has sepals with glandular or eglandular hairs, and *T. brevifolia* has glabrous sepals. *Tradescantia crassifolia* is the only species of section *Mandonia* D. R. Hunt (Hunt, 1980) to occur in the United States.

After this manuscript was completed and reviewed I had the opportunity to reexamine Edwards's collection at the New York Botanical Garden. The sepals and pedicels of the specimen have numerous glandular hairs, a feature that does not agree with *T. crassifolia* or with any other species of section *Mandonia* (Hunt, 1980). Thus, this putative record of *T. crassifolia* from New Mexico is even more doubtful. In view of this new information, I subsequently restudied Havard's specimen and reconfirmed that it is indeed *T. crassifolia*. Although the specimen has only sparsely pubescent leaves (unlike many Mexican collections), it does not match *T. crassifolia* var. *glabrata* C. B. Clarke, which has the lamina glabrous except for a marginal band of dense, white, woolly hairs.

# EL GENERO *INGA* (LEGUMINOSAE: MIMOSOIDEAE) DEL SUR DE MEXICO Y CENTROAMERICA, ESTUDIO PREVIO PARA LA *FLORA MESOAMERICANA*[1]

Mario Sousa S.[2]

## Resumen

En la preparación del género *Inga* para la *Flora Mesoamericana* se discuten someramente la nomenclatura y taxonomía de cada especie, su variación, asi como la posible influencia del hombre. Fue necesario lectotipificar siete nombres: *Inga alba*, *I. densiflora*, *I. multijuga*, *I. oerstediana*, *I. paterno*, *I. ruiziana*, e *I. vera*. También se cita material representativo de todas las áreas donde habita cada especie, incluyendo las de fuera del área de la Flora. Se describen trece especies nuevas para la ciencia: *Inga bella*, *I. cabrerae*, *I. calcicola*, *I. cuspidata*, *I. chiapensis*, *I. dasycarpa*, *I. davidsei*, *I. dwyeri*, *I. ismaelis*, *I. lacustris*, *I. pseudoinvolucrata*, *I. sinacae*, e *I. tenella*. También se hizo un cambio nomenclatural de *Inga cocleensis* var. *megantha* a *I. cocleensis* subsp. *megantha*.

## Abstract

As a precursor to the treatment of *Inga* for the *Flora Mesoamericana*, this summary of the genus is presented, including the nomenclature, taxonomy, and variation of all the species, as well as the possible influence of humans in altering patterns of distribution and variation. Seven names are lectotypified: *Inga alba*, *I. densiflora*, *I. multijuga*, *I. oerstediana*, *I. paterno*, *I. ruiziana*, and *I. vera*. Representative specimens are cited for all species, including areas outside of Mesoamerica. Thirteen species are described as new: *Inga bella*, *I. cabrerae*, *I. calcicola*, *I. cuspidata*, *I. chiapensis*, *I. dasycarpa*, *I. davidsei*, *I. dwyeri*, *I. ismaelis*, *I. lacustris*, *I. pseudoinvolucrata*, *I. sinacae*, and *I. tenella*. A nomenclatural change was made for *Inga cocleensis* var. *megantha* to *I. cocleensis* subsp. *megantha*.

Para la preparación del tratamiento del género *Inga* (Leguminosae: Mimosoideae) para la *Flora Mesoamericana*, que abarca del Sur de México a Panamá, ha sido necesario realizar este artículo que formaliza taxa y da información complementaria y aclaratoria, que las normas editoriales de la *Flora* no permiten.

El género ha sido tratado en forma integral por Bentham (1845, 1875) y para Mesoamérica por Pittier (1916, 1929) y León (1966), y en floras locales como la de Costa Rica por Zamora (en prensa) y la de Panamá por Schery (1950). En el último tratamiento del área, León (1966) incluye 49 especies, de las cuales nosotros estamos reco-

[1] Se agradece al Missouri Botanical Garden que por medio de su beca, financiada por la Fundación Jessie Smith Noyes, así como de la ayuda de la Dirección General de Personal Académico, UNAM, que hicieron posible, durante mi año sabático, realizar la estancia para esta investigación. En el Missouri Botanical Garden mi trabajo fue facilitado grandemente por Enrique Forero y los Davidse, Gerrit y Jeany, tanto en aspectos académicos como logísticos. Agradezco a James Zarucchi por sus atinadas sugerencias al manuscrito; a Roy Gereau por mejorar el manuscrito, agregando información útil; a Nelson Zamora que hizo asequible su investigación inédita en *Inga*; a Bruno Manara por su traducción y a Henk van der Werff por su edición de las diagnosis al latín; a Linda Ellis por sus magníficas láminas botánicas; a mi esposa Glora Andrade de Sousa por toda su ayuda en todos los aspectos, pero particularmente haber pasado el manuscrito a un procesador de textos y su edición; a Fred R. Barrie por su ayuda en la lectotipificación de *Inga vera*; a Terence D. Pennington por facilitar mi acceso a varios prestamos de *Inga* en Kew; y a los curadores de A, BM, BR, CAS, CM, CR, CHAPA, F, EAP, ENCB, G, GH, IEB, K, LL, MEXU, MICH, MO, NY, S, TEFH, TEX, U, US, W, WIS y XAL por facilitar el material botánico para su estudio.

nociendo 47, aunque no necesariamente con los mismos nombres; de las 81 especies que aquí se tratan, tal crecimiento en el número de especies, es, fundamentalmente, por el gran acúmulo de nuevas colectas que se han hecho en el área en los últimos 25 años, que han incorporado tanto nuevas especies para la ciencia como varias otras sólo conocidas para Sudamérica. Este nuevo material también ha permitido interpretar mejor la variación de las especies antes sólo conocidas por escaso material, lo que en algunos casos permite sinonimizar binomios de uso local en nuestra área. Sin embargo, lo anterior no significa que ya el tema esté agotado, por el contrario, como hay varios ejemplares que podrían ser nuevos taxa, que no creo conveniente formalizar por lo incompleto del material, y además algunas especies ya descritas sólo son conocidas por el tipo.

Respecto al material representativo se decidió dar mayor información de la que permiten las normas editoriales de la *Flora Mesoamericana*; ésto es debido a que la *Flora* sólo autoriza usar una colecta por cada una de las diez regiones en las cuales está dividida la flora, además de una referencia muy corta de sus límites geográficos extra mesoamericanos. Así se decidió ampliar esta información por considerarse útil tanto en cuanto al concepto de especie como por sus obvias implicaciones de uso y distribución regional. También se cita el material de fuera de la región mesoamericana por considerase de interés dado que no existe actualmente un tratamiento integral equivalente en América del Sur, sólo trabajos regionales como de Bentham (1876) para Brasil, Poncy (1985) para la Guayana Francesa, y de Macbride (1943) para el Perú. Así se cita un ejemplar para cada uno de los estados de México y departamentos, distritos, estados o provincias de cada país centroamericano, así como de los de Sudamérica, haciendo excepción de sólo una colecta para cada una de las Guayanas y países de las Islas del Caríbe. Brasil se dividió en regiones dado la amplitud del país.

El formato de las descripciones sigue al de la *Flora Mesoamericana*; sin embargo, en general los caracteres usados para el género son los empleados por Pittier (1916, 1929), León (1966), y Poncy (1985), aunque no necesariamente su terminología. Así de Poncy adoptamos el concepto de las brácteas homomorfas y heteromorfas que ella maneja en sus descripciones e ilustra en sus láminas; además aquí estamos empleando en forma extensiva el uso de botones florales que parece ser un carácter útil en la taxonomía de *Inga*. Los botones florales sólo son citados ocasionalmente como en *I. acuminata* (León, 1966), pero en general no son descritos, ni menos usados como un carácter diagnóstico. En la descripción de las especies nuevas y de las del tratamiento de la *Flora* este carácter es usado extensivamente, cuando conocido. Su uso es referido como "botones con el cáliz cubriendo" y las opciones son "abierto" o "cerrado"; aquí hay que aclarar que se refiere al estado de desarrollo del botón floral cuando el tamaño del cáliz es aproximadamente un ⅓ menor al del tamaño normal de una flor en antesis, siendo ésto importante ya que, todos los botones realmente incipientes cuentan con un cáliz cerrado. Así se pueden categorizar los botones florales (con algunos ejemplos claros) de la siguiente forma:

1. Cáliz cerrado, botones casi esféricos: *Inga goldmanii*, *I. rubiginosa*.
2. Cáliz cerrado, botones ovoides a obovoides a tubulares: *I. calcicola* (véase Fig. 1D), *I. exalata*.
3. Cáliz cerrado, botones rostrados, los lóbulos unidos en uno: *I. acuminata*, *I. urabensis*, *I. venusta*.
4. Cáliz abierto en un poro, botones tubulares: *I. leonis*, *I. sierrae*.
5. Cáliz abierto, tubular, los lóbulos aplicados a la corola, la que crece con el cáliz: *I. sinacae*, *I. thibaudiana*.
6. Cáliz abierto, tubular, los lóbulos conniventes en sus ápices, el botón obtuso en el ápice, la protocorola más pequeña que el cáliz: *I. fastuosa*, *I. mucuna*.
7. Cáliz abierto, los lóbulos conniventes en sus márgenes, el botón rostrado, la protocorola más pequeña que el cáliz: *I. pavoniana*, *I. tonduzii*, *I. vera*.
8. Cáliz abierto, los lóbulos erectos no conniventes, la protocorola más pequeña que el cáliz: *I. cookii*, *I. ismaelis* (véase Fig. 4A, E), *I. setosa*.

Respecto a los agrupamientos supraespecíficos en *Inga*, el sistema de Bentham (1845, 1875, 1876) modificado por León (1966), necesita más refinamientos, sobre todo en los límites de la sección *Leptinga* con la sección *Bourgonia* (ver discusiones de *Inga acrocephala*, *I. alba*), basados en el tipo de inflorescencia, la cual puede variar de capituliforme a racimos cortos. Por otro lado en la sección *Leptinga* hay varios grupos naturales como él de alrededor de *I. cordistipula* incluyendo: *I. bella*, *I. portobellensis*, *I. pseudoinvolucrata*, e *I. spiralis*. También alrededor de *I. umbellifera* se puede agrupar a otro contingente de especies como:

*I. brevipes*, *I. polita*, *I. sciadion*, e *I. umbratica*. Con *I. saffordiana* quedaría *I. filiformis*, este último grupo muy natural que ha divergido grandemente del resto de la sección. Como sugirió León (1966: 344) todos estos grupos no parecen tener parentesco entre ellos y el tipo de inflorescencia parece más bien un paralelismo.

De los agrupamientos existentes, quizá uno de los más naturales es la serie *Inga*, definida fundamentalmente por la legumbre, pero que a la vez cuenta con las especies más variables y panmixicas del género.

La sinonimia la hemos tratado cuando en forma original estamos agregando información nueva no tratada por Schery (1950), León (1966), o Poncy (1985); así estamos excluyendo la citación de los cambios que Kuntze (Revis. Gen. Pl. 1: 182–189. 1891) hizo a *Feuilleea*. En algunos casos se dan sinónimos ya reportados por otros autores, pero se toma esta libertad para aclarar problemas. También siempre se apunta el basiónimo cuando éste existe, o el homónimo tardío en el cual se basa el nombre en uso.

Las claves fueron elaboradas tratando de agrupar especies afines y por ello su uso se circunscribe a la identificación de especies y en forma limitada a ejemplares, a este respecto hay que apuntar que en una gran proporción los ejemplares sólo cuentan con un estadío, es decir en flor, fruto o, desde luego, estériles. Sin embargo, la elaboración de las claves de sólo flores o frutos nos llevó frecuentemente a por un lado, ubicar a una misma especie en varias entradas, y por otro lado, agrupar varias especies al final de una dicotomía.

Dado el nivel de conocimiento del género *Inga* en Mesoamérica no estamos formalizando categorías infraespecíficas, con una excepción; sin embargo cuando hemos creido que debería hacerse, lo mencionamos en cada caso, dejando la decisión final para quien revise al género en conjunto y así lo uniformice.

La fitogeografía de *Inga* en Mesoamérica muestra un importante elemento endémico de 33 especies (41.25%) incluyendo al área fitogeográfica del norte, o sea el sur de Veracruz y la zona de Tuxtepec en Oaxaca; si a ella agregamos la otra área natural al Sur, es decir la zona del Chocó colombiano y ecuatoriano, sumariamos 11 especies más o sea un total de 44 especies que representan el 55% de las Ingas del área.

Los otros elementos importantes son las 12 especies amazonicas (15%); las cinco de la flora de México (6.25%); las siete del arco que forma un brazo Colombia-Guayanas y el otro Colombia-Bolivia (8.7%), generalmente en áreas montañosas; las cuatro Colombia-Venezuela y en ocasiones Trinidad (5%); y otros modelos de distribución más amplia que sólo representan a ocho especies o sea el 10% de las Ingas.

Para este análisis estamos considerando a 80 especies, ya que *Inga edulis* muy probablemente se trata de una especie introducida al área mesoamericana.

Del elemento endémico, nueve especies (26.47%) son del área de bajas altitudes de la vertiente del Golfo de México; de las áreas montañosas, cinco especies (14.5%) corresponden a Chiapas–Honduras y siete especies (20.58%) a la de Nicaragua–Panamá, estando las siete presentes en Costa Rica; de las áreas de baja altitud, hay dos especies (5.88%) de Veracruz–Oaxaca a Costa Rica–Panamá, dos especies (5.88%) endémicas a Costa Rica, tres especies (8.82%) a Costa Rica–Panamá, y seis especies (17.65%) sólo de Panamá.

**Inga** Miller Gard. Dict. Abr., ed. 4, 2. 1754.

Arboles inermes; ramas teretes a tetragonales, glabras a pelosas. Hojas alternas, estipuladas, 1-pinnadas, paripinnadas, 1–14-yugadas, los folíolos opuestos; raquis teretes a alados, con glándulas interfoliolares, frecuentemente rematando en un apéndice. Inflorescencias generalmente axilares en fascículos o paniculadas en ramas áfilas, las flores uniformes, en racimos, espigas, capítulos o umbelas; brácteas florales homomorfas a heteromorfas, fértiles a estériles. Flores sésiles a largamente pediceladas; cáliz sinsépalo, campanulado a tubular, con o sin escotaduras, 5-lobado, en botón abierto a cerrado; corola simpétala, tubular, subturbinada a turbinada, 5-lobada, pelosa; estambres numerosos, monadelfos, con el tubo exerto a inserto, las anteras eglandulares; el polen en poliadras; gineceo 1-carpelar, el ovario multiovular; estilo más largo que los estambres, el estigma simple o lobado. Legumbre aplanada, tetragonal o subterete, derecha, curveada, helicoidal a circinado-espiralada, coriácea a leñosa, glabra a pelosa, las valvas en ocasiones reducidas y entonces los márgenes hipertrofiados; irregularmente dehiscente; semillas carnosas, oblongas, desnudas o en ocasiones cubiertas por una delgada testa papirácea que a su vez está cubierta por un tejido endocárpico suculento que ha sido interpretado como arilo, sin línea fisural; cotiledones bien desarrollados, la germinación frecuentemente ocurre en el fruto. Aprox. 350 spp. Trópicos y subtrópicos húmedos de América.

GRUPOS

1a. Inflorescencias racemosas o espigadas.
2a. Cáliz campanulado a brevemente tubular.
3a. Cáliz 1–1.5 mm; legumbre glabrescente a glabra. ..... GRUPO 1
3b. Cáliz 3–6 mm; legumbre densamente pelosa. ..... GRUPO 5
2b. Cáliz tubular a ciatiforme.
4a. Legumbres aplanadas a tetragonales.
5a. Lóbulos del cáliz triangulares a obtusos.
6a. Legumbres maduras glabras a pelosas, pero no tan densamente que impida ver el color o nervación de las valvas, con indumento más o menos rígido.
7a. Cáliz 2–5 mm, generalmente sin escotaduras, en botón obtuso. ..... GRUPO 2
7b. Cáliz 5–15 mm, generalmente con escotaduras, en botón obtuso o apiculado a rostrado. ..... GRUPO 3
6b. Legumbres maduras con pelosidad densa que da el color al fruto, generalmente hirsutas. ..... GRUPO 4
5b. Lóbulos del cáliz cuspidados a caudados. ..... GRUPO 6
4b. Legumbres subteretes, acordonadas. ..... GRUPO 7
1b. Inflorescencias capituliformes o umbeliformes.
8a. Inflorescencias capituliformes, con flores sésiles o pediceladas, los pedicelos hasta 3 veces la longitud del cáliz. ..... GRUPO 8
8b. Inflorescencias umbeliformes, los pedicelos de más de 3 veces la longitud del cáliz. ..... GRUPO 9

GRUPO 1

Flores pequeñas, cáliz 1–1.5 mm, campanulado a brevemente tubular; legumbres aplanadas, glabrescentes a glabras.

1a. Raquis floral largo, más de 2.5 cm.
2a. Valvas de la legumbre aplanadas.
3a. Corola ligeramente infundibuliforme, pelosa, tubo estaminal inserto o cortamente exerto. ..... *I. longispica*
3b. Corola tubular-campanulada, generalmente glabra, tubo estaminal largamente exerto (en el Continente Americano, inserto en las Antillas). ..... *I. laurina*
2b. Valvas de la legumbre abolladas o con proyecciones cónicas a la altura de las semillas.
4a. Legumbre lisa, abollada a la altura de las semillas.
5a. Folíolos hasta 12 cm de ancho; raquis foliar terete a marginado; brácteas florales triangular-obtusas. ..... *I. coruscans*
5b. Folíolos hasta 5 cm de ancho; raquis foliar marginado a alado; brácteas florales aleznadas. ..... *I. semialata*
4b. Legumbre verrugosa, con proyecciones cónicas a la altura de las semillas. ..... *I. riopalenquensis*
1b. Raquis floral corto, hasta 2.5 cm.
6a. Flores sésiles o casi sésiles.
7a. Pedúnculos florales más de 1.5 cm; tubo estaminal menos de 1.5 veces más largo que la corola; árboles generalmente menos de 20 m.
8a. Glándulas interfoliolares urceoladas, el cuerpo glandular 0.7–1.0 × 0.7–1.0 mm; legumbre hasta 2.3 cm de ancho, las valvas aplanadas a la altura de las semillas. ..... *I. belizensis*
8b. Glándulas interfoliolares cupuliformes, el cuerpo glandular 1.5–2.1 × 1.5–2.1 mm; legumbre hasta 3.2 cm de ancho, las valvas abolladas a la altura de las semillas. ..... *I. pezizifera*
7b. Pedúnculos florales hasta 1.1 cm; tubo estaminal 2 veces o más largo que la corola; árboles generalmente más de 25 m. ..... *I. alba*
6b. Flores largamente pediceladas. ..... *I. heterophylla*

GRUPO 2

Cáliz 2–5 mm, generalmente sin escotaduras, en botón obtuso.

1a. Brácteas florales heteromorfas, las distales cuculado-estipitadas, las proximales ovadas a obovadas, oblongas o triangulares.
2a. Raquis foliar terete a marginado; pelosidad de las ramas esparcida.
3a. Hojas (4–)6(–8)-folioladas. ..... *I. acrocephala*
3b. Hojas 10–12-folioladas.
4a. Folíolos simétricos a ligeramente asimétricos; valvas de la legumbre glabras o casi glabras, sin escamas. ..... *I. ruiziana*
4b. Folíolos marcadamente asimétricos en la base; valvas de la legumbre escuamosas. ..... *I. samanensis*
2b. Raquis foliar alado; pelosidad de las ramas densa. ..... *I. hintonii*
1b. Brácteas florales homomorfas, lanceoladas, linear-lanceoladas o triangulares.
5a. Flores proximales sésiles.

6a. Raquis foliar terete. ..... *I. punctata*
6b. Raquis foliar marginado a alado.
7a. Corola de 3–4.5 veces más larga que el cáliz. ..... *I. stenophylla*
7b. Corola hasta 2.5 veces más larga que el cáliz.
8a. Cáliz 1.6–2.2 mm; legumbre hasta 1.6 cm de ancho. ..... *I. tenuipedunculata*
8b. Cáliz 2.5–5 mm; legumbre hasta 4.8 cm de ancho. ..... *I. densiflora*
5b. Flores proximales pediceladas.
9a. Raquis foliar glabro, las glándulas interfoliolares ca. 3 mm de diámetro, escuteladas; cáliz glabrescente; legumbre hasta 4 cm de ancho, glabra. ..... *I. latipes*
9b. Raquis foliar velutino con tricomas pardo-amarillentos, las glándulas interfoliolares ca. 1 mm de diámetro, cupuliformes; cáliz peloso; legumbre hasta 2.6 cm de ancho, pelosa. .. *I. pinetorum*

Grupo 3

Cáliz 5–15 mm, tubular, generalmente con escotaduras, en botón obtuso o apiculado a rostrado.

1a. Hojas 2–6-folioladas.
2a. Legumbres glabras.
3a. Legumbres hasta 2.5 cm de ancho; cáliz en botón largamente rostrado. ..... *I. acuminata*
3b. Legumbres 3.5–6 cm de ancho; cáliz en botón apiculado, obtuso a largamente rostrado.
4a. Raquis foliar generalmente terete; ramas jóvenes teretes. ..... *I. leiocalycina*
4b. Raquis foliar angulado a cuadrangular o marginado a alado; ramas jóvenes anguladas a cuadrangulares.
5a. Hojas 6-folioladas; folíolos acuminados; flores amarillas.
6a. Ramas jóvenes y nervaduras primarias tomentosas con tricomas pardo-amarillentos; folíolos hasta 11 cm de ancho; glándula en el acumen foliolar ocasionalmente presente. ..... *I. urabensis*
6b. Ramas jóvenes y nervaduras primarias glabras; folíolos hasta 7 cm de ancho; glándula en el acumen foliolar frecuentemente presente. ..... *I. venusta*
5b. Hojas 4-folioladas; folíolos obtusos a apiculados; flores blancas. ..... *I. spectabilis*
2b. Legumbres pelosas, con tricomas más o menos rígidos.
7a. Inflorescencias largas y laxas, las flores espaciadas en el raquis. ..... *I. dwyeri*
7b. Inflorescencias cortas y compactas, las flores congestas en el raquis. ..... *I. hayesii*
1b. Hojas 8–18-folioladas.
8a. Raquis floral hasta 9 cm. ..... *I. skutchii*
8b. Raquis floral hasta 3.5 cm.
9a. Glándulas interfoliolares largamente estipitadas. ..... *I. ciliata*
9b. Glándulas interfoliolarees sésiles a casi sésiles.
10a. Valvas de las legumbres maduras glabras.
11a. Hojas (10–)12–22-folioladas; corola 20–25 mm; legumbre hasta 4.6 cm de ancho. ..... *I. multijuga*
11b. Hojas 8–12(–14)–folioladas; corola 12–18 mm; legumbre hasta 2.5 cm de ancho. ..... *I. aestuarorium*
10b. Valvas de las legumbres maduras pelosas.
12a. Corola 16–29 mm; legumbres estrigulosas.
13a. Folíolos concoloros a ligeramente discoloros; glándulas interfoliolares más pequeñas que el raquis foliar; flores robustas; cáliz 11–15 mm. ..... *I. cuspidata*
13b. Folíolos marcadamente discoloros; glándulas interfoliolares tan anchas o más anchas que el raquis foliar; flores esbeltas; cáliz 3–5 mm. ..... *I. thibaudiana*
12b. Corola 7–11 mm; legumbres hispídulas.
14a. Corola 9–11 mm; brácteas 1–1.7 mm; botones florales obtusos. ..... *I. micheliana*
14b. Corola 7–8 mm; brácteas 3–9 mm; botones florales rostrados a apiculados. ..... *I. flexuosa*

Grupo 4

Legumbres maduras con pelosidad densa que da el color al fruto, generalmente hirsutas.

1a. Glándulas interfoliolares generalmente largamente estipitadas.
2a. Raquis foliar terete. ..... *I. exalata*
2b. Raquis foliar alado.
3a. Flores esbeltas.
4a. Cáliz más de 10 mm; brácteas tan largas o más largas que el cáliz, persistentes.
5a. Pelosidad de tallos, ejes foliares y florales hirsuta; estípulas ovadas a triangular-cordatas, persistentes; brácteas generalmente lanceoladas.
6a. Hojas 2–4-folioladas; corola 15–18 mm. ..... *I. jimenezii*
6b. Hojas (4–)6–10-folioladas; corola 20–27 mm. ..... *I. tonduzii*

5b. Pelosidad de tallos, ejes foliares y florales tomentosa; estípulas filiformes a triangular-atenuadas, pronto caducas; brácteas filiformes a oblanceoladas. ____ *I. calderonii*

4b. Cáliz menos de 10 mm; brácteas generalmente menos del ½ de largo del cáliz, caducas.

7a. Cáliz inconspicuamente estriado o totalmente cubierto de indumento; brácteas ovadas a triangulares.

8a. Hojas 6-folioladas; folíolos cartáceos. ____ *I. litoralis*

8b. Hojas 8–12-folioladas; folíolos coriáceos. ____ *I. herrerae*

7b. Cáliz conspicuamente estriado; brácteas oblongas a lineares. ____ *I. tenella*

3b. Flores robustas.

9a. Estípulas cordatas, tan anchas como largas; glándulas sobre las nervaduras medias de los folíolos frecuentemente presentes; inflorescencias multifloras (10–22); corola 24–28 mm. ____ *I. goldmannii*

9b. Estípulas no cordatas, más largas que anchas; glándulas sobre las nervaduras medias de los folíolos ausentes; inflorescencias paucifloras (3–4); corola 28–32 mm. ____ *I. davidsei*

1b. Glándulas interfoliolares sésiles a casi sésiles.

10a. Glándulas sobre las nervaduras medias de los folíolos frecuentemente presentes; folíolos cocleados.

11a. Raquis foliar marginado a generalmente alado; brácteas 6–9 mm. ____ *I. sierrae*

11b. Raquis foliar terete; brácteas ca. 2 mm. ____ *I. cabrerae*

10b. Glándulas sobre las nervaduras medias de los folíolos ausentes; folíolos más o menos aplanados.

12a. Cáliz conspicuamente estriado.

13a. Cáliz glabro excepto en el ápice; corola 35–55 mm. ____ *I. mucuna*

13b. Cáliz peloso en toda su longitud; corola hasta 25 mm.

14a. Pecíolo 4.5–8.5 cm; legumbre hasta 18.5 cm, hirsuta con tricomas ferrugíneos; corola blanca. ____ *I. leonis*

14b. Pecíolo 1–3.5 cm; legumbre hasta 12 cm, hirsuta con tricomas pardo-amarillentos; corola verdosa. ____ *I. chiapensis*

12b. Cáliz sin estriaciones o si las tiene cubiertas por el indumento.

15a. Corola 14–15 mm, subturbinada; raquis foliar terete. ____ *I. cabrerae*

15b. Corola 21 mm o más, tubular; raquis foliar terete o marginado a alado.

16a. Flores proximales sésiles; legumbre hasta 5 cm de ancho. ____ *I. sinacae*

16b. Flores proximales pediceladas; legumbre hasta 2.7 cm de ancho. ____ *I. calcicola*

### Grupo 5

Cáliz 3–6 mm, robusto, campanulado. ____ *I. rubiginosa*

### Grupo 6

Raquis foliar alado; lóbulos del cáliz cuspidados a caudados, cáliz abierto en botón; legumbres aplanadas a tetragonales.

1a. Corola 18–30 mm; legumbres 11–30 × 2–3.5 cm.

2a. Flores proximales pediceladas; cáliz 16–21 mm; legumbre aplanada; tallos jóvenes con tricomas hasta 3 mm. ____ *I. ismaelis*

2b. Flores proximales sésiles; cáliz 9–17 mm; legumbre tetragonal; tallos jóvenes con tricomas hasta 1 mm. ____ *I. pavoniana*

1b. Corola 10–15 mm; legumbres 3.9–7.6 × 1.8–3.2 cm.

3a. Tallos y ejes foliares glabros; estípulas triangular-subuladas; glándulas interfoliolares sésiles. ____ *I. lacustris*

3b. Tallos y ejes foliares híspidos; estípulas setiformes, arqueadas; glándulas interfoliolares largamente estipitadas. ____ *I. cookii*

### Grupo 7

Legumbres subteretes, acordonadas.

1a. Raquis foliar terete.

2a. Hojas (4–)6–8(–10)-folioladas. ____ *I. oerstediana*

2b. Hojas (10 )12 16-folioladas. ____ *I. cocleensis*

1b. Raquis foliar alado.

3a. Glándulas interfoliolares urceoladas a pateniformes, el ósculo circular, generalmente hasta 1.2 mm de diámetro.

4a. Legumbres con los márgenes parcialmente hipertrofiados, las valvas reducidas pero aún claramente se distinguen.

5a. Flores proximales sésiles; cáliz 6 10 mm, tubular, esbelto; corola hasta 20 mm, generalmente el doble de la longitud del cáliz. ____ *I. affinis*

5b. Flores proximales frecuentemente pediceladas; cáliz 10–18 mm, infundibuliforme, robusto; corola hasta 25 mm, menos del doble de la longitud del cáliz. ____ *I. vera*

4b. Legumbres con los márgenes totalmente hipertrofiados, las valvas difícilmente distinguibles de los márgenes; flores proximales sésiles.

6a. Hojas (4–)6–8-folioladas; brácteas hasta 2.3 mm; legumbre hasta 2.2 cm de diámetro. ..... *I. pauciflora*
6b. Hojas 4-folioladas; brácteas hasta 11 mm; legumbre hasta 3.5 cm de diámetro. ..... *I. chocoensis*

3b. Glándulas interfoliolares pateniformes, el ósculo transversalmente oval u oval alargado a frecuentemente lunular, generalmente más de 2 mm de diámetro.
7a. Hojas (4–)6–8(–10)-folioladas; brácteas caducas; legumbre 8–32 × 1.2–1.5 cm, los márgenes parcialmente hipertrofiados, las valvas reducidas pero distinguibles.
8a. Brácteas 1–4 mm, reniformes a ovales. ..... *I. oerstediana*
8b. Brácteas 7–15 mm, oval-oblongas, oblanceoladas. ..... *I. latibracteata*
7b. Hojas 8–12-folioladas; brácteas más o menos persistentes; legumbre 40–150 × 2–3.5 cm, los márgenes totalmente hipertrofiados, las valvas indistinguibles de los márgenes. ..... *I. edulis*

Grupo 8

Inflorescencias capituliformes, con flores sésiles a pediceladas, los pedicelos hasta 3 veces la longitud del cáliz.

1a. Raquis foliar marginado a alado.
2a. Organos vegetativos y legumbres pelosas.
3a. Hojas 4–6-folioladas; flores densamente pelosas; legumbre 4–6.5 cm de ancho. ..... *I. dasycarpa*
3b. Hojas 6–10-folioladas; flores glabras, excepto los lóbulos de la corola; legumbre 1.8–2 cm de ancho. ..... *I. pseudoinvolucrata*
2b. Organos vegetativos y legumbres glabrescentes a glabras.
4a. Raquis foliar marginado, las glándulas interfoliolares piriformes, largamente estipitadas; corola 5–7 mm. ..... *I. allenii*
4b. Raquis foliar alado, las glándulas interfoliolares pateniformes a cupuliformes, sésiles a casi sésiles; corola 20–50 mm.
5a. Cáliz 13–14 mm; corola 20–23 mm, densamente setosa con tricomas pardo-amarillentos en el ⅓ superior; tubo estaminal inserto a cortamente exerto. ..... *I. portobellensis*
5b. Cáliz 24–33 mm, corola 38–50 mm, glabra excepto sericea con tricomas canescentes en el ápice de los lóbulos; tubo estaminal largamente exerto. ..... *I. bella*

1b. Raquis foliar terete.
6a. Estípulas pronto caducas.
7a. Corola pelosa en toda su longitud.
8a. Ramas e inflorescencias tomentosas. ..... *I. quaternata*
8b. Ramas e inflorescencias glabrescentes a glabras.
9a. Cáliz 1.5–3 mm; corola 6–9 mm, la corola 2.2–3.5 veces la longitud del cáliz. ..... *I. acrocephala*
9b. Cáliz 5–7 mm; corola 9–12 mm, la corola hasta 2 veces la longitud del cáliz. ..... *I. mortoniana*
7b. Corola glabra excepto pelosa sobre los lóbulos.
10a. Pedúnculo 0.5–1.5 cm; cáliz 1.2–1.5 mm; corola 6–7 mm; legumbre ca. 7 × 2.5–3 cm, circinado-espiralada. ..... *I. glomeriflora*
10b. Pedúnculo (1–)3–6 cm; cáliz 1.5–2 mm; corola 4–6 mm; legumbre 15–50 × 3.5–5 cm, linear-oblonga. ..... *I. jinicuil*
6b. Estípulas persistentes.
11a. Estípulas oblongas a obovadas.
12a. Cáliz aplicado a la corola; corola 4–7.5 mm. ..... *I. paterno*
12b. Cáliz amplio no aplicado a la corola; corola 17–25 mm.
13a. Hojas 2–4-folioladas; legumbre linear-oblonga. ..... *I. cordistipula*
13b. Hojas 6–8-folioladas; legumbre circinado-espiralada. ..... *I. spiralis*
11b. Estípulas aciculares; lóbulos del cáliz filiformes a lanceolado-aleznados.
14a. Tallos y ejes foliares glabrescentes; glándulas interfoliolares sésiles; legumbre glabra, verrugoso-lenticelada. ..... *I. filiformis*
14b. Tallos y ejes foliares setosos; glándulas interfoliolares largamente estipitadas; legumbre largamente pelosa, sin lenticelas. ..... *I. saffordiana*

Grupo 9

Inflorescencias umbeliformes, los pedicelos más de 3 veces la longitud del cáliz.
1a. Hojas 8–12-folioladas. ..... *I. flagelliformis*
1b. Hojas generalmente 2–6-folioladas.
2a. Estípulas aleznadas; brácteas 1.2–1.4 mm. ..... *I. sertulifera*
2b. Estípulas lanceoladas u oblanceoladas a linear-lanceoladas; brácteas 2–9 mm.
3a. Hojas (2–)4–6-folioladas; pedúnculo floral 2 3 cm; brácteas hasta 5 mm, oblanceoladas. ..... *I. umbellifera*
3b. Hojas 2(–4)-folioladas; pedúnculo floral hasta 1 cm; brácteas hasta 9 mm, lanceoladas a linear-lanceoladas. ..... *I. polita*

**Inga acrocephala** Steudel, Flora 26: 759. 1843. TIPO: Surinam: *Hostmann 1067* (isotipos, BM, F, K, MO).

*Inga brevipedicellata* Harms, Repert. Spec. Nov. Regni Veg. 19: 62. 1923. TIPO: *J. A. Purpus 282* (holotipo, B destruido).

*Inga brevipedicellata* se había mantenido como una especie del sur de México y del norte de Centroamérica, pero han empezado a aparecer ejemplares de Costa Rica y Panamá que extendieron su distribución (Zamora, anotación de ejemplares, com. pers.). También con las nuevas colectas la variación se ha ampliado y así tenemos ejemplares de Veracruz francamente pedicelados y los de Chiapas, hacia el sur, sésiles. En Sudamérica en Colombia y Ecuador las hojas se mantienen con seis folíolos, pero en el área de las Guayanas tenemos hojas 8-folioladas, único carácter que podría mantener separada a *I. brevipedicellata* de *I. acrocephala*.

Sobre el tipo de *Inga brevipedicellata* que designó Harms (1923), *J. A. Purpus 282* del Herbario de Berlin (B), fué destruido y el único aparente duplicado que he visto está en el Smithsonian (US, 1202084): se trata de un ejemplar en flor que muestra claramente las flores sésiles a casi sésiles, las brácteas homomorfas linear-lanceoladas además de hojas 4–6-folioladas características de *Inga punctata* Willd.; además, existe el ejemplar de *J. A. Purpus 281* (G), el cual está correctamente identificado como *I. leptoloba* Schldl. [*I. punctata* Willd.], por lo que debe haber habido una confusión de etiquetas.

Por otro lado, por el momento, mantenemos separada a *Inga acrocephala* de *I. acreana* Harms (véase también *I. allenii*), no por los razonamientos, descripción, y ejemplares citados por Poncy (1985), ni por las observaciones de Macbride (1943) respecto al raquis foliar, sino por el cáliz de mayor tamaño de *I. acreana* Harms. Otro aspecto de variación en *I. acrocephala* es la transición de tipos de inflorescencias (que en ocasiones ocurren en el mismo ejemplar (*Ibarra M. 470*, MEXU)) de racimos cortos a capítulos, y de hecho debilita enormemente la taxonomía actual de secciones definidas por tipos de inflorescencias.

**Inga aestuariorum** Pittier, Contr. U.S. Natl. Herb. 18: 183, t. 89. 1916. TIPO: Costa Rica: *Tonduz 6793* (holotipo, US; isotipos, BR, G).

León (1966) incluye a *Inga aestuariorum* como sinónimo de *I. multijuga* Benth. (véase ésta), adoptando el concepto de Bentham (1875) y reconociendo que ésta "podría quizá ser una variante subespecífica," sugerencia que Bentham también consideró al incluir el ejemplar de Oersted de Costa Rica ("perhaps a variety with rather smaller flowers"). Sin embargo, en el norte del Istmo de Panamá las dos especies son simpátricas, y así Fendler en enero 24 de 1850 las colectó (en flor) en Chagres, única área que él visitó en su único viaje a Panamá (véase Stieber & Lange, 1986). Ambas especies fueron colectadas bajo el mismo número (51) de colecta, estando depositada *I. aestuariorum* en el GH e *I. multijuga* en K, MO, y US. *Inga aestuariorum* la mantengo separada considerando su menor número de folíolos por hoja, la flor más pequeña y el fruto que sólo llega hasta 2.5 cm de ancho. Es interesante agregar que el material de la vertiente del Golfo de México es muy homogéneo, distinguiendose por sus glándulas interfoliolares del raquis foliar característicamente con el ósculo muy cerrado, siendo transversalmente linear-oblongo; en cambio en el material de Nicaragua a Panamá, el ósculo es más o menos circular.

**Inga affinis** DC., Prodr. 2: 433, 1825. TIPO: Brasil: *Raddi s.n.* (holotipo, G-DC, foto MO).

Especie muy relacionada con *Inga vera* Willd. e *I. uraguensis* Hook. et Arn. ["*uruguensis*"]; de la primera difiere *I. affinis* por contar con flores sésiles o casi sésiles, un cáliz más pequeño (6–10 mm), tubular y la corola generalmente el doble del cáliz. De *I. uruguensis*, las diferencias son más tenues, ya que ambas cuentan con flores del mismo tamaño y la diferencia fundamental está en la mayor relación de la longitud del cáliz con respecto a la corola; en *I. uruguensis* la corola es solamente 1.5 vez más larga que el cáliz. Por lo anterior sin grandes problemas *I. uruguensis* podría pasar como sinónimo de *I. affinis*.

En Mesoamérica esta especie había sido interpretada como *Inga edulis* C. Martius o bien *I. vera* Willd.; de la primera, a pesar de contar con flores de similar tamaño y proporción, difiere por las glándulas interfoliolares más pequeñas y el fruto de menor tamaño con las valvas angostas pero aun visibles, caracteres que la acercan más a *I. vera*.

**Inga alba** (Sw.) Willd., Sp. Pl. ed. 4, 4: 1013. 1806. Basiónimo: *Mimosa alba* Sw., Prodr. 85. 1788, non M. Vahl, 1807. TIPO: Guayana Francesa: *von Rohr s.n.* (fl) (lectotipo, designado aquí, BM).

Sobre la lectotipificación de *Inga* y su basiónimo *Mimosa alba* Sw., el mismo O. Swartz (1788) nos informa que se trata del material de "Cayenna," y al estar marcada la descripción de la especie por un pequeño sol similar a un asterisco, el material lo consultó en el Herb. de J. Banks (BM) como el mismo Swartz refiere en su prefacio, sin anotar al colector. Por otro lado Poncy (1985) refiere al ejemplar de *von Rohr* como el tipo de este nombre de Cayenne en el BM, sin lectotipificarlo, así que aquí sólo se está formalizando lo que Poncy apuntó, y yo concuerdo. Existe un ejemplar en flor, anotado como *Mimosa alba* Sw. de Cayenne y colectado por *von Rohr s.n.* (BM).

Especie que alcanza las mayores tallas en el género (hasta 40 m), con flores e inflorescencias inconspicuas, lo que ha contribuido a su escasa representación en herbarios. Sin embargo, existen varios ejemplares estériles, que hacen suponer su aparente frecuencia en el dosel de las selvas altas perennifolias de América cálido húmeda.

*Inga alba* está estrechamente relacionada a *I. lateriflora* Miq. de la sección *Leptinga* Benth. difiriendo fundamentalmente por el tipo de inflorescencia; esta afinidad debilita los límites de las secciones *Bourgonia* Benth. y *Leptinga* Benth.

Esta especie en Mesoamérica ha sido confundida con *Inga fagifolia* (L.) Willd. ex Benth. (*I. laurina* (Sw.) Willd.).

*Material representativo.* MEXICO. OAXACA: *Hernández G. 2495* (MEXU). VERACRUZ: *Wendt et al. s.n.* (MEXU). NICARAGUA. ZELAYA: *Proctor et al. 27032* (NY). COSTA RICA. HEREDIA: *Hammel 11662* (MO). **Inga allenii** León, Ann. Missouri Bot. Gard. 53: 346. 1966. TIPO: Panamá: *Allen 2687* (holotipo, US).

Especie muy característica por sus glándulas interfoliolares piriformes largamente estipitadas. *Inga allenii* en general está relacionada a *I. mor-*

*toniana* León, como ya León (1966) lo había apuntado, pero la encuentro más cercana a *I. acreana* Harms (incluyendo a *I. myriocephala* Pittier) del área suroeste del Amazonas, de la cual es difícil separar, posiblemente siendo *I. allenii* una variedad de *I. acreana*.

*Material representativo.* COSTA RICA. HEREDIA: *Gómez P. et al. 21111* (MO). LIMON: *Grayum et al. 3502* (MO). PUNTARENAS: *Utley & Utley 1201* (F). PANAMA. COCLE: *Ebinger 965* (GH).

**Inga belizensis** Standley, Publ. Field Columbian Mus., Bot. Ser. 4: 307. 1929. TIPO: Belice: *Schipp 24* (holotipo, F; isotipos, BM, K, MO, US).

Como ya apunto León (1966) esta especie está cercanamente relacionada a *Inga fagifolia* (L.) Willd. ex Benth. (*I. lauriana* (Sw.) Willd.); sin embargo se trata de dos especies aparte, no sólo por la inflorescencia sino también por el fruto (véase clave).

*Material representativo.* MEXICO. CHIAPAS: *Martínez S. 8517* (MEXU). BELICE. EL CAYO: *Lundell 6599* (NY). STANN CREEK: *Schipp 24* (MO). GUATEMALA. EL PETEN: *Lundell & Contreras 20841* (MEXU).

**Inga bella** M. Sousa, sp. nov. TIPO: Costa Rica. Puntarenas: Reserva Forestal Golfo Dulce, Osa Península, Rancho Quemado, ca. 15 km W of Rincón, in bottom of S end of valley along Río Riyito, 2 June 1988, *B. Hammel, G. Herrera, M. M. Chavarría & A. Solís 16962* (holotipo, MO; isotipos, CM, CR, MO).

*Inga portobellensis* auct. non Beurling. Ilustración: Pittier, Contr. U.S. Natl. Herb. 18: t. 83–84. 1916.

Similis *Ingae portobellensi* Beurling, a qua tamen inflorescentia pauciflora, calyce ac corolla duplo vel ultra longioribus, calyce laevi, corolla ex sparse canescenti-sericea glabrescenti, nec non tubo stamineo longe exserto differt.

Arboles 6–10 m; ramas subteretes, glabras. Hojas 4-folioladas; estípulas 7–24 mm, foliáceas, ovadas a ovado-lanceoladas, cordatas en la base, persistentes; pecíolo 1–4.5 cm, alado; folíolos concoloros, cartáceos a subcoriáceos, algo abollados, la base ligeramente asimétrica, cuneada, el ápice acuminado a cuspidado, el haz opaco, glabro, el envés opaco, glabro excepto esparcidamente seríceo sobre la nervadura primaria y secundarias, la nervadura primaria eglandular; par basal de folíolos 6–16 × (3–)5–7.5 cm, elípticos, o lanceolados a oblanceolados, el par apical 17–21 × 7–8.5 cm, elípticos a obovados; raquis foliar 4.5–7.5 cm, alado, el ala hasta 18 mm de ancho, oblanceolada a obtriangular; glándulas interfoliolares sésiles o casi sésiles, pateniformes a cupuliformes, el cuerpo glandular 2.5–3 × 2.5–3 mm; apéndice hasta 16 mm, caduco. Inflorescencias capituliformes, solitarias; pedúnculo 0.5–5.5 cm, aplanado, sulcado, glabro; raquis floral muy reducido, las brácteas gradualmente heteromorfas, 4–12 mm, foliáceas, ovadas a oblongas, las de la periferia de mayor talla, persistentes. Flores sésiles o brevipediceladas, los pedicelos hasta 5 mm, robustos; botones florales con el cáliz cubriendo, desconocidos; cáliz 24–33 mm, tubular-infundibuliforme, inflado, liso, glabro, sin escotaduras, los lóbulos 3–4 mm, ampliamente triangulares; corola 38–50 mm, tubular a subturbinada, blanco-verdosa, glabra excepto serícea con tricomas canescentes en el ápice de los lóbulos; tubo estaminal largamente exerto, blanco. Legumbre 18.5–22.5 × 2.6–3 × 0.4–0.7 cm, aplanada, curveada, linear-oblonga, sésil, rostrada en el ápice, esparcidamente puberulenta a glabra, las valvas transversal e inconspícuamente nervadas, las suturas, marginadas, los márgenes de las suturas aplanados.

*Distribución y hábitat.* De la vertiente pacífica de Costa Rica y Panamá; en Costa Rica solamente conocida en la Península de Osa y en Panamá, en el Darién. En altitudes de 5–250 m. Florece de abril a principios de junio, fructifica de abril a junio.

*Paratipos.* COSTA RICA. PUNTARENAS: Parque Nacional Corcovado, Sirena Station, 8°29′N, 83°34′O, *B. Hammel & C. Kernan 16656* (F, MO); Parque Nacional Corcovado, Sirena, Monkey Woods, 8°27′–30′N, 83°33′–38′O; *Kernan 363* (MO); Santo Domingo, Golfo Dulce, *Tonduz 9879* [colección base de la ilustración de Pittier] (BM, BR, F, GH, K, MEXU, MO, NY, US); Playa Blanca, Golfo Dulce, *M. Valerio 468* (F). PANAMA. DARIEN: Cana-Cuasi trail along Río Cuasi, *R. L. Hartman 12486* (MO); main stream of Río Cuasi, 0–2.5 mi. S of Tres Bocas, *J. H. Kirkbride & J. Duke 1132* (MO).

*Inga bella* está muy relacionada con *I. portobellensis* Beurling (sus diferencias son explicadas en la diagnosis, véase *I. portobellensis*); también se relaciona con *I. inflata* Ducke del Amazonas, pero *I. bella* difiere de esta última por las hojas de mayor talla y menos coriáceas, el raquis foliar alado, las estípulas bien desarrolladas y persistentes, las flores sésiles a casi sésiles, y la legumbre que es aplanada a la altura de las semillas. El epíteto hace resaltar la belleza de las hojas y flores de esta *Inga*, que potencialmente podría usarse como ornamental.

**Inga cabrerae** M. Sousa, sp. nov. TIPO: Guatemala. Baja Verapaz: Sierra de las Minas, 3 km SE of Purulhá, 2,000 m, 6 Jan. 1974,

*L. O. Williams, A. Molina R., T. P. Williams & A. R. de Molina 43415* (holotipo, F; isotipo, US).

Frutex vel arbor parva; ramis juvenilibus dense ferrugineo-tomentosis. Folia 3-jugata; stipulis 2–3 mm longis, ex ligulatis suborbiculatis; foliolis coriaceis, nervo medio glandulas interdum terentibus; rhachidi foliari tereti, glandulis interfoliolaribus sessilibus urceolatis. Inflorescentiae spiciformes; rhachidi florali 2–3.5 cm longa; bracteis homomorphis ca. 2 mm longis, late ligulatis. Flores sessiles; calyce ca. 6 mm longo, tubulari; corolla 14–15 mm longa, subturbinata, brunneo-lutescenti-villosa. Legumen usque ad 3 cm latum, lineari-oblongum, ex complanatum subtetragonale, ferrugineo-hirsutum.

Arbustos a árboles 2–6 m; ramas angulosas, ferrugíneo tomentosas cuando jóvenes, posteriormente glabrescentes. Hojas 6-folioladas; estípulas 2–3 mm, liguladas a suborbiculares, caducas; pecíolo 2–3 cm, terete; folíolos ligeramente discoloros, coriáceos, cocleados, la base simétrica, obtusa a aguda, el ápice generalmente apiculado a acuminado, en ocasiones obtuso, el haz brillante, esparcidamente piloso, tomentuloso sobre la nervadura primaria, el envés opaco, esparcidamente tomentuloso por la superficie, más densamente sobre las nervaduras, la nervadura primaria en ocasiones glandular proximalmente; par basal de folíolos 5.5–6.5 × 3.5–5 cm, ovados, el par apical 12–14 × 7–8.5 cm, anchamente elípticos; raquis foliar 6.5–8.5, terete; glándulas interfoliolares sésiles, urceoladas, el cuerpo glandular 1.5–2 × 1.5–2 mm, apéndice ca. 2 mm, grueso, caduco. Inflorescencias en espigas 1–2 fasciculadas; pedúnculo 1.5–3.5 cm, terete, inconspicuamente sulcado, ferrugíneo tomentoso; raquis floral 2–3.5 cm, las flores algo espaciadas proximalmente, congestas distalmente, las brácteas aparentemente homomorfas ca. 2 mm, anchamente ligualadas, caducas. Flores sésiles; botones florales con el cáliz abierto, los lóbulos erectos, obtusos; cáliz ca. 6 mm, tubular, sin estrías aparentes, tomentoso con tricomas pardo-amarillentos, sin escotaduras, los lóbulos ca. 1 mm, anchamente triangulares; corola 14–15 mm, subturbinada, blanca, vellosa con tricomas pardo-amarillentos; tubo estaminal inserto, blanco. Legumbre ca. 22 × 3 × 1 cm, aplanada, subtetragonal, curveada, linear-oblonga, atenuada en la base, apiculada en el ápice, ferrugíneo hirsuta, las valvas aplanadas, las suturas marginadas a acostilladas, las costillas hasta 4 mm de ancho, los márgenes de las suturas nervados.

*Distribución y hábitat.* Conocida del área de las Lagunas de Montebello, Chiapas, México, y de la Sierra de las Minas en Guatemala. En vegetación de transición entre selvas altas y bosques caducifolios, en bosques caducifolios con *Liquidambar* y en bosques de neblina. En altitudes entre los 1,600 y 2,000 m. Florece a principios de enero y fructifica en marzo.

*Paratipos.* MEXICO. CHIAPAS: Mpio. La Trinitaria, a 3 km al O de Tziscao, dentro de los límites del Parque Natural Lagos de Monte Bello, *E. Cabrera C. & H. de Cabrera 6063* (MEXU); a 15 km al E de las Lagunas de Monte Bello, *Cabrera C. et al. 1861* (MEXU, MO).

Especie muy cercana a *Inga dasycarpa* M. Sousa e *I. tenella* M. Sousa de las cuales se distingue fundamentalmente por su raquis foliar terete, sus glándulas interfoliolares sésiles urceoladas, con un cuerpo glandular de mayores dimensiones y la presencia de glándulas en la nervadura primaria. En cuanto a las inflorescencias *I. cabrerae* posee espigas, lo que la acerca más a *I. tenella*, pero el cáliz de este última es tubular-cónico, estriado y esparcidamente peloso. Es interesante anotar que estas tres especies se encuentran simpátricas en el área de las Lagunas de Montebello en Chiapas, estando aparentemente aisladas estacionalmente por floraciones en diferentes períodos; así *Inga cabrerae* florece en enero (aunque hay que aclarar que el dato es de Guatemala), *I. tenella* en marzo–abril, e *I. dasycarpa* en octubre.

Se dedica esta especie a Edgar Francisco Cabrera Cano (1957–), colector botánico del sur de México.

**Inga calcicola** M. Sousa, sp. nov. TIPO: México. Oaxaca. Curva del Diablo, a 4 km al ESE de Temazcal, en el camino al vertedero, Mpio. San Miguel Soyoltepec, Distr. Tuxtepec, 50 m, 30 jun. 1987, *M. Sousa S., G. Andrade, R. Torres C. & L. Cortés A. 13090* (holotipo, MEXU; isotipos, MEXU, MO). Figura 1.

Arbores medianae; folia (3–)4–5-jugata; rhachis foliaris anguste alata, glandulis interfoliolaribus diminutis, sessilibus vel fere sessilibus. Inflorescentiae racemosae corymboideae, pauciflorae; flores 21–27 mm longi, pedicellati vel sessiles; calyx ac corolla tubulares, tubo staminali inserto. Legumen lineari-oblongum angustum, brunneo-lutescenti-hirsutulum.

Arboles 3–12(–20) m; ramas teretes, velutinas con tricomas pardo-amarillentos cuando jóvenes, posteriormente glabrescentes. Hojas (6–)8–10-folioladas; estípulas 5 mm, liguladas a lanceoladas, caducas; pecíolo 1–2.5 cm, terete a marginado; folíolos ligeramente discoloros, cartáceos, la base ligeramente asimétrica, cuneada a obutsa, el ápice acuminado a cuspidado, el haz opaco, esparcidamente tomentoso, después glabrescente, las nervaduras tomentosas con tricomas pardo-amarillentos, el envés pálido con la misma pelosidad pero ésta más densa, la nervadura primaria eglan-

FIGURA 1. *Inga calcicola* M. Sousa. —A. Rama con inflorescencias.—B. Detalle de estípulas.—C. Glándula interfoliolar.—D. Botón floral.—E. Flor.—F. Cáliz.—G. Corola.—H. Tubo estaminal.—I. Gineceo. (Tomado de *Sousa 13090.*)—J. Fruto. (Tomado de *Sousa 10273.*)

dular; par basal de folíolos 3.5–8.5 × 2.1–4.2 cm, elíptico-lanceolados a ovados, el par apical 12.5–17(–19.5) × 4–6.5(–8.4) cm, elípticos en ocasiones obovados; raquis foliar 7–11(–20) cm, alado entre todos los pares de folíolos, el ala hasta 15 mm de ancho, oblanceolada; glándulas interfoliolares sésiles a subsésiles, urceoladas, el cuerpo glandular 0.8–1 × 0.8–1 mm; apéndice ausente. Inflorescencias racimos corimboides, 1–2 fasciculadas; pedúnculo 3.5–7 cm, subterete, sulcado, tomentoso con tricomas pardo-amarillentos; raquis floral 2–3 cm, las flores espaciadas proximalmente, congestas distalmente, las brácteas algo heteromorfas 3–4 mm, concavas, las proximales fre-

cuentemente estériles, ovadas en el ⅓ superior del pedúnculo, persistentes, las distales fértiles, espatuladas, persistentes. Flores proximales pediceladas, el pedicelo hasta 7 mm, las distales sésiles; botones florales con el cáliz cerrado, obtusos; cáliz 11–21 mm, tubular, estriado, tomentoso con tricomas pardo-amarillentos, sin escotaduras, los lóbulos 1–1.5 mm, triangular-obtusos; corola 21–27 mm, tubular, verde pálido, canescente sericea; tubo estaminal inserto, blanco. Legumbre 19–23.5 × 2–2.7 × 0.4–0.5 cm, aplanada, subespiralada a espiralada, linear-oblonga, sésil en la base, apiculada a rostrada en el ápice, hirsútula con tricomas pardo-amarillentos, las valvas aplanadas, las suturas derechas, los márgenes de las suturas aplanados.

*Distribución y hábitat.* Especie solamente conocida del norte de Oaxaca, en el distrito de Tuxtepec, en suelos de litosoles negros calizos. En selvas altas subperennifolias con *Brosimum* (Moraceae), como un elemento del estrato bajo arbóreo. En altitudes entre 30 y 130 m. Florece desde finales de mayo a la primera quincena de junio, la fructificación de septiembre a diciembre, con frutos en el suelo en febrero.

*Nombre vernáculo.* Guatope.

*Usos.* "Los frutos maduros son comestibles."

*Paratipos.* MEXICO. OAXACA: Distr. Tuxtepec, Mpio. San Miguel Soyaltepec, Presa de Temazcal, al NO sobre la cortina de la presa, *L. Cortés & R. Torres C. 3* (MEXU, MO); Isla Isabel Maria, cerca de San Miguel Soyaltepec, *Cortés & Torres 841* (MEXU); Temazcal, cerros cerca de los vertederos, a 7 km al SE de la cortina de la presa Miguel Alemán, *Martínez S. & L. Rico A. 6132, 6785* (MEXU); cortina de la Presa Alemán, Temazcal, *M. Sousa & L. Rico A. 10273* (MEXU); a 4 km al SE de Temazcal, camino a los vertederos de la presa, *Sousa e I. Calzada 13028, 13048, 13066* (MEXU, MO); enfrente de la caseta de vigilancia de los vertederos de la presa Miguel Alemán, Temazcal, *R. Torres & E. Cabrera 6151* (MEXU); Mpio. Santa Maria Jacatepec, El Aguila, La Joya del Obispo, *Martínez S. & C. H. Ramos 24021* (MEXU, MO).

*Inga calcicola* podría incluirse en la serie *Longiflorae* de Bentham, y se parece a *I. longiflora* Spruce ex Benth. de Brasil, por contar con flores pediceladas, pero no es muy cercana, difiriendo de ella en un gran número de caracteres.

Es interesante anotar, para la interpretación del uso de los caracteres en *Inga*, que la corola de esta especie continua creciendo aún después de la antesis, la cual ocurre al inicio del día; así en la mañana (*Sousa 13048, 13066*) la flor ya abrió y los estambres están erectos, pero la corola no sobrepasa el cáliz, mientras que en la tarde (*Sousa 13090*) la corola ya creció y mide casi el doble del largo del cáliz (sólo en el segundo caso se revisaron las flores mañana y tarde; las primeras colectas ocurrieron en la mañana). Por otro lado cuando en botón, la protocorola es más pequeña que el cáliz.

**Inga calderonii** Standley, J. Wash. Acad. Sci. 13: 352. 1923 (como "calderoni"). TIPO: El Salvador: *Calderón 1392* (holotipo, US; isotipo, GH).

Especie muy interesante la cual en flor se parece mucho a y de hecho ha sido confundida con *Inga vera* Willd., pero se distingue de ésta por las glándulas interfoliolares largamente estipitadas. En fruto sus relaciones se inclinan hacia el grupo de *I. villosissima* Benth. y quizá podría haber tenido su origen en la cruza de *I. vera* e *I. tenella* M. Sousa. Se mantiene como especie válida ya que sus caracteres parecen estables.

*Material representativo.* MEXICO. CHIAPAS: *Sousa et al. 11820* (MEXU). GUATEMALA. ESCUINTLA: *Harmon 1934* (MO). SACATEPEQUEZ: *Roe 786* (WIS). SUCHITEPEQUEZ: *Standley 88950* (F). EL SALVADOR. AHUACHAPAN: *Croat 42101* (MO). LA LIBERTAD: *Calderón 1513* (GH). SONSONATE: *Tucker 1338* (F).

**Inga ciliata** C. Presl, Symb. Bot. 2: 11, t. 58. 1834. TIPO: Brasil: *Lhotky s.n.* (holotipo, PR; isotipo, G).

Para sinónimos véase a Bentham (1876) agregando a *I. leptantha* Benth.

Especie hasta hace poco reportada sólo de la costa este de Brasil, sin embargo han empezado a obtenerse colectas de Ecuador y Perú así como de Mesoamérica en Costa Rica y Panamá, estas últimas reconocidas por Zamora (en prensa).

*Inga ciliata* C. Presl es una especie muy variable en cuanto al número de sus folíolos y sus glándulas interfoliolares largamente estipitadas a sésiles. Este último carácter varía aun en la misma rama (*Martius 1093*, MO), y siendo el carácter que empleó Bentham (1845) para distinguir a *I. ciliata* (elevada) de *I. leptantha* (largamente estipitada), no es posible mantenerlas aparte; además de que la lámina (t. 58) de la descripción original de *I. ciliata* claramente ilustra a las glándulas estipitadas.

Dentro de la variación de *Inga ciliata*, con folíolos un poco más grandes y raquis floral más robustos, dísticos y nudosos, podría entrar muy bien *I. disticha* Benth. de las Guayanas y del norte de Brasil; sin embargo, por el momento las mantenemos separadas.

Con la nueva distribución de *Inga ciliata*, tam-

bién se agrega una serie más para Mesoámerica, la serie *Leptanthae* Benth.

*Material representativo.* COSTA RICA. LIMON: *Mori 348* (WIS). PANAMA. COCLE: *Folsom 3147* (MO). ECUADOR. NAPO: *Neill et al. 7960* (MO). PERU. AMAZONAS: *Huashikat 1446* (MO). BRASIL. (NORDESTE) BAHIA: *Salzmann s.n.* (MO); (SUDESTE) RIO DE JANEIRO: *Luschnath s.n.* (K).

**Inga cocleensis** Pittier, Contr. U.S. Natl. Herb. 18: 211. 1916. TIPO: Panamá: *R. S. Williams 405* (holotipo, NY).

De esta especie Elias (1967) nombró una variedad de flor más grande para Sudamérica, *Inga cocleensis* var. *megantha* T. S. Elias, la cual debe ser una subespecie ya que se trata una variación geográfica.

**Inga cocleensis** subsp. **cocleensis**

**Inga cocleensis** subsp. **megantha** (T. S. Elias) M. Sousa, stat. nov. *I. cocleensis* var. *megantha* T. S. Elias, Phytologia 14: 211. 1967. TIPO: Colombia: *Pérez-Arbelaez & Cuatrecasas 6458* (holotipo, US).

*Material representativo.* COLOMBIA. CHOCO: *Gentry & Libenson 30366* (MO). VALLE: *Mazuera 30* (MO). VENEZUELA. ZULIA: *Davidse et al. 18297* (MO).

**Inga cookii** Pittier, Contr. U.S. Natl. Herb. 18: 203. 1916. TIPO: Guatemala: *Cook & Griggs 505* (holotipo, US).

*Inga subvestita* Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 22: 27. 1940. TIPO: Guatemala: *C. L. Wilson 315* (holotipo, F).

Especie cuya legumbre no se conocia hasta su colecta (*Contreras 10337*) en 1970, la cual tiene dimensiones de 4–7.5 × 1.8–2.5 × 0.3 cm, es aplanada, oblonga, derecha, sésil, apiculada y tomentosa con tricomas pardo-amarillentos. Sin embargo, se le han adjudicado frutos de otras especies: así primero Standley y Steyermark (1946) le asignan el fruto de *Inga pavoniana* Don, tanto por su descripción, nombre vulgar de "machetón," localidad y colecta (véase *Standley 92857*, F). Después León (1966) sí cita dos colecciones de Honduras (*Yuncker et al. 6292, 6678*), tratandose de *I. tenella* M. Sousa. En el caso de León (1966) es interesante comentar que en efecto existen ejemplares (como *Molina R. 24244*, NY; *25431*, BM) que en gran medida son intermedios entre *I. cookii* e *I. tenella*.

*Material representativo.* GUATEMALA. ALTA VERAPAZ: *Steyermark 45159a* (F). EL PETEN: *Lundell & Contreras 20655* (MO). IZABAL: *Contreras 10337* (LL). HONDURAS. ATLANTIDA: *Standley 54256* (A).

**Inga cordistipula** C. Martius, Flora 20(2): Beibl. 111. 1837. *Mimosa plana* Vell. Conc., Fl. Flumin. 11: t. 10, non 28. 1831. TIPO: Brasil: *Vellozo, Fl. Flumin. 11: t. 10. 1831.*

*Inga urceolata* Zamora, Brenesia 33: 117. 1991. TIPO: Panamá: *McPherson 10496* (holotipo, MO; isotipos, BM, CR, MEXU, US).

Martius (1837) transfiere de género y crea un nuevo nombre específico para *Mimosa plana* Vell. Conc., lámina 10, ésto debido a que la lámina 28 de Vellozo corresponde a una especie de *Acacia* que lleva el mismo nombre.

*Inga cordistipula* es una especie hasta ahora conocida sólo del sureste de Brasil. En Panamá, su variación es reducida, pero en Brasil varía grandemente, estando representados todos los caracteres que la podrían distinguir en Mesoamérica; así su raquis foliar terete, está ilustrado por Barroso (1965) para Guanabara [=Rio de Janeiro] y los folíolos más anchos, se aprecian en el sinónimo *I. fluvii-novi* Harms (*Schwacke 8811*, B, foto MO). Sin embargo, el material de Panamá tiende a contar con estípulas un poco más angostas, pero tan largas (véase *de Nevers et al. 7382*, MO) como su análogo de Brasil.

*Material representativo.* PANAMA. COLON: *McPherson 8451* (MO). PANAMA: *Nee et al. 8787* (MO). SAN BLAS: *de Nevers et al. 7382* (MO). BRASIL. (SUDESTE) MINAS GERAIS: *Schwacke 8811* (B, foto MO). RIO DE JANEIRO: *Glaziou 2977* (BR).

**Inga coruscans** Humb. et Bonpl. ex Willd., Sp. Pl. ed. 4, 2: 1017. 1806. TIPO: Colombia: *Bonpland 1574* (holotipo, B-W, foto MO).

*Inga caldasiana* Britton et Killip, Ann. New York Acad. Sci. 35: 115. 1936. TIPO: Colombia: *Mutis 3539* (holotipo, US).

Esta especie se caracteriza, dentro de la sección *Bourgonia* Benth., por contar con folíolos relativamente grandes y hojas brevipecioladas.

*Inga coruscans* es de amplia distribución, pero

muy mal colectada o quizá de distribución esporádica, tanto en Mesoamérica como en Sudamérica.

*Material representativo.* COSTA RICA. CARTAGO: *Tonduz 12991* (BM). PUNTARENAS: *Liesner 1829* (MO). PANAMA. CHIRIQUI: *Croat 22161* (WIS). DARIEN: *Duke 13004* (NY). COLOMBIA. **Inga cuspidata** M. Sousa, sp. nov. TIPO: Panamá. Bocas del Toro: Río San Pedro, Jan. 1978, *B. L. Gordon 3* (holotipo, MO).

Specie *Ingae multijugae* Bentham propinqua, ab ea tamen foliolis ex anguste lanceolatis ellipticis, apice cuspidato, inflorescentiis paucifloris, rhachide florifera brevi, necnon legumine angustiore valvis strigulosis praedito satis diversa.

Arboles 10–12 m; ramas teretes, ferrugíneo tomentulosas cuando jóvenes, posteriormente glabrescentes. Hojas 12–18-folioladas; estípulas 4–6 mm, liguladas, triangulares a filiformes, más o menos persistentes; pecíolo 0.7–2.5 cm, terete; folíolos tenuemente discoloros, cartáceos, la base cuneada, el ápice cuspidado, el haz opaco, glabro excepto tomentoso sobre la nervadura primaria, el envés rojizo, esparcidamente seríceo con tricomas canescentes a pardo-amarillentos, la nervadura primaria eglandular; par basal de folíolos 3–4 × 0.9–1.6 cm, lanceolados a elípticos, el par apical 10.5–12.5 × 2.6–3.6 cm, lanceolados a angostamente elípticos; raquis foliar 8.5–20 cm, generalmente terete, rara vez angostamente alado, el ala hasta 4 mm ancho, oblanceolada; glándulas interfoliolares casi sésiles a brevistipitadas, el estípite robusto, cupuliformes, el cuerpo glandular 1.8–2 × 1.8–2 mm; apéndice 3–4 mm, filiforme. Inflorescencias en espigas solitarias; pedúnculo 4–6 cm, terete, inconspicuamente estriado, tomentoso a velutino con tricomas ferrugíneos; raquis floral 1–2 cm, paucifloro, las flores congestas, las brácteas aparentemente homomorfas ca. 2 mm, cuculadas, pronto caducas. Flores sésiles; botones florales con el cáliz abierto, apiculados; cáliz 11–15 mm, tubular, estriado, seríceo con tricomas pardo-amarillentos, con escotaduras, los lóbulos 2.5–3 mm, triangulares; corola 25–29 mm, tubular a subturbinada, amarillenta, vellosa con tricomas pardo-amarillentos; tubo estaminal inserto. Legumbre 10–17.5 × 1.5–2.1 × 0.8–1.1 cm, algo aplanada a más bien túrgida, derecha a curveada, linear-oblonga, sésil o casi sésil, apiculada en el ápice, estrigulosa (más densamente sobre las suturas), las valvas inconspicuamente nervadas, las suturas derechas, multisulcadas, los márgenes de las suturas redondeados.

*Distribución y hábitat.* Endémica de la vertiente Caribe de Panamá, en las provincias de Bocas del Toro y San Blas. Esta especie habita bajo condiciones riparias y de vegetación secundaria, en altitudes hasta de 200 m. Florece en diciembre y enero y fructifica a partir de enero a abril.

*Nombres vernáculos.* Guamo de monte, bungguagua (en Guaymí).

*Usos.* Los Kuna usan la pulpa dulce alrededor de las semillas como comestible.

*Paratipos.* PANAMA. BOCAS DEL TORO: Río San Pedro, *B. L. Gordon 41* (MO). SAN BLAS: Río Cartí Grande, 9°21′N, 79°03′W, *G. de Nevers & H. Herrera 4146* (MO); Río Congandi from village of Congandi to just above its confluence with Río Titamibe, 9°27′N, 79°8′W, *de Nevers et al. 4644* (MO); El Llano–Cartí road, km 26.5, along Río Cartí Chico, 9°19′N, 78°55′W, *de Nevers et al. 5336* (MO); along the Río Sidro at base of Cerro Habú, 9°23′N, 78°49′W, *K. Sytsma et al. 2613* (MO).

*Inga cuspidata* está emparentada con *I. multijuga* Benth., de la cual difiere por varios caracteres (véase diagnosis), además de que en ocasiones los raquis foliares de *I. cuspidata* son alados y el fruto (maduro) es cilíndrico en vez de aplanado. El epíteto hace énfasis en el ápice cuspidado de los folíolos.

**Inga chiapensis** Miranda ex M. Sousa, sp. nov. TIPO: México. Chiapas: en cañada hacia El Aguacate, al N de La Chacona [NO de Tuxtla Gutiérrez], 800 m, en selva alta subdecidua, 19 mar. 1950, *F. Miranda G. 6127* (holotipo, MEXU).

Arbores e mediano procerae, ramis juvenilibus brunneo lutescenti-tomentosis. Folia 2–4-jugata; stipulae 3–4 mm longae, ex ovatae triangulares, deciduae; foliola tenuiter discoloria, chartacea; rhachis foliaris late alata, glandulis ex sessilibus breviter stipitatis, urceolatis. Inflorescentiae spiciformes; rachis floralis 2.5–4 cm longa; bracteae homomorphae cochleatae, deciduae. Flores sessiles; alabastra floralia calyce aperto; calyx tubulosus, striatus, pilosus, emarginatus; corolla tubuloso-subturbinata, brunneo-lutescenti-villosa. Legumen breve, latum, incrassatum, complanatum, brunneo-lutescenti-hirsutum.

Arboles 5–18 m; ramas teretes, tomentosas con tricomas pardo-amarillentos cuando jóvenes, posteriormente glabrescentes. Hojas 4–8-folioladas; estípulas 3–4 mm, ovadas a triangulares, caducas; pecíolo 1–3.5 cm, terete a alado; folíolos ligeramente discoloros, cartáceos, la base ligeramente asimétrica, cuneada a obtusa, el ápice acuminado a cuspidado, el haz ligeramente brillante, piloso después glabrescente, el envés opaco, esparcida-

mente tomentoso, las nervaduras tomentosas con tricomas pardo-amarillentos; la nervadura primaria eglandular; par basal de folíolos 3.7–7 × 2.2–3.5 cm, generalmente elípticos en ocasiones ovados, el par apical 9.5–16 × 4–7.5 cm, lanceolados a elíptico-lanceolados; raquis foliar (2.8–)3.5–9(–15) cm, alado, el ala hasta 16 mm de ancho, oblanceolada, raramente obtriangular; glándulas interfoliolares sésiles a brevistipitadas, urceoladas, el cuerpo glandular 0.6–0.7 × 0.6–0.7 mm; apéndice 9–11 mm, setiforme, pronto caduco. Inflorescencias en espigas, generalmente solitarias; pedúnculo (1.5–)3–6.5 cm, subterete, inconspicuamente sulcado, tomentoso con tricomas pardo-amarillentos; raquis floral 2.5–4 cm, las flores esparcidas proximalmente, congestas distalmente, las brácteas homomorfas 1.3–1.8 mm, cóncavas, oblanceolado-cocleadas a ovado-cocleadas, caducas, las bases cortamente decurrentes. Flores sésiles; botones florales con el cáliz abierto, obtusos; cáliz 8–10 mm, tubular, estriado, piloso, con escotaduras, los lóbulos 1.5–2 mm, triangulares; corola 15–18 mm, tubular-subturbinada, verdosa, moderadamente vellosa con tricomas pardo-amarillentos; tubo estaminal inserto, blanco. Legumbre 8–12.5 × 3.2–3.6 × 1.5–2 cm, aplanada, derecha, oblonga, sésil en la base, apiculada a obtusa en el ápice, hirsuta con tricomas pardo-amarillentos, las valvas aplanadas, las suturas derechas, redondeadas, los márgenes de las suturas 1-sulcados.

*Distribución y hábitat.* Conocida solamente de dos áreas bien definidas, el margen norte de la Depresión Central de Chiapas en vegetación de selvas bajas a altas subcaducifolias a caducifolias y en la zona de Uxpanapa, Veracruz, en selvas altas perennifolias con *Dialium*, *Ormosia* (Leguminosae), *Terminalia* (Combretaceae), *Licania* (Chrysobalanaceae), *Calophyllum*, *Symphonia* (Guttiferae), *Guarea* (Meliaceae), *Sloanea* (Elaeocarpaceae), *Sterculia* (Sterculiaceae), y *Tapirira* (Anacardiaceae). En altitudes de 200 m y de 850–1,100 m. Florece de mediados de marzo a principios de mayo; fructifica de junio a septiembre.

*Paratipos.* MEXICO. VERACRUZ: Mpio. Jesús Carranza, lomas al S de Poblado 2 (±3 6 km al S del entronque de terracería La Laguna–Sarabia con camino a Ejido La Paz), 17°12′N, 94°38′30″O, *T. Wendt et al. 5304, 5633* (CHAPA, MEXU). CHIAPAS: Mpio. Ocozocoautla, a 1 km al NO del entronque Aeropuerto–Ocozocoautla–México, carretera 190, *A. Reyes G. 555* (MEXU, MO); Mpio. San Fernando, San Fernando, *F. Miranda G. 7219* (MEXU); Mpio. Tuxtla Gutiérrez Cerro Hueco, al SSE de Tuxtla Gutiérrez, *Miranda 5570, 6878* (MEXU); en cañada hacia El Aguacate, cerca y al N de La Chacona, *Miranda 6413* (MEXU); adelante Mirador La Coyota, El Sumidero, *Miranda 7662, 7718* (MEXU); entre los km 18–22 de la carretera de Tuxtla Gutiérez hacia el Cañon del Sumidero, *O. Téllez V. et al. 6690, 7578* (MEXU).

*Inga chiapensis* muestra en Mesoamérica similitudes con *I. mucuna* Walp. et Duchass. e *I. leonis* Zamora; con esta última son más estrechas, pero no suficientes para unirlas. Su variación se puede agrupar en la de la Depresión Central de Chiapas y la de Uxpanapa, Veracruz: en la primera área *I. chiapensis* muestra el cáliz ligeramente mayor, la corola más chica y las hojas que tienden a poseer más folíolos que en el área de Uxpanapa, además que varían en cuanto a hábitats y altitud. Sin embargo, por el momento las mantengo bajo un sólo epíteto con la posible distinción posterior en categorías infraespecíficas, dependiendo de más colectas, sobre todo del área baja húmeda de Uxpanapa. Esta especie fue reconocida como entidad nueva por Faustino Miranda González hace más de 40 años y en su honor se emplea el epíteto que él designó, a pesar de que ya se le conoce hoy en día fuera de Chiapas.

**Inga chocoensis** Killip ex T. S. Elias, Phytologia 14: 210. 1967. TIPO: Colombia: *Cuatrecasas 16372* (isotipo, F).

*Inga coprocarpa* Zamora et Poveda, Brenesia 33: 101. 1991. TIPO: Costa Rica: *Herrera & Rivera 842* (holotipo, CR; isotipos, MEXU, MO).

Esta interesante especie está cercanamente emparentada con *Inga longipes* Benth. del alto Amazonas de Perú e *I. duquei* Harms del Valle de Cauca en Colombia; sin embargo, hay varios caracteres que las separan.

*Material representativo.* NICARAGUA. MATAGALPA: *Neill 1746* (MO). COSTA RICA. ALAJUELA: *Utley & Utley 3213* (F). HEREDIA: *Bawa 544* (MO). PANAMA. BOCAS DEL TORO: *Proctor Cooper 527* (F). **Inga dasycarpa** M. Sousa, sp. nov. TIPO: México. Chiapas: 12 km al E de Tziscao, sobre el camino a Santa Elena, en el Parque Nacional Lagos de Monte Bello, 1 oct. 1983, *E. Cabrera & H. de Cabrera 5885* (holotipo, MEXU; isotipo, MO). Figura 2.

Arbores medianae; rami juveniles dense ferrugineo-tomentosi. Folia 2–3-jugata; stipulae 1.5–2 mm longae, ligulatae; foliola ex chartacea coriacea; rhachis foliaris alata glandulalis ex subsessilibus stipitatis praedita. Inflorescentiae capituliformes; pedunculus 1 1.3 cm longus; rhachis floralis subglobosa; bracteae ligulatae. Flores sessiles; calyx 7–9 mm longus, tubularis, inconspicue stria-

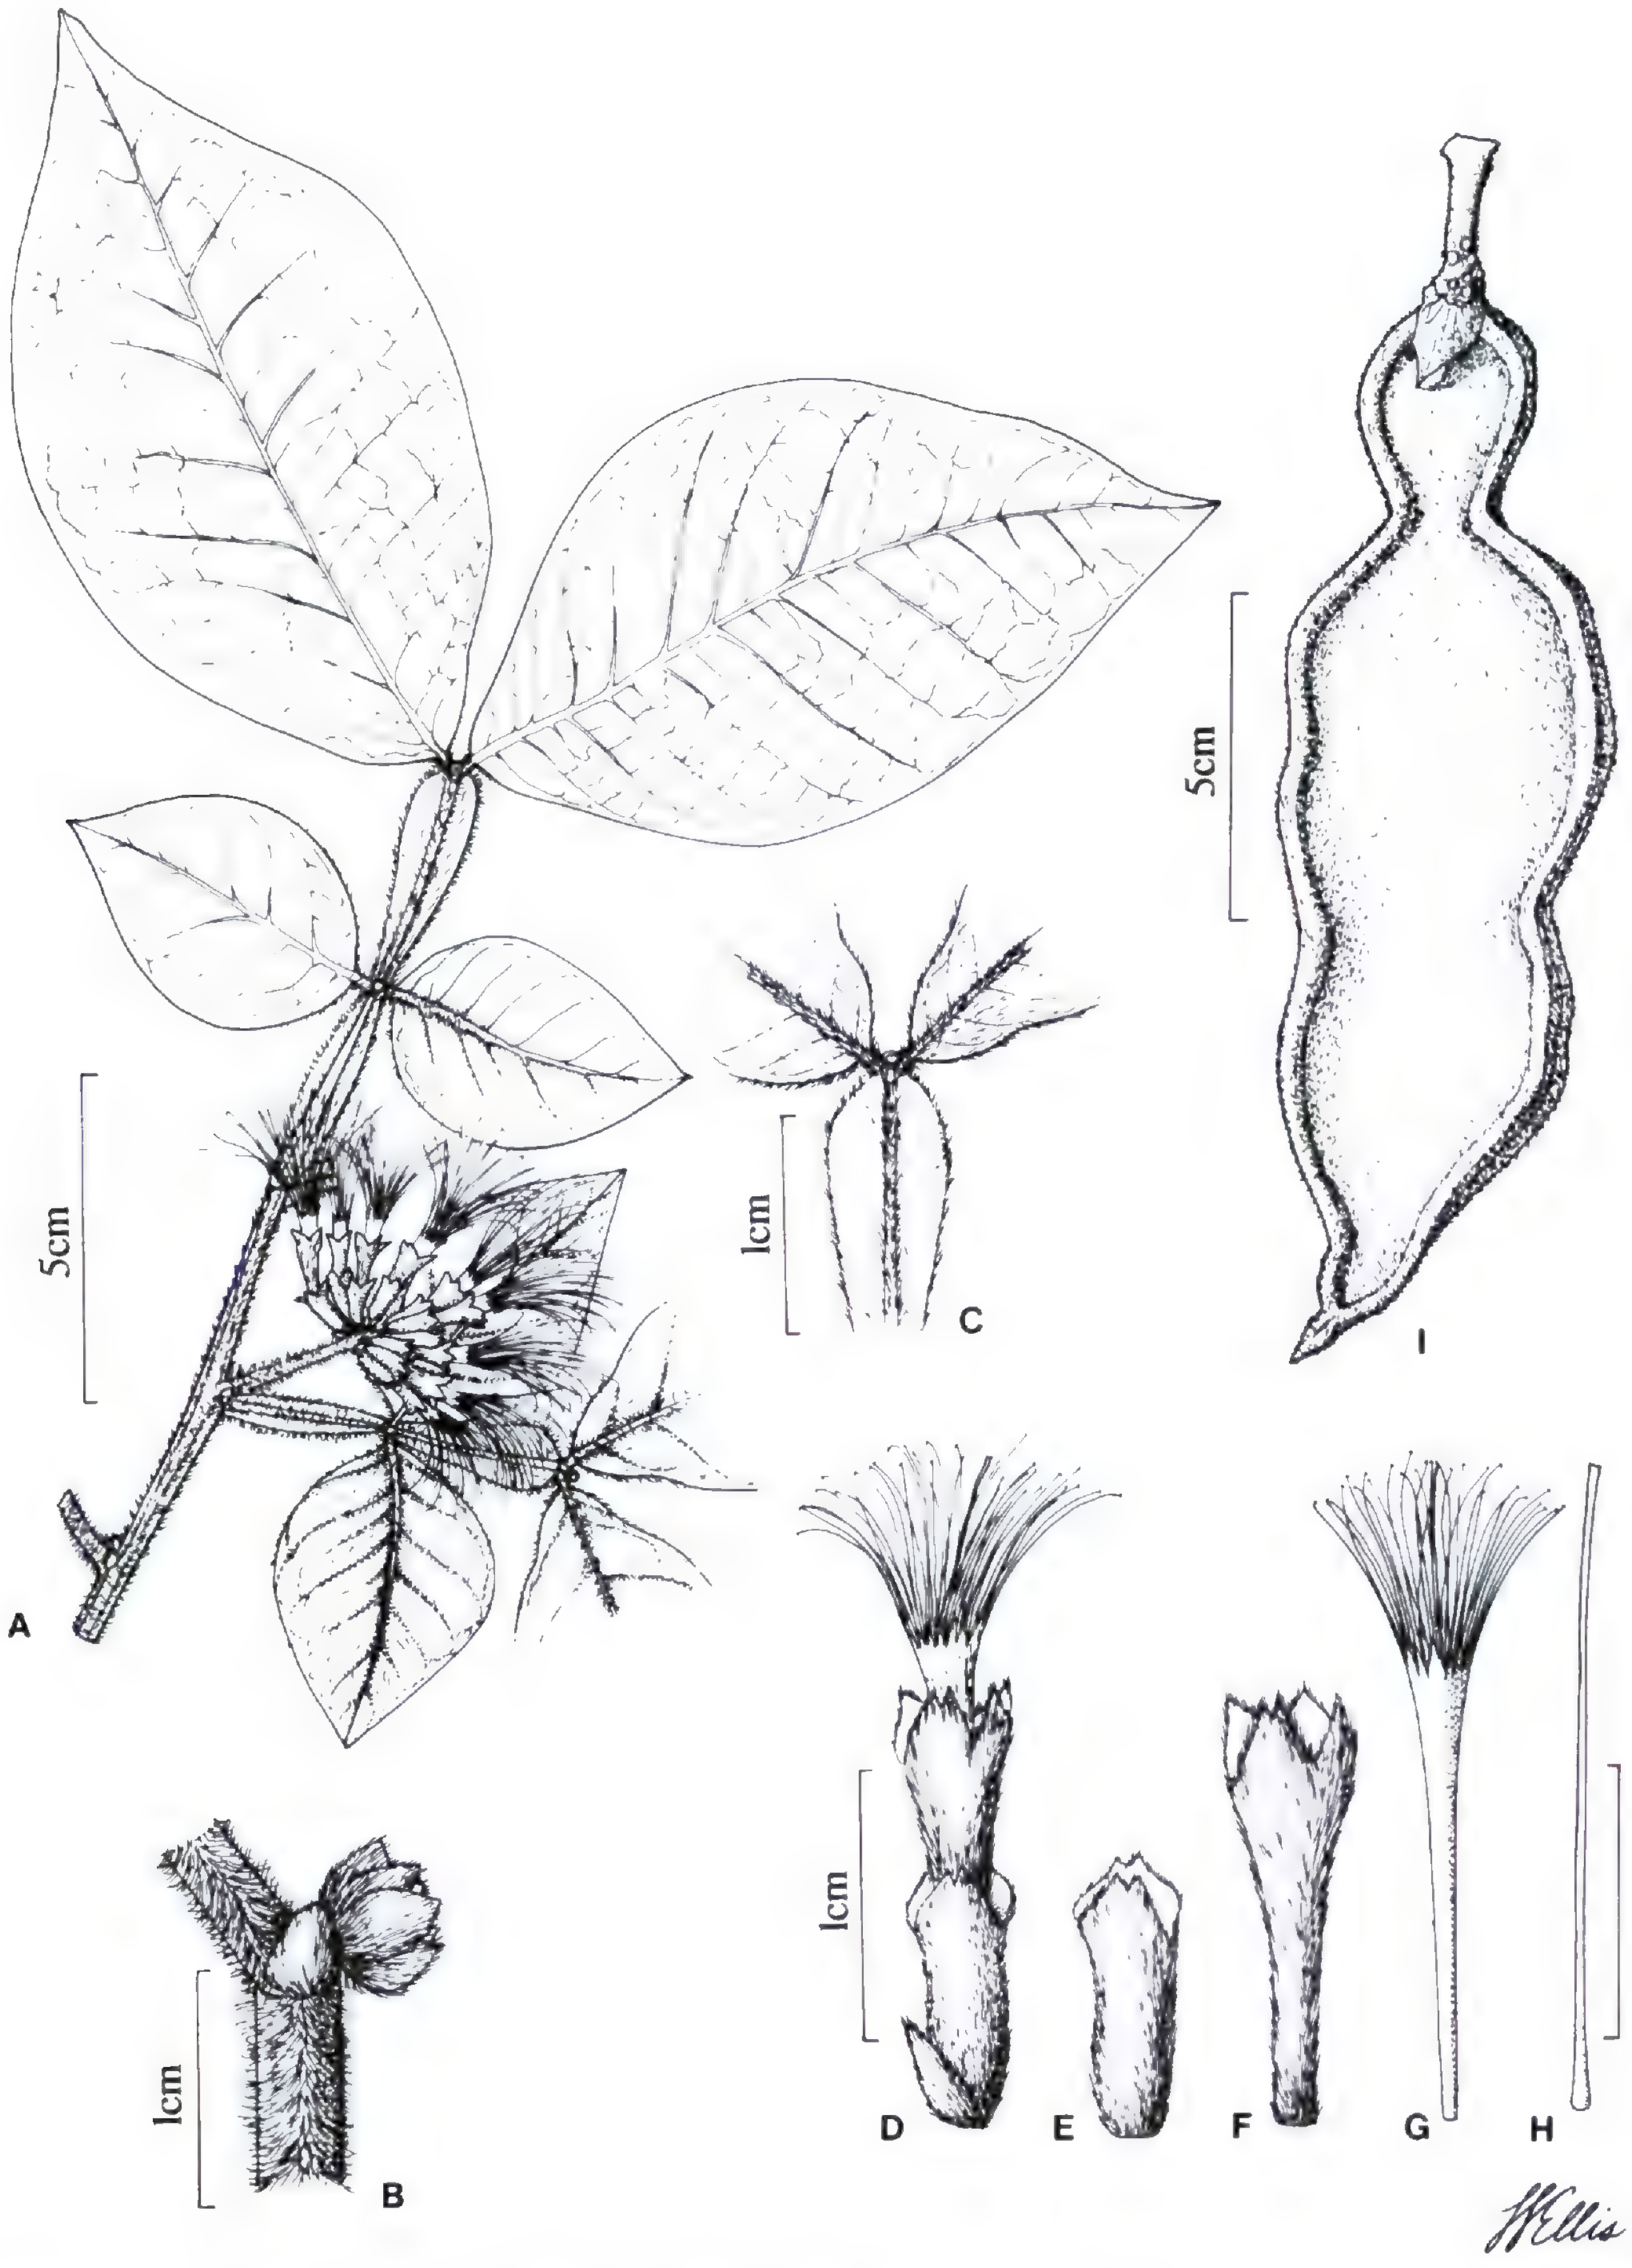

FIGURA 2. *Inga dasycarpa* M. Sousa.—A. Rama con inflorescencia.—B. Detalle de estípulas.—C. Glándula interfoliolar.—D. Flor.—E. Cáliz.—F. Corola.—G. Tubo estaminal. -H. Gineceo. (Tomado de *E. Cabrera 5885.*)—I. Fruto. (Tomado de *O. Téllez 642.*)

tus; corolla 17–19 mm longa. Legumen usque ad 6.5 cm latum, complanatum, oblongum, ferrugineo-hirsutum.

Arboles 4–15 m; ramas teretes, densamente ferrugíneo tomentosas cuando jóvenes, posteriormente glabrescentes. Hojas 4–6 folioladas; estípulas 1.5–2 mm, liguladas, caducas; pecíolo 1–2 cm, terete a alado; folíolos generalmente concoloros, en ocasiones ligeramente discoloros, cartá-

ceos a coriáceos, la base simétrica a ligeramente asimétrica, obtusa a cuneada, el ápice agudo a acuminado, el haz ligeramente brillante, moderadamente a esparcidamente piloso, el envés opaco, moderadamente piloso, la nervadura primaria eglandular; par basal de folíolos 3.3–5.1(–7) × 1.1–2.5(–4.5) cm, ovados a lanceolados, el par apical 7–10(–12.5) × 3.2–5.2(–7) cm, elípticos a obovados; raquis foliar 2.5–4(–7) cm, alado, el ala 5–7(–13) mm de ancho, elíptica, generalmente oblanceolada, rara vez obtriangular; glándulas interfoliolares subsésiles a estipitadas, clavuliformes, el cuerpo glandular 0.7–0.9 × 0.7–0.9 mm; apéndice, ausente. Inflorescencias capituliformes, 1–2 fasciculadas; pedúnculo 1.1–3 cm, subterete, inconspicuamente sulcado, ferrugíneo tomentoso; raquis floral ca. 4 mm, subgloboso, las flores congestas, las brácteas homomorfas 1.5–2 mm, cóncavas, liguladas, caducas. Flores sésiles; botones florales con el cáliz cubriendo, desconocidos; cáliz 7–9 mm, tubular, inconspicuamente estriado, tomentoso con tricomas pardo-amarillentos, con escotaduras, los lóbulos 1.5–2 mm, ligulados; corola 17–19 mm, infundibuliforme, blanca, canescente vellosa; tubo estaminal inserto, blanco. Legumbre 15–21 × 4–6.5 × 0.8–1.5 cm, aplanada, derecha, oblonga, sésil, apiculada a rostrada en el ápice, ferrugíneo hirsuta, las valvas aplanadas, las suturas más o menos derechas, marginadas, los márgenes de las suturas 1-sulcados.

*Distribución y hábitat.* De Chiapas, México a Cortés, Honduras en regiones montañosas, en vegetación de bosques caducifolios con *Liquidambar* (Hamamelidaceae), *Magnolia* (Magnoliaceae), *Clethra* (Clethraceae), *Vochysia* (Vochysiaceae), también en bosques de *Pinus* y *Quercus*. En altitudes entre los 1,350 a 1,600 m. Florece en octubre y fructifica de diciembre a abril.

*Paratipos.* MEXICO. CHIAPAS: Mpio. La Trinitaria, 15 km E of La Trinitaria on road to Montebello, *D. E. Breedlove 42062* (MEXU, MO); E of Laguna Tziscao, Monte Bello National Park, *M. Sousa et al. 11876* (BM, MEXU, MO); a 10 km al E de Montebello, a 1 km de la Laguna de Tziscao, *O. Téllez V. et al. 642* (MEXU). HONDURAS. CORTES: Montaña San Idalfonso entre Bañaderos y Cusuco, *A. Molina R. 11459* (LL, NY, US).

*Inga dasycarpa* se encuentra muy relacionada con *I. villosissima* Benth. de las montañas de Venezuela, pero en *I. dasycarpa* las inflorescencias tienden a ser capituliformes, las brácteas más pequeñas y pronto caducas, las flores más chicas y las estípulas de menor tamaño y pronto deciduas. También está muy relacionada con *I. tenella* M. Sousa, difiriendo de ella por tener *Inga dasycarpa* inflorescencias capituliformes, flores y legumbres de mayor talla, y las hojas coriáceas que en general poseen menos folíolos. *Inga dasycarpa* e *I. tenella* son dos especies que en gran medida son simpátricas, tanto en áreas geográficas generales como en los mismos hábitats, sin que hayamos encontrado posibles híbridos. Estas especies aparentemente refuerzan su aislamiento con períodos de floración diferentes. El epíteto hace referencia a la pelosidad de la legumbre.

**Inga davidsei** M. Sousa, sp. nov. TIPO: Guatemala. Izabal: El Estor, 23 Mar. 1972, *E. Contreras 11483* (holotipo, MEXU; isotipos, LL, MO). Figura 3.

Species *Ingae goldmanii* Pittier proxima, a qua tamen foliis foliola numerosiora habentibus, stipulis longioribus quam latioribus, foliolis coriaceis et supra nitentibus, glandulis per nervum medium absentibus, appendice rhachidea praesente, glandulis interfoliolaribus longe stipitatis, floribusque maioribus recedit.

Arboles 7–20 m; ramas subteretes, ferrugíneo hirsútulas cuando jóvenes, posteriormente glabrescentes. Hojas (6–)8(–10)-folioladas; estípulas (5–)7–14 mm, liguladas a triangulares, caducas; pecíolo (1.5–)2.5–5 cm, terete; folíolos discoloros subcoriáceos, la base simétrica a casi simétrica, cuneada, el ápice obtuso a acuminado, el haz brillante, glabro excepto ferrugíneo tomentoso en la nervadura primaria, el envés opaco, piloso con la nervadura primaria tomentosa como el haz, la nervadura primaria eglandular; par basal de folíolos 7–9.5(–13) × 3.2–4.3(–9) cm, elípticos a oblongo-elípticos, el par apical 15–18(–23) × 5.5–9 (–11.5) cm, generalmente elípticos, en ocasiones obovados; raquis foliar 9.5–15 cm, ferrugíneo tomentoso, terete, marginado a angostamente alado principalmente entre los 3 pares distales de folíolos, el ala hasta 9 mm de ancho, elíptica; glándulas interfoliolares generalmente largamente estipitadas, clavuliformes, el cuerpo glandular 0.5–0.9 × 0.5–0.9 mm; apéndice 10–25 mm, setiforme, arqueado, caduco. Inflorescencias en espigas solitarias; pedúnculo 6–8.5 cm, terete, aparentemente liso, ferrugíneo tomentoso; raquis floral 0.6–1 cm, las flores congestas, las brácteas homomorfas 6–9 mm, gruesas, ligeramente concavas triangular-liguladas, una estéril en el ⅓–½ superior del pedúnculo, persistentes. Flores sésiles; botones florales con el cáliz cubriendo desconocidos; cáliz 17–19 mm, ciatiforme, lanoso con tricomas pardo a pardo-amarillentos, sin escotaduras, los lóbulos 3–4 mm, triangular-ligulados; corola 28–32 mm, subturbinada, pardo-amarillento lanosa; tubo estaminal inserto, blanco. Legumbre 24–30 × 3.3–6.5

FIGURA 3. *Inga davidsei* M. Sousa.—A. Rama con inflorescencia.—B. Detalle de estípulas.—C. Glándula interfoliolar.—D. Flor.—E. Cáliz.—F. Tubo estaminal.—G. Gineceo. (Tomado de *E. Contreras 11483.*)—H. Fruto. (Tomado de *G. Davidse & A. Brant 32330.*)

× 0.9–1.5 cm, aplanda, ligeramente espiralada, oblonga sésil en la base, apiculada en el ápice, ferrugíneo hirsuta, las valvas aplanadas, las suturas derechas, redondeadas, los márgenes de las suturas aplanados a 1-sulcados.

*Distribución y hábitat.* Al sur de la Península de Yucatán, en el norte de Guatemala, Belice, y Honduras en selvas bajas a medianas caducifolias, en sitios riparios y en la orilla de un pinar, sobre suelos someros arcillosos, en altitudes entre los 100

a 900 m. Florece de mediados de febrero a marzo y fructifica de marzo a abril.

*Nombres vernáculos.* Palo de paterno silvestre, cola de mico.

*Usos.* El fruto es comestible y tiene sabor a frijoles.

*Paratipos.* BELICE. EL CAYO: Dent's Drive, Augustine Mountain Pine Ridge *D. R. Hunt 484* (BM, LL, US). TOLEDO: lower part of Richardson Creek, affluent of Bladen Branch, lower part of Maya Mountains, 16°33′N, 88°46′–48′W, *G. Davidse & A. E. Brant 32330* (MEXU, MO). GUATEMALA. ALTA VERAPAZ: *Cook & Griggs 380* (US). HUEHUETENANGO: Cerro Jolomtac, above Finca San Rafael, Sierra de los Cuchumatanes, *J. A. Steyermark 49146* (A, F, US). IZABAL: Lago de Izabal, Mariscos, *T. D. Pennington & D. MacQueen 13437* (K). HONDURAS. ATLANTIDA: Lancetilla, Miramar -San Isidro, *R. Cruz 275* (TEFH); Las Mangas road La Ceiba–Yaruca, above Las Mangas, *Pennington & P. House 13404* (K).

*Inga davidsei* está emparentada con *I. goldmanii* Pittier del sur de Mesoamérica al norte de Sudamérica; sin embargo, difiere de ella tanto en caracteres vegetativos como en cuanto al tamaño de la flor (véase diagnosis).

Se dedica esta especie al Gerrit Davidse (1942–), botánico distinguido de Jardín Botánico de Missouri y colega del autor en el proyecto *Flora Mesoamericana*, quien colectó esta especie bajo el desarrollo del proyecto.

**Inga densiflora** Benth., Trans. Linn. Soc. London 30: 617. 1875. TIPO: Perú. San Martín: Tarapoto, *Spruce 4504* (fl, fr) (lectotipo, designado aquí, K herb. Benth.; isolectotipos, GH, K (3 ej.)).

Para sinónimos véase León (1966).

León (1966) designó a *Spruce 4504* como el tipo de *Inga densiflora* sin mencionar el herbario en que está depositado ni qué ejemplar, por lo que se considera una lectotipificación incompleta. Aquí se lectotipifica designando a K en el herb. Bentham, al ejemplar con flores y frutos.

*Inga densiflora* Benth., como ya lo apuntó León (1966), es una especie muy variable, particularmente en la pelosidad y en la forma de sus glándulas interfoliolares. También a esta variación, seguramente, el hombre ha contribuido, así como a ampliar su distribución, por su uso como sombra de café. Es muy probable que en el área cafetalera del Soconusco en Chiapas, México, el hombre sea el responsable de la presencia de esta especie, aunque en la actualidad se encuentra también en estado silvestre "escapada."

**Inga dwyeri** M. Sousa, sp. nov. TIPO: Panamá. Panamá: Cerro Jefe to 2,900 ft., 5 Jan. 1972, *J. D. Dwyer & A. Gentry 9494* (holotipo, MO; isotipo, MEXU).

Arbores parvae ramis juvenilibus ferrugineo-hirsutulum. Folia (2–)3-jugata; stipulae 2–3.5(–5) mm longae, persistentes; foliola chartacea bullata; rhachis foliaris teres, interdum anguste alata, glandulis ex subsessilibus stipitatis, claviformibus ornata. Inflorescentiae spicatae, angustae; rhachis floralis brevis, floribus distantibus, bracteis concavis, ovatis, persistentibus (in fructificacatione interdum lignescentibus). Flores sessiles; alabastra floralia calyce clauso, attenuato; calyx tubulosus, striatus, sparse ferrugineo-villosus, emarginatus, corolla tubulosa, canescenti luteo-villosa. Legumen parvum, complanatum, oblongum, brunneo-luteo-hirsutum.

Arboles 3–10 m; ramas teretes, ferrugíneo hirsútulas cuando jóvenes, posteriormente glabrescentes. Hojas (4–)6-folioladas; estípulas 2–3.5(–5) mm, ovado-cordatas a triangular-subuladas, persistentes; pecíolo 1–1.8(–3) cm, terete a marginado; folíolos ligeramente discoloros, cartáceos, abollados, la base asimétrica a ligeramente asimétrica, cuneada a truncada, el ápice mucronulato a acuminado, el haz opaco, casi glabro excepto ferrugíneo tomentoso en la nervadura primaria, el envés opaco con pelosidad similar al haz, la nervadura primaria eglandular; par basal de folíolos 3.2–7(–11) × 2.1–3.7(–4.8) cm, ovados a elípticos, el par apical 7–9 × 2.8–4.2 cm, elípticos a subobovados; raquis foliar 1.5–4.1(–7.5) cm, generalmente terete, en ocasiones alado, el ala hasta 4 mm de ancho, angostamente oblanceolada; glándulas interfoliolares subsésiles a robustamente estipitadas, claviformes, el cuerpo glandular 0.6–0.8 × 0.6 0.8 mm; apéndice 2–3 mm, pronto caduco. Inflorescencias en espigas, 1–3 fasciculadas; pedúnculo (0.5–)2.5–4.5 cm, delgado, más o menos aplanado, sulcado, ferrugíneo hirsútulo; raquis floral 1.3–3 cm, las flores espaciadas, las brácteas homomorfas, 2–3 mm, cóncavas, ovadas,

persistentes (en fruto en ocasiones lignifican). Flores sésiles; botones florales con el cáliz cerrado, atenuado-apiculado; cáliz 6–9 mm, tubular, estriado, esparcidamente ferrugíneo velloso, con escotaduras, los lóbulos 1.2–1.8 mm, triangulares; corola 13–17 mm, tubular, vellosa con tricomas canescentes a amarillos; tubo estaminal exerto, blanco. Legumbre 9–10.5 × (1.9–)2.6–2.9 × 0.3–0.7 cm, aplanada, derecha, oblonga, sésil, apiculada a rostrada en el ápice, moderadamente hirsuta con tricomas pardo-amarillentos, las suturas derechas a constrictas, nervadas, los márgenes de las suturas aplanados a sulcados.

*Distribución y hábitat.* Sólo conocida de Panamá, entre 225 y 950 m. Florece en febrero, abril, y septiembre y fructifica de noviembre a enero.

*Paratipos.* PANAMA. DARIEN: Rio Pierre, 10 mi. S of El Real near Dos Bocas, *R. Foster & T. Lowenbach 2272* (MO). PANAMA: Goofy Lake to ca. 8 mi. S of Goofy Lake toward Cerro Jefe, *J. D. Dwyer 7069A* (MO); Cerro Azul, *A. Gentry 6132* (F, MO); along El Llano to Cartí road, about 8 mi. from Pan-American highway, *G. McPherson 10487* (MO). SAN BLAS: El Llano–Cartí Road, 9°19′N, 78°55′W, *H. Herrera & S. Kaza 7334* (MO).

Especie muy variable, cuyas hojas de brotes vegetativos además de ser de mayor talla, tienden a tener el raquis foliar alado. Muy característica por sus folíolos abollados y sus inflorescencias esbeltas y laxas con brácteas persistentes. Sus relaciones en Mesoamérica parecen ser con *Inga pinetorum* Pittier e *I. hayesii* Benth.

Se dedica esta especie a John D. Dwyer (1915–), quien ha contribuido grandemente al conocimiento de la florística mesoamericana.

**Inga edulis** C. Martius, Flora 20: Beibl. 113. 1837. *Mimosa ynga* Vell. Conc., Fl. Flumin. 11: t. 3. 1831, non L. TIPO: Brasil: *Vellozo, Fl. Flumin. 11: t. 3. 1831.*

Especie muy característica por su robustez tanto de hojas y flores como de fruto. Bajo este concepto *Inga edulis* no se le ha colectado o es escasa en las Guayanas, donde *I. scabriuscula* Benth. habita.

*Inga edulis* es sin duda una especie de la Amazonia, que como propone León (1966) posiblemente fue introducida por el hombre a Mesoamérica y quizá también en Colombia: Antioquia y Chocó, ya que siempre está asociada con asentamientos humanos y en plantaciones de café y cacao.

**Inga exalata** T. S. Elias, Phytologia 14: 208. 1967. TIPO: Costa Rica: *Brenes 3634* (holotipo, F; isotipo, NY).

Esta especie sólo hasta hace poco se colectó en Panamá. Sus relaciones no son muy claras, sin embargo se le puede colocar tentativamente en el complejo de *Inga villosissima* Benth., tanto por su pelosidad general y glándulas interfoliolares como por su legumbre.

*Material representativo.* COSTA RICA. ALAJUELA: *Brenes 17057* (F). CARTAGO: *Poveda 941* (F). PANAMA. COCLE: *McPherson 13632* (MO). PANAMA: *McPherson 12347* (MO).

**Inga filiformis** Zamora, Brenesia 33: 103. 1991. TIPO: Panamá: *Mori et al. 6824* (holotipo, MO; isotipo; CR).

Esta especie tan característica se relaciona, al menos en parte, con *Inga saffordiana* Pittier, en cuanto a la forma de sus estípulas, el raquis foliar terete, y los lóbulos de cáliz filiformes, pero no casi libres.

Esta especie presenta una variante en el Cerro Jefe con folíolos velutinos en el envés (*Systma & Anderson 1984*, MO), la cual se encuentra en un piso altitudinal mayor.

*Material representativo.* PANAMA. COLON: *Correa & Dressler 686* (MEXU). PANAMA: *Sytsma & Anderson 4442* (MO). SAN BLAS: *Herrera & Paredes 400* (MO). ZONA DEL CANAL: *Tyson et al. 4536* (MO).

**Inga flagelliformis** (Vell. Conc.) C. Martius, Flora 20(2): Beibl. 112. 1837. Basiónimo: *Mimosa flagelliformis* Vell. Conc., Fl. Flumin. 11: t. 27. 1831. TIPO: Brasil: *Vellozo, Fl. Flumin. 11: t. 27. 1831.*

*Inga jefensis* Liesner et D'Arcy, Ann. Missouri Bot. Gard. 75: 385, fig. 1. 1988. TIPO: Panamá: *Foster y Kennedy 1828* (isotipos, F, MO, US).

*Inga flagelliformis* es una especie muy variable, la cual tiende a tener la inflorescencia sobre tallos gruesos ya sin hojas. En Panamá y Colombia y en la mayoría del material de Brasil, las umbelas son axilares y solitarias a fasciculadas; sin embargo, en un ejemplar de Minas Gerais (*Duarte et al. 2765*, MO) las inflorescencias se presentan en tallos gruesos. La legumbre se presenta de casi recta (*Foster y Kennedy 1828*) a helicoidal (*Monsalve B. 988*).

Dentro de esta variación *Inga jefensis* Liesner et D'Arcy encaja muy bien, por lo que la incluimos bajo *I. flagelliformis*.

Esta especie está cercanamente emparentada al complejo de *Inga tenuistipula* Ducke, *I. lallensis* Spruce ex Benth., e *I. tessmannii* Harms, todas ellas con una flor muy similar y pedicelos más cortos o faltantes.

*Material representativo.* PANAMA. COCLE: *Porter et al. 4400* (MO). COLON: *Gentry et al. 8854* (MO). DARIEN: *Antonio & Hahn 4325* (MO). PANAMA: *Churchill & de Nevers 4968* (MO). COLOMBIA. CHOCO: *Duke 9580* (NY). VALLE: *Monsalve B. 988* (MO). BRASIL. (NORTE) AMAPA: *S. Mori et al. 15781* (K). AMAZONIA: *Cid et al. 77* (GH). PARA: *Ducke 10021* (US). (SUDESTE) MINAS GERAIS: *Duarte et al. 2765* (MO). RIO DE JANEIRO: *Luschnath s.n.* (MO).

**Inga flexuosa** Schldl., Linnaea 12: 559. 1838. TIPO: México. Veracruz: *Schiede 674* (isotipos, BR, G, GH).

*Inga pringlei* Harms, Repert. Spec. Nov. Regni Veg. 13: 526. 1915. TIPO: México. Veracruz: *Pringle 8125* (isotipos, A, BM, F, MEXU, MO, US).

Steudel creó un nuevo nombre, *Inga schiedeana*, para *Inga flexuosa* Schldl. aduciendo la ya existente *I. flexuosa* de Graham, sin embargo, este último nombre carece de descripción (nom. nud.) y sólo se encuentra en una lista en manuscrito (copia en MO), y por lo tanto no se considera válidamente publicado y no se puede crear un homónimo tardío.

La identidad de *Inga flexuosa* ha permanecido en duda desde Bentham (1875) y Standley (1922), ésto debido a la pobre descripción original de la parte fértil, así como lo estéril de los duplicados vistos; sin embargo, Britton & Rose (1928) la equiparan como *I. pringlei* Harms, lo cual parece posible por eliminación, considerando las pocas especies que hay en el área de la localidad del tipo, en los alrededores de Jalapa, Veracruz.

En *Inga flexuosa* las brácteas lineares muy largas que en ocasiones sobrepasan al cáliz, los botones florales con el cáliz abierto cuyos lóbulos son conniventes a todo lo largo formando un ápice rostrado a apiculado, así como la corola más pequeña la separan de *I. micheliana* Harms, especie que le es muy afín.

*Material representativo.* MEXICO. OAXACA: *Sousa et al. 9355* (MEXU). VERACRUZ: *Castilleja 66* (XAL).

**Inga glomeriflora** Ducke, Arch. Jard. Bot. Rio de Janeiro 3: 50. 1922. TIPO: Brasil. Pará: *A. Ducke RB16609* (isotipos, BM, G, US).

*Inga golfodulcensis* Zamora, Brenesia 33: 107. 1991. TIPO: Costa Rica: *Hammel et al. 16963* (holotipo, CR; isotipos, MEXU, MO).

Esta especie se ubica en la sección *Bourgonia*, teniendo relaciones estrechas, pero es diferente a *Inga fanchoniana* Poncy de la Guayana Francesa, con la cual comparte varios caracteres, así ambas especies tienden frecuentemente a carecer de glándulas interfoliolares en los últimos pares de folíolos, sus hojas son glabras con ejes teretes, y las legumbres son circinado-espiraladas.

*Material representativo.* COSTA RICA. PUNTARENAS: *Hammel et al. 16963* (MO). PANAMA. PANAMA: *Dwyer et al. 7252* (US). COLOMBIA. META: *Callejas 7013* (MEXU). BRASIL. (NORTE) AMAZONIA: *Ducke 1207* (US). PARA: *Ducke RB16609* (US).

**Inga goldmanii** Pittier, Contr. U.S. Natl. Herb. 18: 198. 1916. TIPO: Panamá: *Goldman 1866* (holotipo, US).

Esta vistosa especie muestra grandes afinidades con *Inga davidsei* M. Sousa en Mesoamérica (véase ésta), de ella León (1966) nombró la serie *Goldmanianae* León basandose en las características florales, particularmente su robusto cáliz. En esta especie también son notables las glándulas foliolares supernumerarias (presentes también en *I. sierrae* Britton et Killip); este último carácter parece haber aparecido más de una vez en el género *Inga* ya que también está presente en *I. adenophylla* Pittier e *I. chocoensis* Killip ex T. S. Elias, especies claramente de la sección *Inga* que cuentan con la legumbre subterete y acordonada que es característica de la sección.

*Material representativo.* NICARAGUA. MATAGALPA: *Grijalva & Grijalva 1382* (MO). ZELAYA: *Ortiz 1255* (MO). COSTA RICA. ALAJUELA: *Holm & Iltis 951* (A). LIMON: *Lent 3690* (MO). PANAMA. **Inga hayesii** Benth., Trans. Linn. Soc. London 30: 617. 1875. TIPO: Panamá: *Sutton Hayes 62* (holotipo, K).

Especie conocida hasta hace poco sólo de Panamá, pero con las colectas recientes ya se cuenta con material de Costa Rica y Colombia.

*Material representativo.* COSTA RICA. PUNTARENAS: *Poveda 658* (MO). PANAMA. DARIEN: *Stern et al. 964* (MO). PANAMA: *Dwyer 1484A* (MO). ZONA DEL CANAL: *Croat 14912* (MO). COLOMBIA. ANTIOQUIA: *Zarucchi et al. 4950* (MO). CHOCO: *Gentry & Brand 36969* (MO).

**Inga herrerae** Zamora, Brenesia 33: 107. 1991. TIPO: Costa Rica: *Herrera 1524* (holotipo, CR; isotipos, MEXU, MO).

Especie endémica de las montañas de Guanacaste, Costa Rica, característica por sus folíolos subcoriáceos a coriáceos y numerosos, y como Zamora (en prensa) ya ha apuntado sus peciólulos muy cortos. Es muy probable que el material en fruto de *Wilbur & Stone 10703* pertenezca a esta especie.

*Material representativo.* COSTA RICA. GUANACASTE: *Wilbur & Stone 10703* (NY).

**Inga heterophylla** Willd., Sp. Pl. ed. 4, 4: 1020. 1806. TIPO: Brasil: *Hoffmansegg s.n.* (holotipo, B-W, foto MO).

Para sinónimos véase Poncy (1985).

Especie que ha sido confundida en Mesoamérica con *Inga sertulifera* DC. *Inga heterophylla* Willd. se trata de una especie fundamentalmente de la Amazonía que marginalmente entra a Mesoamérica, en el Darién, en Panamá. Su inflorescencia es muy variable y va de un racimo corto corimboide hasta una umbela, lo que ha creado problemas en su identificación, ya que se le ha colocado generalmente en la sección *Leptinga* Benth., sección que en general varios autores la caracterizan por contar con inflorescencias en umbelas. Sin embargo Bentham (1845) claramente la define como de racimos umbeliformes.

**Inga hintonii** Sandw., Bull. Misc. Inform. 1937: 304. 1937 (como "*hintoni*"). TIPO: México. Edo. México: *Hinton 7617* (holotipo, K; isotipo, US).

*Inga davidsoniae* Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 22: 79. 1940. TIPO: Panamá: *Davidson 943* (holotipo, F; isotipos, MO, US).

*Inga nubigena* A. R. Molina, Ceiba 18: 99. 1971. TIPO: Honduras: *Molina R. 10656* (holotipo, F; isotipo, ENCB).

*Inga hintonii* es una especie muy variable, que se localiza en México y Mesoamérica de Nayarit, México a Chiriquí, Panamá; siempre en bosques húmedos de montaña, en ocasiones a más de 2,100 m de altitud. Su pariente más cercano es, sin duda, *I. micheliana* Harms, especie endémica a la vertiente del Golfo de México de Veracruz a Guatemala; de ella se distingue fundamentalmente por la flor más grande de *I. micheliana.*

**Inga ismaelis** M. Sousa, sp. nov. TIPO: México. Veracruz: km 5 camino Plan de Arroyo–Arroyo Alegre, Mpio. Hidalgotitlán, 17°15'N, 94°35'O, 140 m, 24 abr. 1974, *J. Dorantes et al. 3011* (holotipo, MEXU; isotipo, NY). Figura 4.

Arbores ex mediano procerae; rami juveniles ex modice flavescenti-ferrugineo-setosi hispidi. Folia (3–)4–5-jugata; stipulae 10–14 mm longae, triangulari-subulatae; foliola chartacea; rhachis foliaris alata, glandulis sessilibus vel fere sessilibus, urceolatis. Inflorescentiae racemosae corymboideae, rhachide florali brevi, bracteis elongatis persistentibus. Flores proximales pedicellati, distales fere sessiles; alabastra floralia calyce aperto; calyx tubulosus, lobulis longissimis triangulari-subulatis; corolla tubulosa, canescenti-villosa. Legumen usque ad 27 cm longum, complanatum, crassum, oblongum, sparse hispidum.

Arboles 6–20 m; ramas teretes, moderadamente setosas a híspidas con tricomas amarillos a ferrugíneos cuando jóvenes, posteriomente glabrescentes. Hojas (6–)8–10-folioladas; estípulas 10–14 mm, triangular-subuladas, persistentes; pecíolo 1–2 cm, angostamente alado; folíolos tenuemente

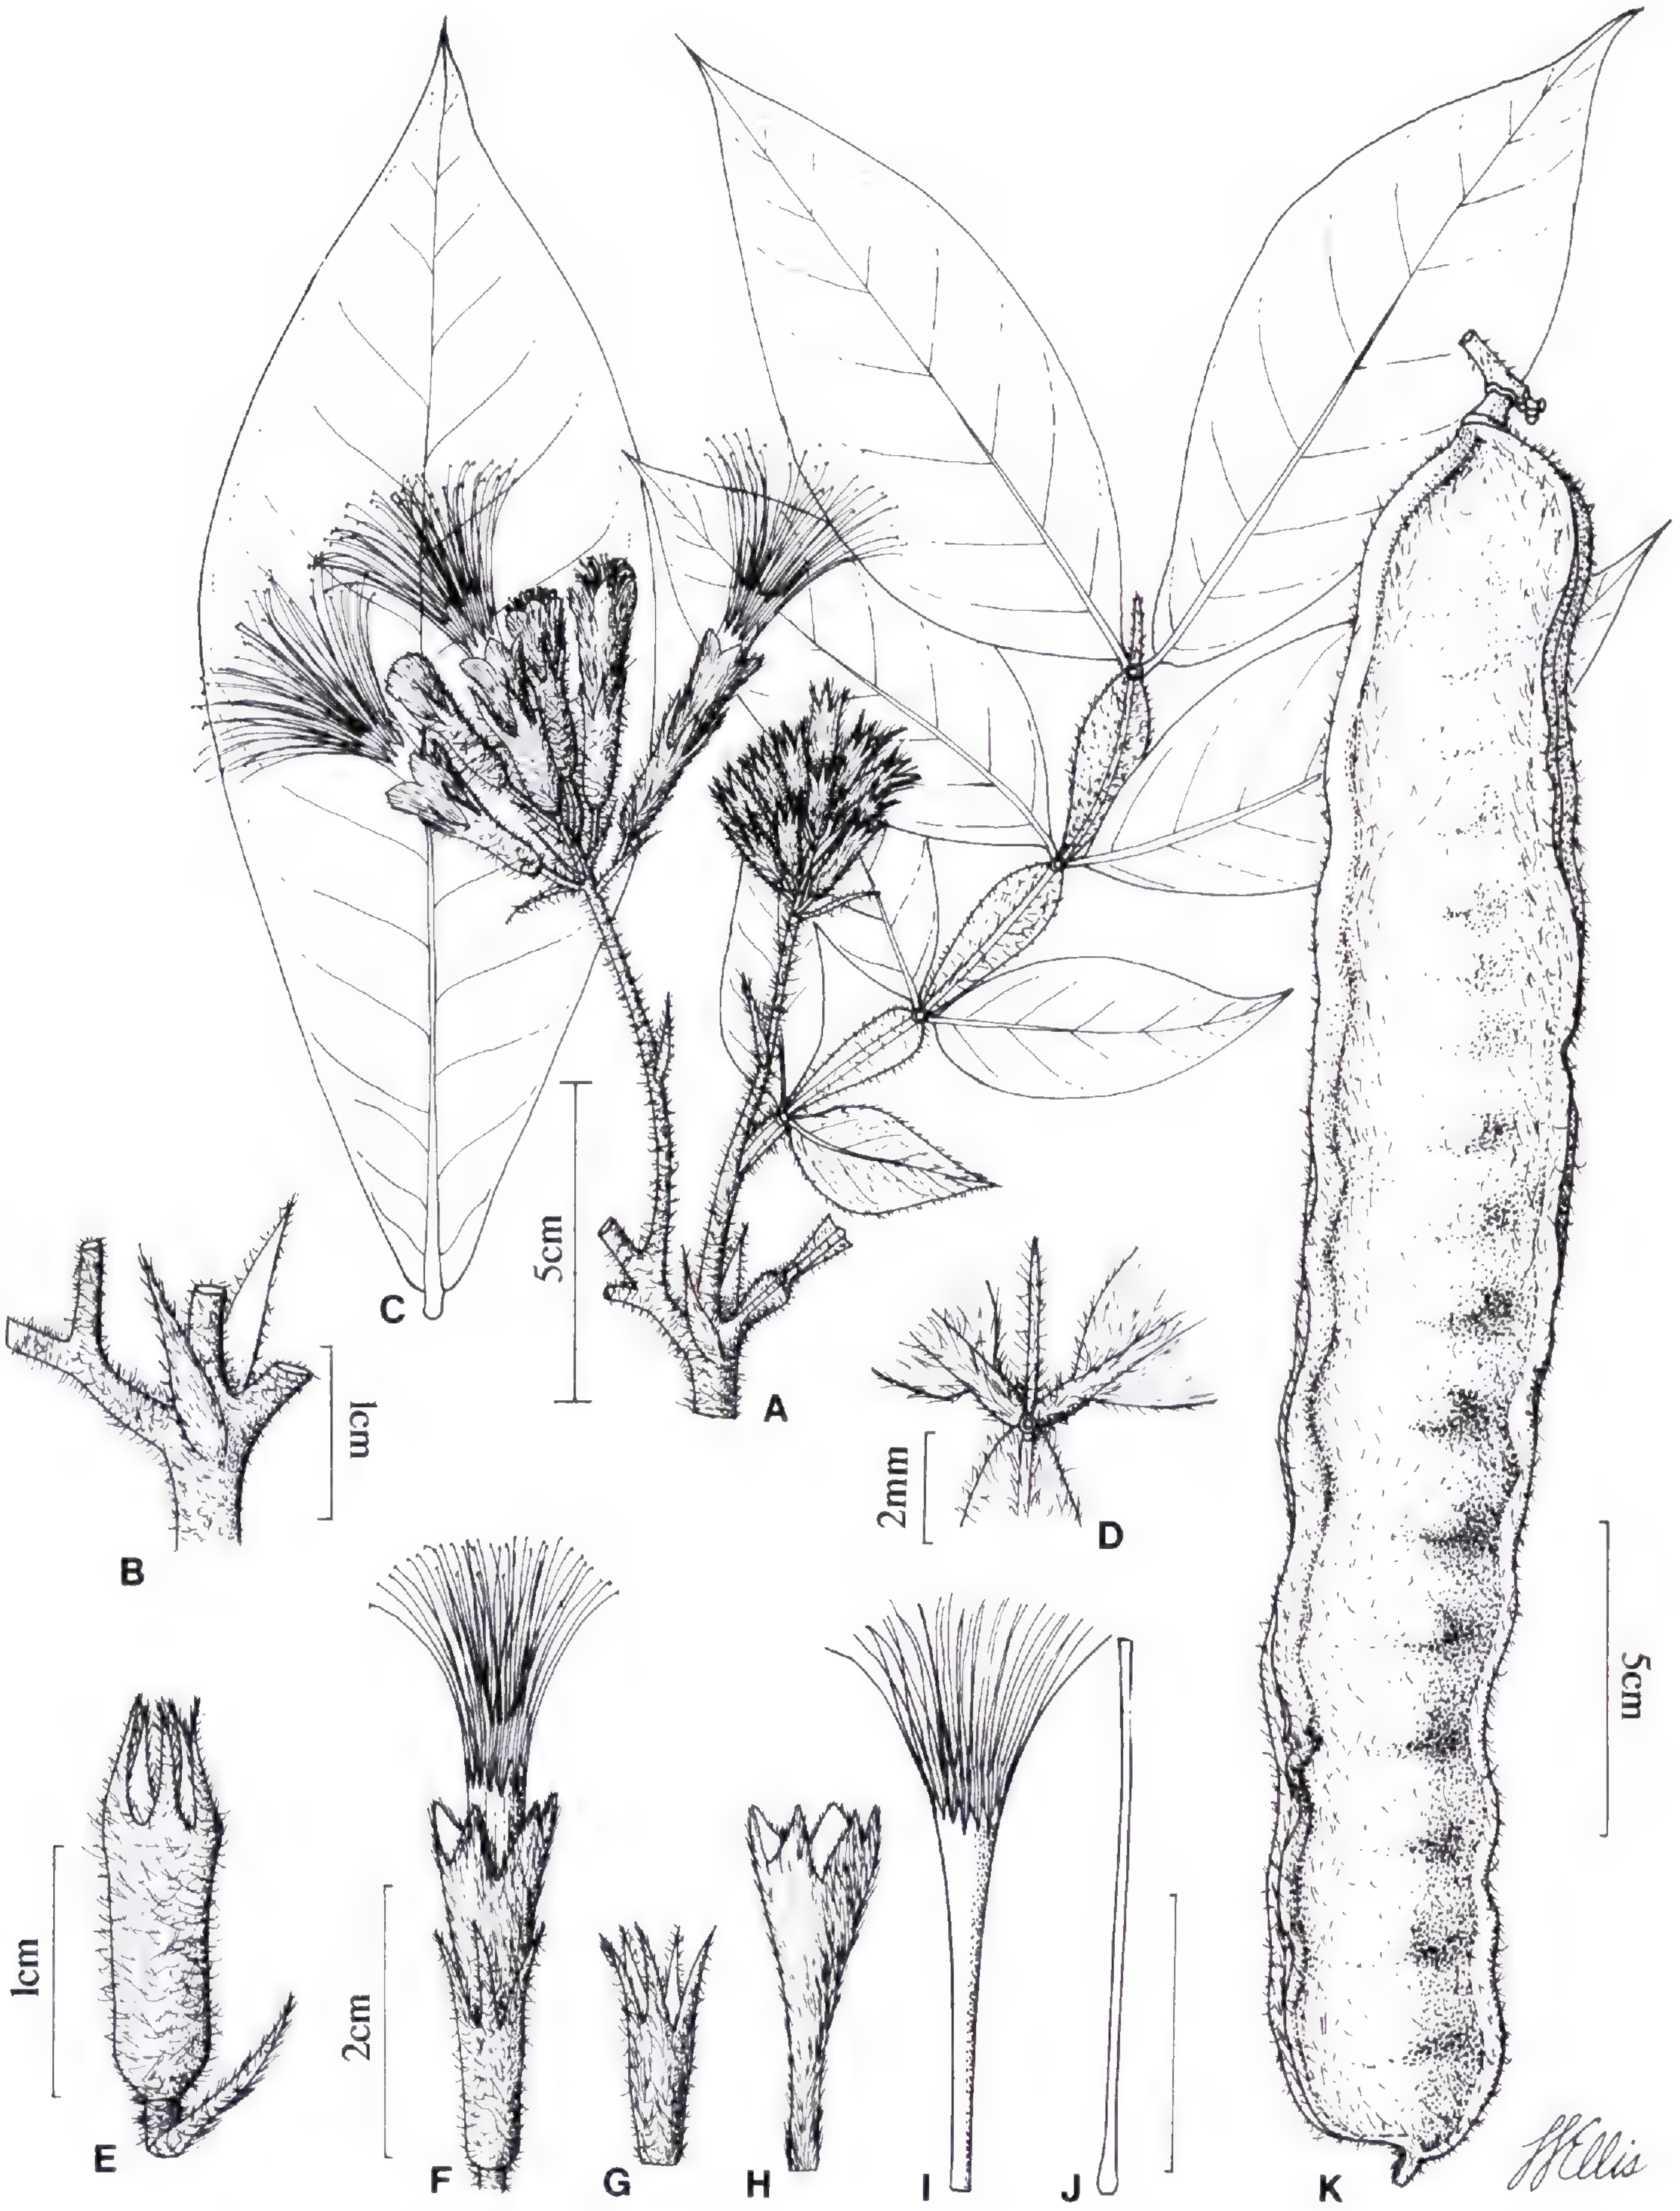

FIGURA 4. *Inga ismaelis* M. Sousa.—A. Rama con inflorescencias.—B. Detalle de estípulas.—C. Folíolo.—D. Detalle de glándula interfoliolar y ápendice. (Tomado de *J. Grimes et al. 2817.*)—E. Botón floral.—F. Flor.—G. Cáliz.—H. Corola.—I. Tubo estaminal.—J. Gineceo. (Tomado de *J. Dorantes et al. 3011.*)—K. Fruto. (Tomado de *J. Dorantes 3493.*)

discoloros, cartáceos, la base ligeramente asimétrica, cuneada a obtusa, el ápice agudo a cuspidado, el haz opaco, moderadamente a esparcidamente piloso, el envés pálido, moderadamente piloso, la nervadura primaria eglandular; par basal de folíolos 4.5–7.5 × 2.5–4.3 cm, ovados a elípticos, el par apical 15–20 × 5.5–8 cm, lanceolados o elípticos a oblanceolados; raquis foliar 5.5–16 cm, alado, el ala 5–11(–18) mm de ancho, generalmente elíptica, en ocasiones oblanceolada; glándulas interfoliolares en ocasiones ausentes, sésiles o casi sésiles, urceoladas cuando presentes, el cuerpo glandular 0.8–1 × 0.8–1 mm; apéndice 6–12 mm, setiforme. Inflorescencias en racimos corimboides, 1–2 fasciculadas; pedúnculo 5–8 cm, más o menos aplanado, sulcado, setoso; raquis floral 1.5–3 cm, las flores espaciadas proximalmente, congestas distalmente, las brácteas homomorfas 13–16 mm, triangular-subuladas a lanceolado-subuladas, generalmente con una estéril en el ⅓ superior del pedúnculo, persistentes. Flores pediceladas las proximales a casi sésiles las distales, el pedicelo hasta 9 mm, delgado; botones florales con el cáliz abierto, los lóbulos erectos no conniventes; cáliz 16–21 mm, tubular, estriado, piloso, sin escotaduras, los lóbulos 5–7 mm, triangular-subulados; corola 23–27 mm, tubular a subturbinada, blanca, canescente vellosa; tubo estaminal inserto a cortamente exerto, blanco. Legumbre ca. 27 × 3.5 × 0.6 cm, aplanada, más o menos derecha, linear-oblonga, sésil, rostrada en el ápice, esparcidamente híspida, las valvas aplanadas, inconspicuamente nervadas, las suturas prominentes, los márgenes de las suturas 1-sulcados.

*Distribución y hábitat.* Del área de Uxpanapa en el sur de Veracruz y del área de Tuxtepec en el norte de Oaxaca, México, en sitios riparios en selvas altas perennifolias con *Dialium*, *Ormosia* (Leguminosae), *Licania* (Chrysobalanaceae), y *Brosimum* (Moraceae), en suelos profundos, arcillosos, amarillentos, en afloramientos de rocas calizas en altitudes entre los 100 a 150 m. Florece en abril y fructifica en septiembre.

*Nombres vernáculos.* Chacaruite, guagenecuil de la montaña, vaina, jinicuil.

*Usos.* Los frutos maduros son comestibles.

*Paratipos.* MEXICO. OAXACA: Distr. Tuxtepec, Mpio. Jalapa de Díaz, Río Uluapan, carr. Jalapa de Díaz a San Bartolomé Ayautla, *I. Calzada 16860* (MEXU). VERACRUZ: Mpio. Jesús Carranza, 20 km S del Poblado 2, 3 4 km S del entronque de la terracería La Laguna Boca del Monte en el camino al N del Poblado 2, *J. Grimes 2817* (MO, NY, TEX). Mpio. Hidalgotitlán, 4 km camino a La Laguna, *M. Avendaño 40* (MEXU, XAL); km 0 2 del camino Plan de Arroyos–Alvaro Obregón, 17°15′N, 94°40′O, *J. Dorantes et al. 2806* (NY, XAL); km 4–5 caminito que cruza la carretera La Laguna, *Dorantes 3493* (MEXU, XAL); 1 km al N Campamento Hermanos Cedillo, 17°16′N, 94°37′O, *M. Vázquez et al. 385* (ENCB, NY, WIS, XAL).

*Inga ismaelis* está emparentada con *I. setosa* Don e *I. pavoniana* Don, siendo más cercana a *I. setosa* Don del Perú, de ésta difiere *I. ismaelis* por tener las glándulas del raquis foliar sésiles o casi sésiles, las flores más grandes, las estípulas mucho más largas que anchas así como las brácteas alargadas en vez de cordatas. El largo de los lóbulos del cáliz sólo se equipara al de los de *I. velutina* Willd. del Amazonas.

Esta especie se dedica a Juan Ismael Calzada (1950–), colector de las selvas de México, quien trabajó para el proyecto Flora de Veracruz, cuyo personal es el que fundamentalmente ha colectado a esta especie.

**Inga jinicuil** Schldl., Linnaea 12: 559–560. 1838.
TIPO: Costa Rica: *Jiménez & Zúñiga 815* (holotipo, CR; isotipo, MO).

Especie conocida de la vertiente Pacífica, San José, Costa Rica, y del Cerro Pierre en el Darién en Panamá. Sus relaciones en Mesoamérica parecen ser con *Inga calderonii*, difiriendo de ella en varios caracteres; también muestra, aunque no tan cercanamente, relaciones con la sección *Vulpinae* Benth. De este último grupo *Inga jimenezii* difiere fundamentalmente por los lóbulos cortos del cáliz.

*Material representativo.* COSTA RICA. SAN JOSE: *Jiménez & Zúñiga 815* (MO). PANAMA. DARIEN: *Gentry 1612* (BM).

**Inga jinicuil** Schldl., Linnaea 12: 559–560. 1838.
TIPO: México. Veracruz: *Schiede 675* (isotipos, CAS, G, GH, MO).

*Inga jinicuil*, a pesar de disponerse a partir del trabajo de León (1966) con nuevas y numerosas colectas, se mantiene aparte, sin que pueda incluirse con *I. paterno* Harms; sus diferencias son tanto en caracteres vegetativos, florales, como en los hábitats. *Inga jinicuil* se encuentra en un piso altitudinal mayor que el de *I. paterno* (véase clave de especies).

*Material representativo.* MEXICO. CHIAPAS: *Martínez S. 22146* (MEXU). MICHOACAN: *Emrick 38* (F). Morelos: *Cordero C. 2* (MEXU). OAXACA: *Rivera R. 1491* (MEXU). PUEBLA: *Miranda G. 1435* (MEXU). VERACRUZ: *Calzada 1969* (MEXU). GUATEMALA. BAJA VERAPAZ: *Lundell & Contreras 20885* (LL).

**Inga lacustris** M. Sousa, sp. nov. TIPO: México. Veracruz: costa N de la Punta Levisa, en la Laguna de Sontecomapan, Mpio. Catemaco, 18°32′N, 95°11′O, 15 abr. 1973, *F. Menén-*

*dez L. 144* (holotipo, MEXU; isotipos, MEXU, MO, XAL). Figura 5.

Arbores parvae; rami juveniles sparse tomentosi cito glabrescentes. Folka 2-jugata; stipulae 9–12 mm longae, triangulari-subulatae; foliola ex lanceolata elliptica apice ex acuminato cuspidata; rhachis foliaris ex marginata alata glandulis sessilibus patellatis. Inflorescentiae racemosae floribus distantibus; bracteae sensim heteromorphae. Flores pedicellati; alabastra floralia attenuato-obtusa, calyce aperto; calyx tubulosus, laevis, marginatus; corolla tubulosa, sparse canescenti-sericea; tubus stamineus longe exsertus. Legumen (immaturum) parvum, complanatum, oblongum, sparse hispidulum.

Arboles 3–7 m; ramas teretes a tenuemente anguladas, esparcidamente tomentosas cuando jóvenes, pronto glabras y rojizo brillante. Hojas 4-folioladas; estípulas 9–12 mm, triangular-subuladas, persistentes; pecíolo 0.7–2.2 cm, terete a alado; folíolos tenuemente discoloros, cartáceos a subcoriáceos, la base simétrica cuneada a ligeramente cordata, el ápice acuminado a cuspidado, el haz brillante a opaco, glabro, el envés algo brillante a opaco, glabrescente, la nervadura primaria eglandular; par basal de folíolos 3.5–9.5(–14) × 1.8–4(–6) cm, lanceolados a elípticos, el par apical (8–)18–23(–27.5) × (3–)5–6.5(–8) cm, elípticos; raquis foliar 2.5–5 cm, marginando a alado, el ala 5–9 mm de ancho, oblanceolada; glándulas interfoliolares sésiles, pateniformes, el cuerpo glandular, ca. 1 × 1 mm; apéndice 4 mm, setiforme, pronto caduco. Inflorescencias en racimos solitarios; pedúnculo 4.5–9 cm, estriado, esparcidamente tomentoso a glabrescente; raquis floral 5–7.5 cm, las flores esparcidas, particularmente las proximales, las brácteas gradualmente heteromorfas, 1–4 mm, las proximales cóncavas ovado-lanceoladas, las distales estipitado-cuculadas, en ocasiones con una estéril del ½ al ápice del pedúnculo, persistentes. Flores proximales pediceladas, el pedicelo esbelto hasta 3.5 mm, las distales casi sésiles; botones florales con el cáliz abierto y los lóbulos imbricados, atenuado-obtusos; cáliz 3–9 mm, tubular, liso, esparcidamente tomentoso, seríceo a glabrescente, con escotaduras, los lóbulos ca. 1 mm, triangular-cuspidados; corola 13–15 mm, tubular, blanca, esparcidamente canescente sericea; tubo estaminal largamente exerto, blanco. Legumbre (inmadura) 4.5–7.6 × 2.5–3.2 × 0.2 cm, aplanda, derecha, oblonga, truncada en la base, apiculada en el ápice, esparcidamente hispídula, las valvas aplanadas, las suturas onduladas, marginadas.

*Distribución y hábitat.* Sólo conocida de la orilla N de la Laguna de Sontecomapan, en la región volcánica de Los Tuxtlas en Veracruz, México, en una selva perennifolia que está delimitada por manglares de *Laguncularia racemosa*, sobre suelos arenosos; al nivel del mar. Esta especie está muy restringida en área y se limita a unos cuantos árboles. Florece en abril y junio, inicia la fructificación en abril y aún tiene frutos inmaduros a fines de julio.

*Paratipos.* MEXICO. VERACRUZ: Mpio. Catemaco, Punta Levisa, Laguna de Sontecomapan, *I. Calzada 987* (MEXU), *s.n.* [15 abr. 1973] (MEXU), *1805* (MEXU), *11658* (MEXU, XAL), *12004* (MEXU, MO, XAL); Rancho Levisa, en Punta Levisa, orilla N Laguna de Sontecomapan, *M. Sousa & I. Calzada 13021* (MEXU, MO).

*Inga lacustris* está emparentada con *I. cookii* Pittier; sin embargo, difiere de ella, particularmente en su pelosidad, estípulas y glándulas interfoliolares, así como brácteas florales y pelosidad de la legumbre. El epíteto se emplea para hacer énfasis en el tan particular hábitat, de una especie en inminente peligro de extinción.

**Inga latibracteata** Harms, Repert. Spec. Nov. Regni Veg. 19: 64. 1923. TIPO: México. Veracruz: *Pringle 8159* (isotipos, F, MEXU, US).

*Inga borealis* T. S. Elias, Phytologia 14: 208. 1967. TIPO: México. San Luis Potosí: *King 4275* (holotipo, NY; isotipos, F, MICH, TEX, US).

Para demás sinónimos, excepto *I. zacuapanica* Harms, véase León (1966).

Especie muy variable que se caracteriza por tener flores con una bráctea subyacente muy bien desarrollada que llega a proporciones foliáceas en *Inga borealis* que representa el extremo de variación de este carácter, así como el extremo norte de distribución de la especie. El otro extremo de variación sería *I. oerstediana* Benth., de la cual *I. latibracteata* representa una variación geográfica; sin embargo, creo deben mantenerse separadas por el momento. Existen varias formas intermedias entre esta especie e *I. vera* Willd. que interpretamos como híbridos; el nombre más antiguo que corresponde a este híbrido propuesto es *I. xalapensis* Benth. (véase a éste para mayores detalles).

*Material representativo.* MEXICO. CHIAPAS: *Ton 5576* (MEXU). OAXACA: *Torres C. & Ramírez 8461* (MEXU). PUEBLA: *Campos V. & Toris A. 204* (MEXU). QUERETARO: *Fernández N. 3891* (ENCB). SAN LUIS POTOSI: *King 4275* (TEX). VERACRUZ: *Velázquez L. 171* (MO).

**Inga latipes** Pittier, Contr. U.S. Natl. Herb. 18: 183. 1916. TIPO: Costa Rica: *Tonduz 13056* (holotipo, US; isotipos, BM, K, NY).

Esta especie es sólo conocida de las áreas montañosas de la Provincia de Cartago en Costa Rica.

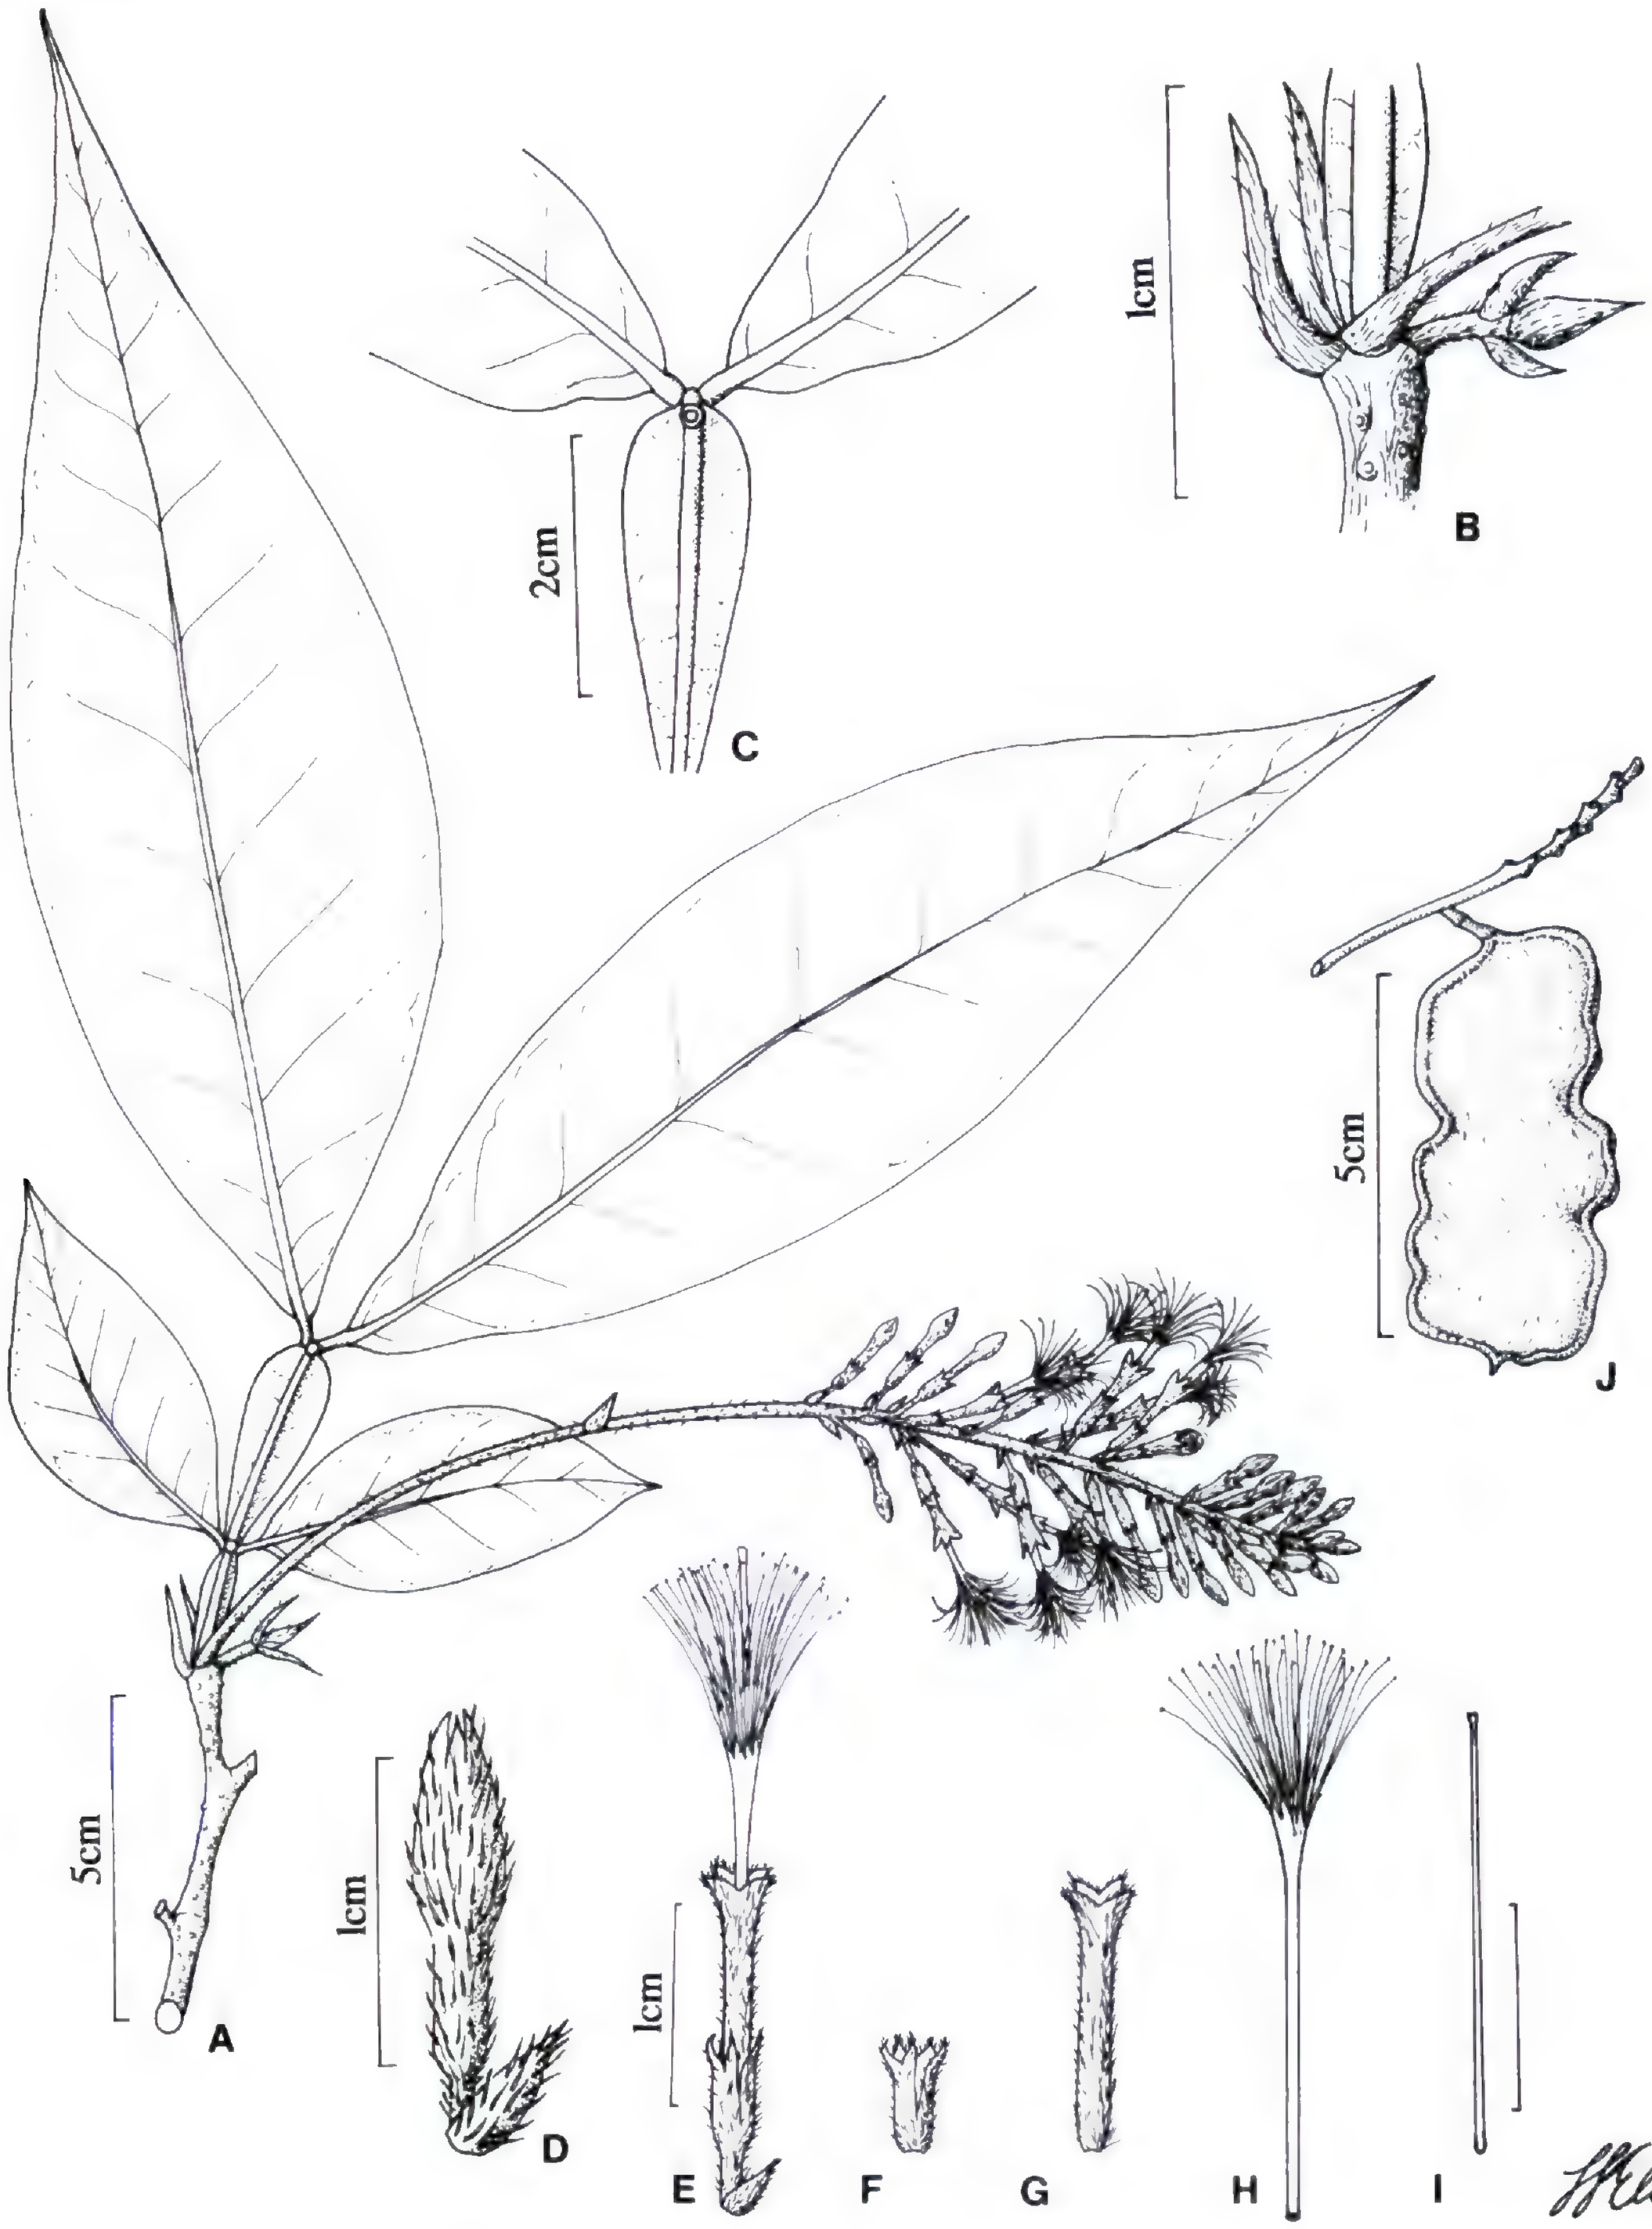

FIGURA 5. *Inga lacustris* M. Sousa.—A. Rama con inflorescencia. -B. Detalle de estípulas.—C. Glándula interfoliolar.—D. Botón floral.—E. Flor.—F. Cáliz.—G. Corola.—H. Tubo estaminal.—I. Gineceo. *F. Menéndez L. 144.*—J. Fruto. (Tomado de *Sousa 13021.*)

A pesar de estar muy cerca de *I. punctata* Willd., no creo que se pueda sinonimizar con ella, como sugirió pero no hizo León (1966). *Inga latipes* difiere de *I. punctata* tanto en caracteres vegetativos (glándulas interfoliolares muy promimentes) y florales (flores pediceladas y el cáliz casi glabro) como en el fruto (mucho más grande). Por su cáliz casi glabro y su fruto de grandes dimensiones se parece más a *I. leiocalycina* Benth., pero *I. latipes* tiene hojas de menor tamaño, 6-folioladas, las glán-

dulas interfoliolares más grandes, además de las flores pediceladas.

*Material representativo.* COSTA RICA. CARTAGO: *Lent 2111* (F).

**Inga laurina** (Sw.) Willd., Sp. Pl. ed. 4, 4: 1018. 1806. Basiónimo: *Mimosa laurina* Sw., Prodr. 85. 1788. TIPO: St. Kitts: *Masson s.n.* (holotipo, BM, no localizado).

*Inga fagifolia* (L.) Willd. ex Benth., Trans. Linn. Soc. London 30: 607. 1875. Basiónimo: *Mimosa fagifolia* L., Sp. Pl. 516. 1753, non *Inga fagifolia* Don, Gen. Hist. 2: 391. 1832. [= *I. ruiziana* Don].

A pesar de que el basiónimo más antiguo de esta especie es el de Linneo no se le puede emplear como lo hizo León (1966), ya que Willdenow (véase descripción de *Inga semialata*) no formalizó el cambio a *Inga*, siendo hasta Bentham (1875) que lo hizo, pero antes G. Don (1832) lo empleó para otro taxon.

Sobre si el material de las Antillas difiere significativamente de él del continente americano, León (1966) da una buena discusión del problema y concuerdo con él, ya que en términos generales la diferencia se reduce a un sólo carácter: el tubo estaminal exerto o inserto.

**Inga leiocalycina** Benth., London J. Bot. 4: 598. 1845. TIPO: Guyana: *Schomburgk 829* (lectotipo, designado por Poncy (1985), P: isolectotipos, BM, F, G, K).

*Inga yunckeri* Standley, Field Mus. Nat. Hist., Bot. Ser. 9: 296. 1940. TIPO: Honduras: *Yuncker et al. 8805* (holotipo, F; isotipos, BM, G, K, MO, US).

Especie hasta hace poco sólo conocida de Brasil y las Guayanas (Poncy, 1985), pero en realidad se extiende hasta el sur de México. En Mesoamérica ya tenía un nombre: *Inga yunckeri* Standley como endémica de Honduras (León, 1966). *Inga leiocalycina* es en general una especie bastante homogénea, la cual debido a su similitud con *I. punctata* Willd. (véase ésta) se le ha identificado como tal (véanse también comentarios de Poncy, 1985).

Poncy (1985) sinonimiza bajo esta especie a *Inga strigillosa* Spruce ex Benth. (Trans. Linn. Soc. London 30: 612. 1875) e *I. dumosa* Benth. (loc. cit., 30: 612. 1875), lo cual no me parece justificable, ya que estas dos presentan los cálices pelosos que se parecen más a *I. punctata* Willd.

*Inga leiocalycina* es un elemento amazónico de selvas altas perennifolias que se extiende en las áreas bajas cálido húmedas de Norte y Sudamérica.

**Inga leonis** Zamora, Brenesia 33: 111. 1991. TIPO: Costa Rica: *Lent 3541* (holotipo, CR; isotipos, F, MEXU).

Esta especie está en el complejo de *Inga villosissima* Benth., *I. dasycarpa* M. Sousa, *I. te-*

*nella* M. Sousa, *I. chiapensis* Miranda ex M. Sousa, e *I. sierrae* Britton et Killip. Es más cercana a *I. chiapensis*, de la cual difiere en sus hojas, en sus frutos, así como el color de la corola.

*Material representativo.* COSTA RICA. ALAJUELA: *Lent 3541* (MEXU). HEREDIA: *Utley & Utley 2825* (F). LIMON: *Hammel et al. 17061* (MO). PANAMA. BOCAS DEL TORO: *McPherson 9855* (MO). COCLE: *Sytsma 1883* (NY). CHIRIQUI: *McPherson 12830* (MO).

**Inga litoralis** Zamora, Brenesia 33: 115. 1991. TIPO: Costa Rica: *Burger et al. 10572* (holotipo, CR; isotipos, BM, F, MEXU, NY).

Esta especie, sólo conocida del tipo, está cercanamente emparentada a *Inga tenella* M. Sousa, de la cual difiere por la pelosidad del cáliz, el pedúnculo floral, y la forma de las brácteas, además de que desconocemos su fruto.

*Material representativo.* COSTA RICA. PUNTARENAS: *Burger et al. 10572* (MEXU).

**Inga longispica** Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 18: 497. 1937. TIPO: Costa Rica: *Brenes 6371* (holotipo, F).

Especie poco conocida que hasta hace poco se colectó en Panamá y Colombia.

*Material representativo.* COSTA RICA. ALAJUELA: *Skutch 3705* (A). PUNTARENAS: *Koptur & Guindon SK-217* (MO). SAN JOSE: *Utley 5752* (MEXU). PANAMA. BOCAS DEL TORO: *McPherson 8408* (MO). COLOMBIA. VALLE DE CAUCA: *Monsalve B. 1730* (MEXU).

**Inga micheliana** Harms, Repert. Spec. Nov. Regni Veg. 13: 525. 1915. TIPO: Guatemala: *Heyde & Lux 3319* (isotipos, GH, K, MO, US).

Esta especie tiene como parientes cercanos por un lado a *Inga flexuosa* Schldl. y por otro a *I. hintonii* Sandw. (véanse discusiones de éstas).

En *Inga micheliana* el raquis foliar es más frecuentemente terete, pero en ocasiones se presenta alado, como lo es en el tipo.

*Material representativo.* MEXICO. CHIAPAS: *Miranda G. 7116* (MEXU). GUATEMALA. CHIQUIMULA: *Hughes 1461* (MEXU). QUICHE: *Heyde & Lux 3319* (GH).

**Inga mortoniana** Léon, Ann. Missouri Bot. Gard. 53: 351, fig. 6. 1966. TIPO: Costa Rica: *A. Smith 1230* (holotipo, NY; isotipos, F, US).

Esta especie está muy relacionada a *Inga acrocephala* Steudel, particularmente con la variante de inflorescencias capituliformes, pero con flores más grandes: cáliz 5–7 mm de largo en *I. mortoniana* (versus 1.5–3 mm en *I. acrocephala*) y corola (7–)9–12 mm de largo (versus 6–9 mm), la corola más grande de menos de 2 veces el largo del cáliz (versus. la corola de 2.2–3.5 veces el largo que el cáliz); *I. mortoniana* tiende también a tener un cáliz glabrescente a esparcidamente canescente seríceo. Ambas especies característicamente tienen campos glandulares en los lóbulos del cáliz, que en cálices maduros adquieren un aspecto calloso. En fruto ambas especies, hasta donde puedo ver, son indiferenciables, y de hecho, *Inga mortoniana* podría pasar a una categoría infraespecífica de *I. acrocephala*, pero debido a las antedichas diferencias florales creo prudente mantenerlas aparte. En general *Inga mortoniana* habita en un piso altitudinal mayor que *I. acrocephala*.

El material de Venezuela (*Steyermark 91992*) tiene la corola más pequeña pero el cáliz grande y glabrescente.

*Material representativo.* COSTA RICA. ALAJUELA: *Skutch 3780* (MO). PUNTARENAS: *Hartshorn 1790* (NY). VENEZUELA. DISTRITO FEDERAL: *Steyermark 91992* (NY).

**Inga mucuna** Walp. et Duchass., Ann. Bot. Syst. 2: 459. 1852. TIPO: Panamá: *Duchassaing 81* (isotipo, GH).

Coincidimos con León (1966) en que *Inga mucuna* está estrechamente emparentada a *I. fastuosa* (Jacq.) Willd., pero a pesar de las nuevas colectas hechas posteriormente al trabajo de León (1966), estos taxa, aún se sostienen aparte. Por otro lado *Inga vera* Griseb. ex Benth., que León (1966) apuntó como especie endémica de Trinidad relacionada con *I. mucuna*, se puede considerar sinónimo de *I. fastuosa*. Así tenemos *I. fastuosa* de Trinidad, Venezuela, y las Guayanas e *I. mucuna* de Panamá y Colombia.

*Material representativo.* PANAMA. COLON: *Nee 9101* (MO). DARIEN: *Kennedy 2899* (MO). PANAMA: *Duchassaing 81* (GH). SAN BLAS: *Dwyer 6847* (MO). ZONA DEL CANAL: *Croat 12234* (MO), COLOMBIA. ANTIOQUIA: *Brand & Cogollo 214* (MO). CHOCO: *Juncosa 2508* (MO).

**Inga multijuga** Benth., Trans. Linn. Soc. London 30: 615. 1875. TIPO: Panamá: *Sutton Hayes 645* (lectotipo, designado aquí, K, el colector y colecta lo dió Pittier en 1929, pero no el herbario; isolectotipos, BM, BR, G, P).

Bajo este nombre se ha aglutinado desde la descripción original, una amplia variación que el mismo Bentham (1875) reconoció; posteriormente Pit-

tier (1916) segregó *Inga aestuariorum* Pittier, la cual León (1966) volvió a unir pero que aquí considero aparte (véase discusión de *I. aestuariorum*). También se ha determinado bajo *I. multijuga*, material recientemente colectado que al estudiarlo lo estoy describiendo como *I. cuspidata* M. Sousa (véase ésta).

*Material representativo.* COSTA RICA. LIMON: *Robles 1889* (MO). PUNTARENAS: *Khan et al. 501* (BM). PANAMA. COLON: *Holdridge 6512* (MO). DARIEN: *Garwood et al. 2048A* (BM). SAN BLAS: *Lewis et al. 194* (MO). ZONA DEL CANAL: *Croat 5403* (MO). VENEZUELA. TACHIRA: *Liesner et al. 9621* (MO).

**Inga oerstediana** Benth., Bot. Herald 117. 1853. TIPO: Panamá: *Seemann 1688* (lectotipo, designado aquí, BM, el colector lo dió Pittier en 1929, pero no el herbario ni la colecta).

*Inga endlicheri* (Kuntze) J. F. Macbr., Field Mus. Nat. Hist., Bot. Ser. 13: 23. 1943. Basiónimo: *I. fasciculata* Poeppig, Nov. Gen. Sp. Pl. 3: 79. 1845, non Willd. 1806. TIPO: Perú: *Poeppig 1340* (holotipo, NY).

*Inga minutula* (Schery) T. S. Elias, Phytologia 14: 211. 1967. Basiónimo: *I. edulis* C. Martius var. *minutula* Schery, Ann. Missouri Bot. Gard. 37: 209, fig. 81. 1950. TIPO: Panamá: *Allen 968* (holotipo, MO; isotipos, F, US).

Para demás sinónimos véase León (1966).

*Inga oerstediana* es una especie muy variable, fundamentalmente de las montañas mesoamericanas, donde frecuentemente es empleada como sombra de café. Sin embargo existen poblaciones de baja altitud en las que en ocasiones varia la pelosidad de sus flores hacia tonos cinéreos en vez de ferrugíneos. Esta variación ha sido elevada a especie (*I. minutula* (Schery) T. S. Elias), lo que no parece justificable mantener; podría considerarse como variedad, pero bajo *I. oerstediana* en vez de *I. edulis* C. Martius. Este complejo, al noreste montañoso de su distribución, adquiere una bráctea de grandes proporciones y así tenemos *I. latibracteata* Harms, especie que mantenemos por la combinación de caracteres que presenta (véase discusión de *I. latibracteata*). En Sudamérica *I. oerstediana* se parece mucho, particularmente en sus flores y frutos, a *I. scabriuscula* Benth. de las Guayanas, el Territorio Delta Amacuro de Venezuela, y la Amazonía de Brasil, pero difiere por las hojas (la forma de los folíolos, nervaduras, y pelosidad). A su vez *I. scabriuscula* es similar a *I. edulis* (véase discusión bajo *I. edulis*).

Las especies de este grupo de *Inga* de la sección *Inga* con glándulas interfoliolares prominentes forman una serie interconectada teniendo en un extremo *I. edulis* y en otro *I. latibracteata*, pero creo que deben mantenerse separadas para su mejor entendimiento.

**Inga paterno** Harms, Repert. Spec. Nov. Regni Veg. 13: 419. 1914. TIPO: Guatemala. Santa Rosa: Barberena, 1,000 m, July 1893, *Heyde & Lux 3280* (lectotipo, redesignado aquí, US; isolectotipos, G, GH).

*Inga radians* Pittier, Contr. U.S. Natl. Herb. 18: 178. 1916. TIPO: México. Chiapas: *Cook 805* (holotipo, US).

Harms (1914) al describir a *Inga paterno* no designó holotipo y la basó en varias colectas, sintipos; de ellos León (1966) escogió como tipo a *Preuss 1387*, ejemplar que ya para esas fechas

había sido destruido en B, y en vista que no se han encontrado duplicados en otros herbarios, considero la lectotipificación de León fue inapropiada y designo aquí el lectotipo en base a un isosintipo existente, en vista que los otros sintipos de B también fueron destruidos.

Especie muy afín a *Inga cinnamomea* Spruce ex Benth. de la Amazonia, pero lo suficientemente diferenciada para considerarla en una sola entidad con *I. cinnamomea*.

Se cultiva ampliamente en México y Centroamérica por lo apetecido de la pulpa de su fruta, la cual es muy popular desde épocas precolombinas y que se vende ampliamente en mercados muy distantes a su área de cultivo, también se usa grandemente como sombra de café y cacao. Así sabemos que se ha introducido en la Península de Yucatán, y también en Nicaragua donde se le conoce como "guava extranjera," y muy probablemente en Costa Rica.

**Inga pauciflora** Duchass. et Walp., Linnaea 23: 746. 1850. TIPO: Panamá: *Duchassaing s.n.* (holotipo, B; isotipo, GH).

*Inga pauciflora* Duchass. et Walp., endémica de Panamá, está muy estrechamente relacionada a *I. meissneriana* Miq. de las Guayanas y noreste de Brasil; en fruto no es posible diferenciarlas y en flor son similares, excepto que la flor de *I. pauciflora* es totalmente sésil mientras que en *I. meissneriana* las flores proximales muestran pedicelos. Afortunadamente *I. meissneriana* fue publicada un año después que *I. pauciflora*, por lo que dejamos pendiente la decisión de unirlas.

*Material representativo.* PANAMA. CHIRIQUI: *Croat 26800* (MO). DARIEN: *Stern et al. 968* (MO). VERAGUAS: *Allen 4417* (MO). ZONA DEL CANAL: *Croat 8756* (MO).

**Inga pavoniana** Don, Gen. Hist. 2: 388. 1832. TIPO: Perú: *Ruíz & Pavón s.n.* (holotipo, OXF herb Lamb.).

*Inga lindeniana* Benth., London J. Bot. 4: 608. 1845. TIPO: México. Tabasco: *Linden 726* (holotipo, K; isotipos, G (2 ej.)).

*Inga donaeana* J. F. Macbr., Field Mus. Nat. Hist., Bot. Ser. 13: 22. 1943. TIPO: Perú. San Martín: Tarapoto, *Spruce 4503* (holotipo, K; isotipos, NY, OXF).

Para demás sinónimos véase León (1966) bajo *Inga sapindoides* Willd.

Usamos el nombre de G. Don en vez de *Inga sapindoides* Willd., que fue él que escogió León (1966), ya que *I. sapindoides* se basa en un ejemplar estéril y fragmentado de Venezuela (*Bredemeyer 4*, microficha IDC. 7440. 19024 MO ex B-W) que no muestra ni la inserción de la hoja con el tallo ni las estípulas. Además, en la descripción de Willdenow (Sp. Pl. ed. 4, 4: 1012. 1806), la corola es blanca y glabra, mientras que, en la especie generalmente referida como *I. sapindoides*, la corola es verde pálido y canescente vellosa, siendo blancos los estambre. Bentham (1875) ya había discutido este problema agregando que Willdenow nunca vio las flores, sino que Bredemeyer le dio el dato. Por lo anterior empleamos a *I. pavoniana* Don, basada en un ejemplar en flor del herb. Lambert, colectado por Ruíz y Pavón, del cual no hay duda de su identidad, y dejamos a *I. sapindoides* como un nombre de aplicación dudosa.

**Inga polita** Killip, Ann. New York Acad. Sci. 35: 192. 1936. TIPO: Colombia: *Lehmann 3824* (holotipo, K). Figura 6.

Esta especie muestra claras relaciones con el complejo de *Inga umbellifera*, de la cual difiere por los pedúnculos cortos, por las brácteas florales hasta 9 mm de largo, las cuales cubren totalmente a los botones florales, y por las hojas fundamentalmente 2-folioladas.

*Inga polita* varía en sus extremos de distribución; así en Costa Rica, en el Golfo Dulce, sus hojas en la misma rama van de 2–4-folioladas mientras que, en Colombia, los folíolos son de mayor tamaño que el material mesoamericano.

*Material representativo.* COSTA RICA. PUNTARENAS: *Jiménez & Poveda 446* (MO). PANAMA. COCLE: *Davidse & Hamilton 23683* (MO). PANAMA: *McPherson 11895* (MO). SAN BLAS: *de Nevers 4651* (MO). **Inga portobellensis** Beurling, Kongl. Vetensk. Acad. Handl. 1854. 122. 1856. TIPO: Panamá: *Billberg s.n.* (holotipo, S).

Especie endémica al área más húmeda de Panamá, en los alrededores de Portobelo en la provincia de Colón y norte de la Zona del Canal.

Pittier (1916) interpretó a esta especie con material de Golfo Dulce, en Costa Rica; Schery (1950) y León (1966) la han aceptado, aunque con dudas, ya que la descripción de Beurling (1856) no concuerda bien con el material de Costa Rica. Las diferencias entre ambas especies no sólo radican en el tamaño de la flor, sino también en la forma del cáliz y pelosidad de la corola (véase *I. bella* M. Sousa).

*Material representativo.* PANAMA. COLON: *Knapp & Schmalzel 3591* (MO). ZONA DEL CANAL: *Gentry 3565* (MO).

**Inga pseudoinvolucrata** M. Sousa, sp. nov. TIPO: Panamá. Panamá: Gorgas Memorial Labs yellow fever research camp, "Campamento Quatro," 5–10 km NE of Altos de Pacora, ca. 600 m, on ridge top, 21–24 Nov. 1974, *S. Mori & J. Kallunki 3406* (holotipo, MO).

Arbores e mediano procerae; rami juveniles ferrugineohirsuti. Folia 3–5-jugata; stipulae 4–5 mm longae, triangulares; foliola lanceolato-elliptica, ex ovata tenuiter obovata, apice acuminata; rhachis foliaris alata, glandulis ex subsessilibus longe stipitatis, claviformibus. Inflorescentiae capituliformes, solitariae; bracteae oblanceolatae, florum peripheric orum interdum in pseudoinvolucrum coaduna-

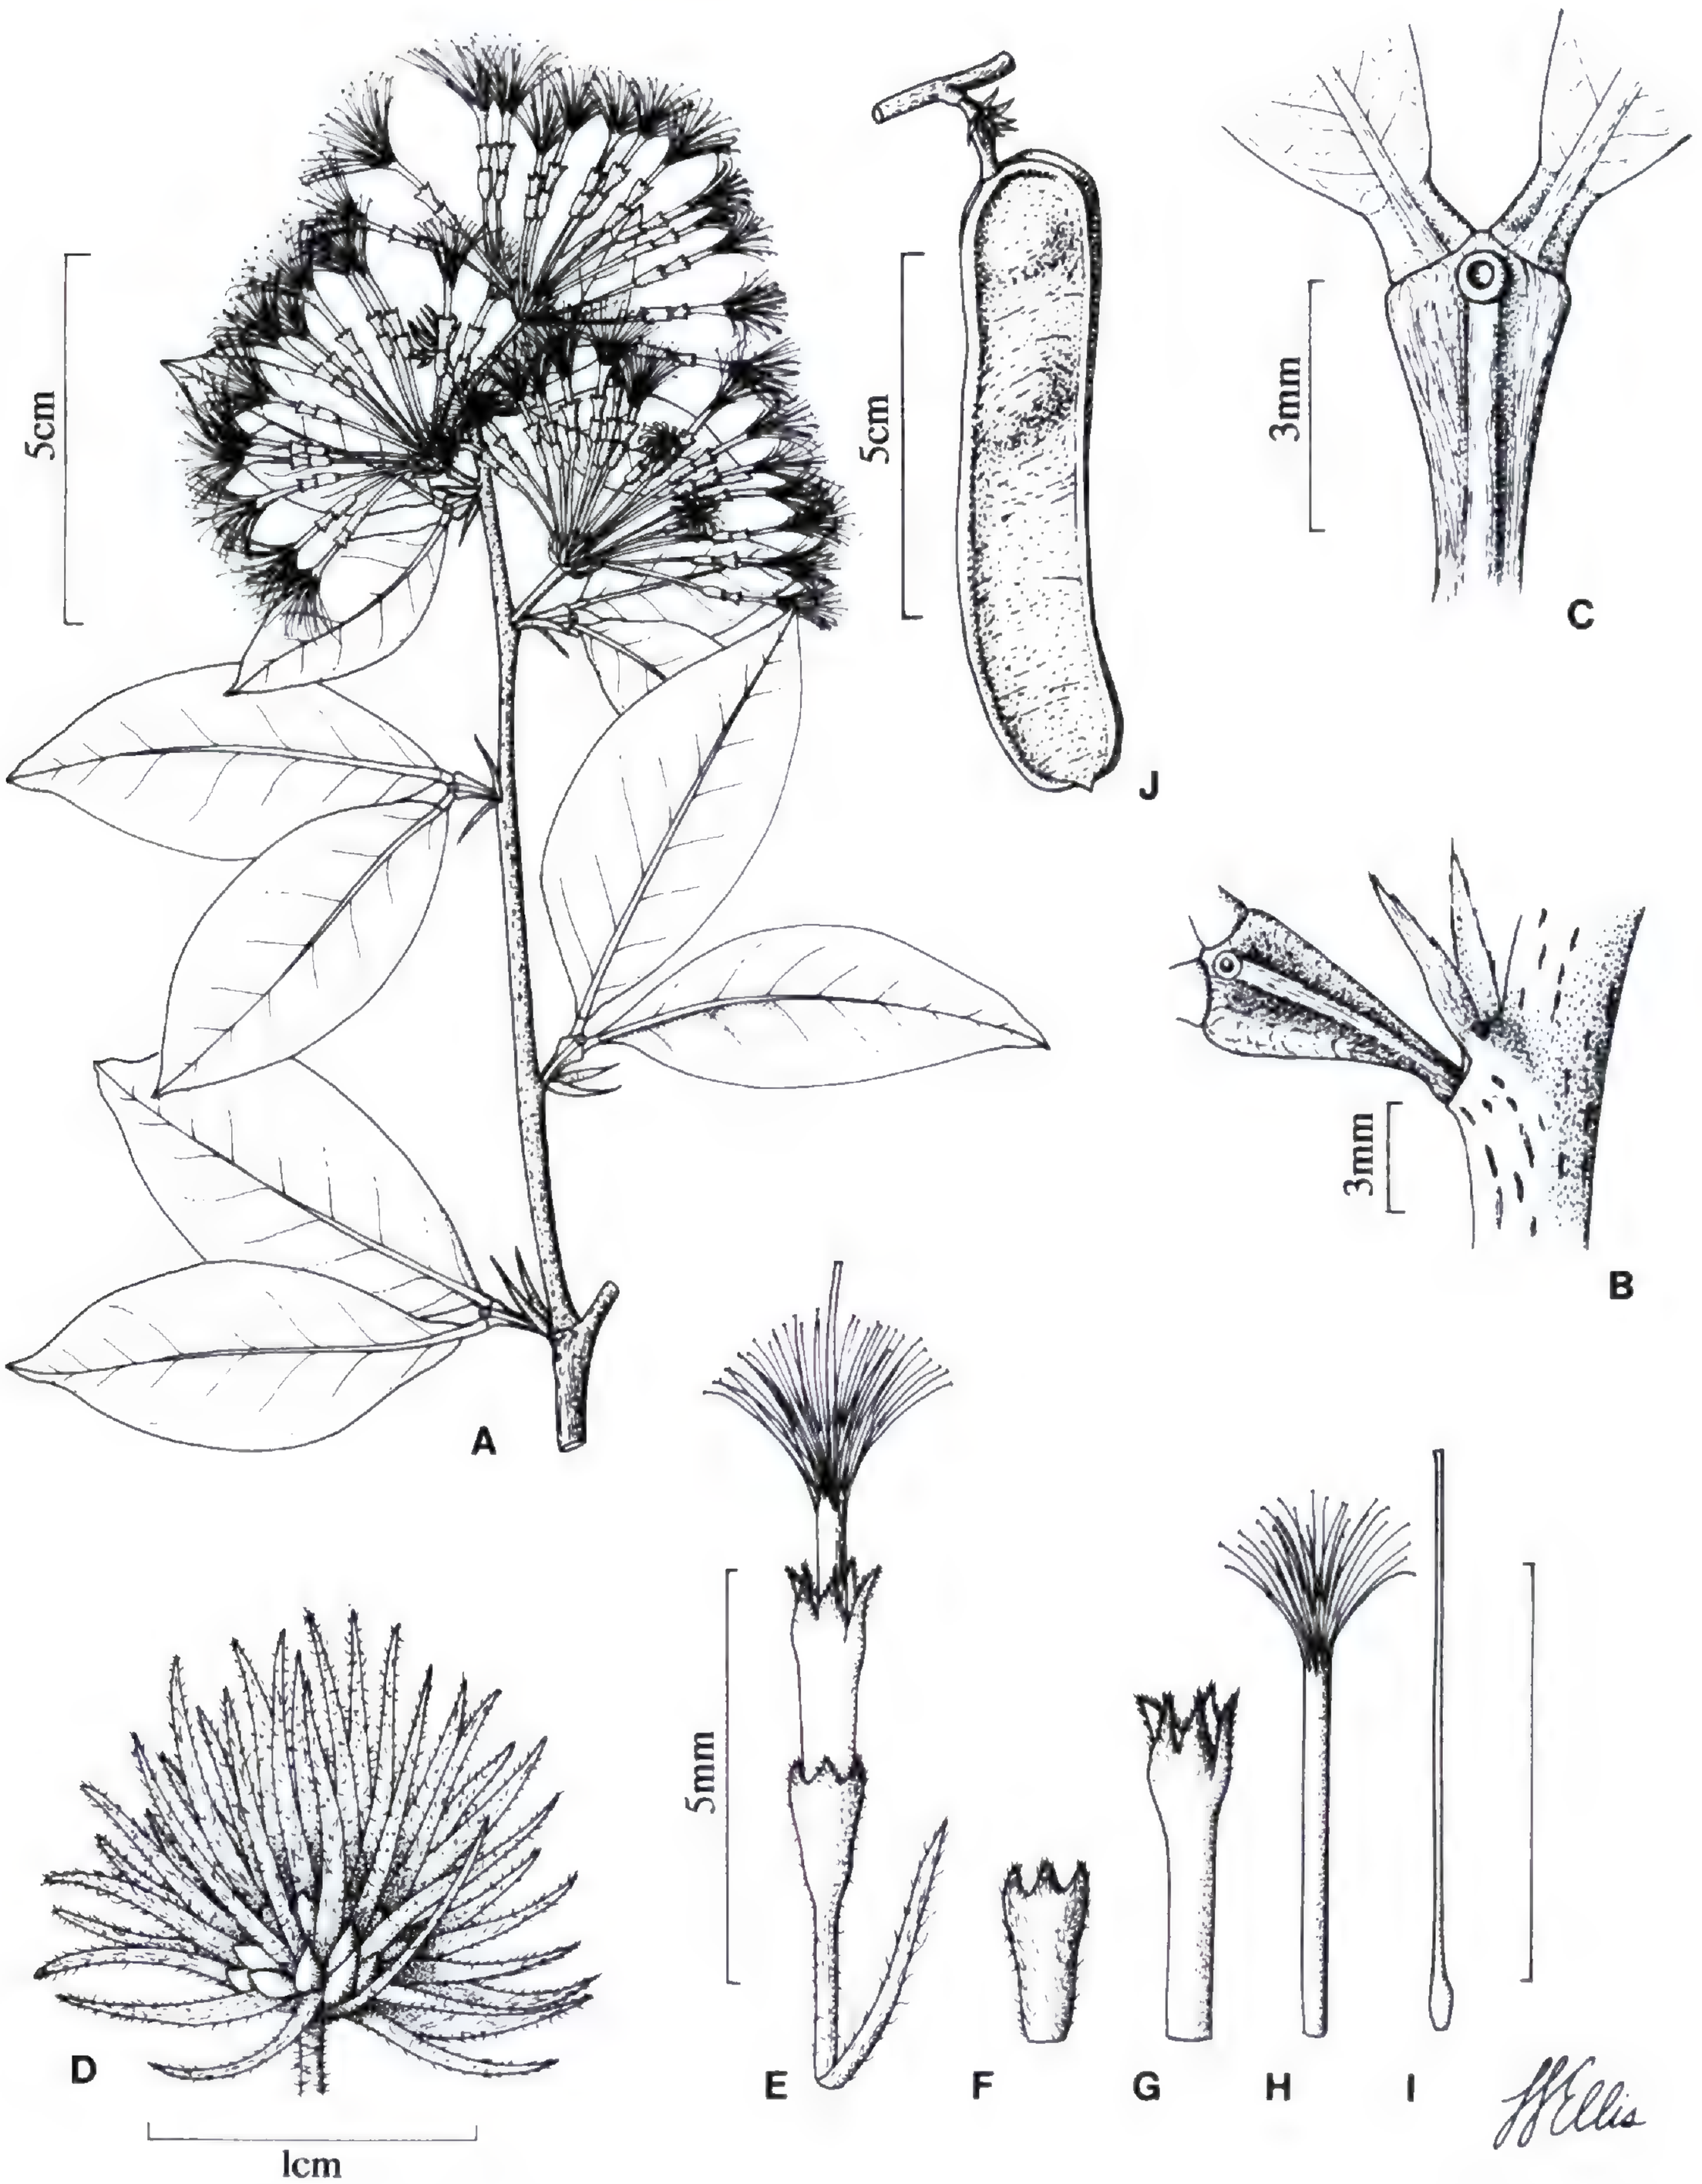

FIGURA 6. *Inga polita* Killip.—A. Rama con inflorescencia.—B. Detalle de estípulas.—C. Glándula interfoliolar. (Tomado de *McPherson 11915.*)—D. Inflorescencia en botón. (Tomado de *G. de Nevers et al. 7062.*)—E. Flor.—F. Cáliz.—G. Corola.—H. Tubo estaminal.—I. Gineceo.—J. Legumbre. (Tomado de *G. Mori et al. 6360.*)

tae; calyx tubulosus paullo inflatus, striatus, glaber; corolla tubuloso-infundibuliformis, fere glabra; tubus stamineus insertus. Legumen 18–21 cm longum, 1.8–2 cm latum, lineari-oblongum, complanatum, hirsutum, valvari-nervatum.

Arboles 5–7(–18) m; ramas teretes, tomentosas a hirsútulas con tricomas pardo-amarillentos, cuando jóvenes, posteriormente glabrescentes. Hojas 6–10-folioladas; estípulas 2–7 mm, liguladas, estria-

das, persistentes; pecíolo 0.5–1.2 cm, marginado a angostamente alado; folíolos discoloros, cartáceos, la base en ocasiones asimétrica, cuneada, rara vez obtusa, el ápice acuminado-mucronato, el haz opaco, glabro excepto seríceo a tomentoso con tricomas pardo-amarillentos sobre las nervaduras y los márgenes, el envés pálido, esparcidamente tomentoso a hirsútulo, la nervadura primaria eglandular; par basal de folíolos 2.5–3.5 × 1.5–2.2 cm, lanceolados a ovados, el par apical 4.5–7 × 2.2–3.5 cm, lanceolados elípticos en ocasiones obovados; raquis foliar 4–8 cm, alado, el ala 3–5 mm de ancho, angostamente elíptica; glándulas interfoliolares subsésiles a largamente estipitadas, clavuliformes, el cuerpo glandular 0.3–1 × 0.3–1 mm; apéndice 4–8 mm, setiforme, pronto caduco. Inflorescencia capituliforme, solitaria; pedúnculo 2–3 cm, aplanado, sulcado, hirsútulo; raquis floral muy reducido, las brácteas algo heteromorfas, las de la periferia 3 mm, frecuentemente uniéndose y formando un seudoinvolucro, cordatas a oblanceoladas, las centrales 3–4 mm, lanceoladas a oblanceoladas, persistentes. Flores sésiles o casi sésiles; botones florales con el cáliz cubriendo, se desconocen; cáliz 5–7 mm, tubular, algo inflado, estriado, glabro, sin escotaduras, los lóbulos 1–1.5 mm triangulares; corola 16–18 mm, tubular, blanca, glabra excepto pilosa con tricomas pardo-amarillentos sobre los lóbulos; tubo estaminal inserto a cortamente exerto, blanco. Legumbre 17.5–21 × 1.8–2 × 0.3 cm, más o menos aplanada a ligeramente túrgida, derecha, linear, brevistipitada en la base, rostrada en el ápice, híspida con tricomas pardo-amarillentos, las valvas inconspicuamente nervadas transversalmente, las suturas marginadas, los márgenes de las suturas aplanados.

*Distribución y hábitat.* Sólo conocida de dos áreas en los alrededores de El Llano en la Prov. Panamá, Panamá, y en el Bajo Calima en Valle, Colombia. En selvas húmedas asociada a *Catoblastus* y *Hedyosmum scaberrimum*. En altitudes entre los 100 a 600 m. Florece de finales de septiembre a noviembre (con flores marchitas en marzo) y fructifica a partir de finales de marzo.

*Paratipos.* PANAMA. PANAMÁ: along El Llano–Cartí Tupile road, 12 mi. above Pan-American Hwy., *R. L. Liesner 1177* (MO, TEX, US, WIS); EL Llano–Cartí road, km 19.1, 9°19′N, 78°15′W, *G. de Nevers & H. Herrera 5134* (MO). COLOMBIA. VALLE: Bajo Calima, Concesión Pulpapel/Buenaventura, 3°55′N, 77°W, *M. Monsalve B. 1827* (MEXU, MO).

Especie relacionada al grupo de *Ingae* con flores glabrescentes en las cuales el cáliz es amplio (inflado) y no se aplica a la corola como en *Inga bella*, *I. cordistipula*, *I. portobellensis*, e *I. spiralis*; además, es muy interesante por la combinación de caracteres tales como, glándulas interfoliolares variando de subsésiles a largamente estipitadas y clavuliformes con las inflorescencias capituliformes, combinación que sólo conocemos en *Inga saffordiana* Pittier, de la cual difiere grandemente. Un carácter muy distintivo de la nueva especie es su tendencia a formar un involucro incompleto en la periferia de capítulo y de cual toma su nombre específico.

**Inga punctata** Willd., Sp. Pl. ed. 4, 4: 1016. 1806. TIPO: Venezuela: *Bredemeyer 7* (holotipo, B-W, foto MO).

*Inga leptoloba* Schldl., Linnaea 12: 560. 1838. TIPO: México. Veracruz: *Schiede s.n.* (isotipos, BM, F, G, GH).

Para demás sinónimos véanse Schery (1950) y León (1966).

Con *Inga punctata* Willdenow creó un nuevo nombre para *Mimosa fagifolia* sensu Jacq. (Select. Stirp. Amer. Hist. 264, t. 164. 1763) non L. (Sp. Pl. 516. 1753); sin embargo, Jacquin claramente, en su publicación, se refiere a la *M. fagifolia* de Linneo (que corresponde a *Inga laurina* (Sw.) Willd.; véase ésta), además de que todos los demás elementos concuerdan con ella. Por lo anterior, Willdenow interpretó la descripción y lámina de Jacquin como otra especie de la cual él tenía un ejemplar de Caracas, Venezuela, con la que basó su descripción. *Inga punctata* Willd. está basada en elementos heterogéneos, de los cuales, afortunadamente los subsecuentes autores a partir de DeCandolle (Prodr. 2: 435. 1825) han interpretado la especie con el material de Venezuela y no con él de La Martinica. Así *Mimosa fagifolia* en la obra de Jacquin no debe ser interpretada como un homónimo tardío, y por tanto no se trata de un nombre ilegítimo.

El concepto de esta especie para Mesoamérica, fue muy bien interpretado, por Schery (1950) y León (1966); sin embargo, debido a sus similitudes, pero discernibles diferencias con *Inga latipes* Pittier (véase ésta y discusión de León, 1966) e *I. leiocalycina* Benth. (véase ésta y discusión de Poncy, 1985) se les ha querido incluir como extremos de variación de *I. punctata*. En Sudamérica el problema es más complejo; así tenemos a *I. strigillosa* Spruce ex Benth., la cual Poncy (1985) sugiere que con más información debería ser sinonimizada con *I. punctata* pero, por lo pronto la coloca de sinónimo de *I. leiocalycina* Benth., tanto el tipo (*Spruce 1755*, BM, G, K (2 ej.)) como de varios ejemplares de la Amazonía (Perú. Amazonas:

*Ferreyra 5037*, MO. Bolivia. Pando: *Sperling & King 6534*, NY. Brasil (Norte). Amazonas: *Berg et al. 19714*, NY; Maranhâo: *Daly et al. D.669*, MO; Rondônia: *Prance et al. 5467*, NY). Aquí considero a *I. strigillosa* como una especie aparte, que se caracteriza por un raquis floral muy corto, paucifloro y las brácteas filiformes que sobrepasan a los botones florales, dando un aspecto de inflorescencia parecido a *Dalea*.

En cuanto a los taxa infraespecíficos descritos para *Inga punctata*, no los estamos considerando aquí. Así *I. punctata* var. *elongata* J. F. Macbr. del Ecuador y Perú (holotipo, *Killip & Smith 29406*, F), con flores cuya corola llega hasta 14 mm de largo y raquis foliar angostamente alado, debe corresponder a otra especie. Por otro lado la subespecie *chagrensis* Pittier (tipo, *W. R. Maxon 4788*; isotipo, BM) y la variedad *panamensis* Benth. (sintipos, *Sutton Hayes 357*, BM, K; *Seemann 406*, K (2 ej.)) no parecen diferentes al resto de *I. punctata*.

**Inga quaternata** Poeppig, Nov. Gen. Sp. Pl. 3: 79. 1845. TIPO: Brasil: *Poeppig 121* (holotipo, W; isotipo, F).

Para sinónimos véase León (1966).

Especie muy variable que León (1966) caracterizó muy bien y seguimos su concepto. Sólo agregamos que en su extremo norte en Veracruz, México, la inflorescencia en ocasiones pasa de capituliforme a una espiga corta corimbosa, dandole aspecto de *Inga nobilis* Willd.

**Inga riopalenquensis** A. H. Gentry, Selbyana 2: 39, pl. 12A. 1977. TIPO: Ecuador: *Dodson 5463* (holotipo, MO; isotipo, US).

Especie cercana a *Inga pezizifera* Benth., de la cual difiere fundamentalmente por el tan particular fruto leñoso con proyecciones en las valvas, la pelosidad de la corola, y el cáliz de mayor tamaño. En el material de Costa Rica, sus legumbres son más verrugosas que las de Ecuador.

Aquí se da una nueva distribución a una especie descrita recientemente como endémica del Chocó ecuatoriano (Río Palenque). Gentry (1982) tabula las relaciones fitogeográficas de Río Palenque con Mesoamérica y encuentra que el 18% de las es-

pecies tienen el patron de "América Central a Ecuador occidental (sin incluir el Amazonía)," lo que representa una alta proporción de una área que él considera natural.

**Inga rubiginosa** (Rich.) DC., Prodr. 2: 434. 1825. Basiónimo: *Mimosa rubiginosa* Rich., Actes Soc. Hist. Nat. Paris 1: 113. 1792. TIPO: Guayana Francesa: *Leblond s.n.* (holotipo, G-DEL, foto TEX).

*Inga standleyana* Pittier, Contr. U.S. Natl. Herb. 18: 204. 1916. TIPO: Panamá: *Pittier 5496* (holotipo, US; isotipo, US).

Dentro de la variabilidad de *Inga rubiginosa*, *I. standleyana* Pittier parece representar un extremo con flores más robustas y en general un poco más cortas, con distribución en Panamá a Venezuela, mientras que *I. rubiginosa* sensu stricto es de las Guayanas y norte de Brasil. Sin embargo, a diferencia de León (1966), las unimos en base a su débil diferencia, proponiendo que posteriormente podría formalizarse a nivel infraespecífico.

**Inga ruiziana** Don, Gen. Hist. 2: 391. 1832. TIPO: Perú: *Ruíz & Pavón s.n.* (lectotipo, designado aquí, OXF herb. Lamb., con hoja y flores; isolectotipos, BM, OXF).

*Inga fagifolia* Don, Gen. Hist. 2: 391. 1832. TIPO: Perú: *Ruíz & Pavón s.n.* (holotipo, OXF).

Para demás sinónimos véase Schery (1950).

León (1966: 301) cita como tipo de *Inga ruiziana* Don a *Ruíz 5*, de la cual he visto un ejemplar en el Smithsonian (US); por otro lado Macbride (1943: 40) citó como tipo una colecta de Ruíz y Pavón, sin informar sobre el herbario ni alguna colecta determinada. Sin embargo, el material que George Don vió y citó en la descripción original fue el del Herbario de H. B. Lambert que fue comprado por Fielding, ahora Herbario Fielding en la Universidad de Oxford, donde existen tres ejemplares de *I. ruiziana* colectados por Ruíz y Pavón: uno está anotado como "*Mimosa fagifolia* sp. nov. del Perú" (se trata del tipo de *I. fagifolia* Don) y los otros dos como "*Mimosa* sp. nov. del Perú." De estas dos se escogió el ejemplar con hoja y flores como lectotipo.

Especie poco variable de la Amazonía que llega hasta las selvas de la vertiente Caribe de Nicaragua.

**Inga saffordiana** Pittier, Contr. U.S. Natl. Herb. 18: 176. 1916. TIPO: Panamá: *Pittier 5676* (holotipo, US).

De esta notable especie de *Inga* lo que más ha llamado la atención de los botánicos es su inflorescencia caulinar, carácter que ahora sabemos se presenta en al menos cinco especies de *Inga*, tres de las cuales se encuentran en Mesoamérica. Sin embargo, el carácter de esta especie que me parece único, es su cáliz, el cual es casi totalmente partido en cinco lóbulos lanceolado-aleznados, que persisten en el fruto.

*Material representativo.* PANAMA. DARIEN: *Hammel et al. 16128* (MO). COLOMBIA. ANTIOQUIA: *Rentería et al. 3790* (MO). CHOCO: *Fernández 267* (US).

**Inga semialata** (Vell. Conc.) C. Martius, Flora 20(2): Beibl. 111. 1837. Basiónimo: *Mimosa semialata* Vell. Conc., Fl. Flumin. 1: t. 5. 1831. TIPO: *Velloso, Fl. Flumin. 11: t. 5. 1831.* Figura 7.

*Inga marginata* Willd., nom illeg., Sp. Pl. ed. 4, 4: 1015. 1806. TIPO: Venezuela: *Bredemeyer s.n.* (holotipo, B-W, foto, MO).

*Inga tysonii* T. S. Elias, Ann. Missouri Bot. Gard. 53: 377. 1966. TIPO: Panamá: *Tyson y Blum 3803* (holotipo, MO).

Aquí estoy usando el nombre de Martius ya que él de *Inga marginata* Willd. es superfluo, porque Willdenow no había hecho el cambio que correspondía de *Mimosa fagifolia* L. (Sp. Pl. 516. 1753) a *Inga fagifolia*, sino creó un nuevo nombre que resulta ilegítimo. La descripción de *I. marginata* Willd., y el ejemplar citado (*Bredemeyer s.n.* de Caracas, Venezuela, B-W) corresponden a otra especie diferente a la de Linneo; además se cita como sinónimo a *Mimosa bourgonii* Aublet (Hist. Pl. Guiane 2: 941, t. 358. 1775), la cual corresponde a otra tercera especie. El nombre de Willdenow ha persistido en uso debido a que Bentham (1875) lo citó como, "*Inga marginata* Willd. excl. syn.," excluyendo los "sinónimos." En la lista de sinónimos de *I. marginata* desde Bentham (1875), *I. sapida* Kunth (in Humb., Bonpl. et Kunth, Nov. Gen. Sp. 6: 286. 1823) es el binomio más antiguo a escoger; sin embargo, se trata de un nombre basado en un ejemplar estéril de difícil determinación, y la descripción del fruto es muy general ("legumina qunique-aut sex pollicaria subarcuata") para permitir su identificación a nivel de especie; además como el mismo Kunth aclaró, él no vio el fruto sino la información se la proporcionó Humboldt, así *I. sapida* queda incertae sedis.

Aquí también incluyo como sinónimo a *Inga tysonii* T. S. Elias, la cual parece no sostenerse como especie aparte debido a la gran variabilidad de *I. semialata*. Los caracteres diagnósticos usados por Elias (1966) son la inflorescencia congesta y el pedúnculo corto.

Respecto a la gran variación de esta especie es necesario apuntar que la población del Cerro Jefe, en Panamá, entre los 800 a 1,800 m de altitud ha sido identificada como *Inga fagifolia* (L.) Willd. ex Benth. [*I. laurina* (Sw.) Willd.], debido quizá a que sus raquis foliares son teretes a submarginados. Lo interesante de esta población del Cerro Jefe es que fácilmente se diferencia de las del resto de Mesoamérica: así de ellas difiere por tener estípulas más cortas, el raquis foliar terete a submarginado, las láminas foliares coriáceas, la corola más larga, esparcidamente serícea, y el fruto más ancho con las valvas verrugoso-lenticeladas; pero si se revisa el material de esta extensa especie se ve que en Sudamérica cada uno de los caracteres de la población del Cerro Jefe aparece. Así, por ejemplo, las poblaciones del Perú (*Ancuash 263*, MO) cuentan con los frutos tan o más anchos. Por estas razones parece que la llegada de *I. semialata* a Mesoamérica ocurrió al menos en dos ocasiones y que la población de Cerro Jefe es una muestra de caracteres diferentes a la de las áreas más bajas de Costa Rica y Panamá.

En el límite norte de esta especie (Chiapas y Veracruz), existen otras poblaciones que muestran el raquis foliar terete a submarginado, pero con otras combinaciones de caracteres a las de Cerro Jefe, incluyendo: folíolos de mayor tamaño, cartáceos a subcoriáceos, y un fruto grande, pero con las valvas aplanadas; este último carácter no ha sido reportado para la especie. Esta última variante aparentemente (desconocemos el fruto) está también representada en Costa Rica (Cartago, *Lent 1122*, GH; Guanacaste, *Herrera 753*, MO) y Panamá (Chiriquí, *McPherson 9886*, MO), pero es más escasa que la forma de raquis foliar alado.

La ilustración que aquí se muestra (Fig. 7) corresponde a la población del Cerro Jefe.

Para demás sinónimos véase Poncy (1985).

Esta especie ha sido identificada en Mesoamérica como *Inga heterophylla* Willd., y por ello no se había reportado para el área. Es una especie amazónica bastante variable cuyos límites aún no me están claros y por ello no estoy considerando las variedades descritas. En nuestra área los raquis foliares son teretes.

**Inga sinacae** M. Sousa et Ibarra-Manríquez, sp. nov. TIPO: México. Veracruz: Estación de Biología Tropical Los Tuxtlas, Mpio. San Andrés Tuxtla, 18°34′–36′N, 95°04′–09′O, 4 mayo 1984, *G. Ibarra, B. G. Gómez V. & S. Sinaca C. 1547* (holotipo, MEXU; isotipos, MEXU, MO). Figura 8.

Arbores medianae, ramis juvenilibus brunneo-luteo-tomentosis. Folia 2–4(–5)-jugata; stipulae 2.5–4 mm longae, ovatae; foliola chartacea; rhachis foliaris ex teres anguste alata glandulis sessilibus urceolatis. Inflorescentiae racemosae; rachis floralis 2.5–5(–8) cm longa; bracteae crassae, ex ovatae suborbiculares, deciduae. Flores sessiles; alabastra floralia calice aperto; calyx tubulosus, laevis, cinereo-tomentosus; corolla tubulosa, e canescenti-villoso lanata. Legumen usque 35 cm longum, latum, incrassatum, complanatum, oblongum, brunneo-lutescenti-hirsutum.

Arboles 6–22 m; ramas teretes, tomentosas con tricomas pardo-amarillentos. Hojas 4–8(–10)-folioladas; estípulas 2.5–4 mm, ovadas, caducas; peciólo 1.5–3.5(–7) cm, terete; folíolos discoloros, cartáceos, la base de simétrica a ligeramente asimétrica, generalmente cuneada en ocasiones obtusa, el ápice obtuso a acuminado, el haz opaco, posteriormente brillante, esparcidamente canescente seríceo después glabro, el envés opaco, esparcidamente canescente velutino, las nervaduras primaria y secundarias canescentes a tomentosas con tricomas amarillo pálido, la nervadura primaria eglandular, el par basal de folíolos 6–9 × 3–4.5 cm, generalmente elípticos, en ocasiones ovados, el par apical 11–17 × 4.5–6 cm, lanceolados a elípticos; raquis foliar 4–12 cm, tomentoso con tricomas pardo-amarillentos, terete, marginado a angostamente alado principalmente entre los pares distales de folíolos, el ala hasta 6 mm de ancho, elíptica a oblanceolada; glándulas interfoliolares sésiles, urceoladas, el cuerpo glandular 0.9–1 × 0.9–1 mm; apéndice muy reducido o ausente. Inflorescencias en racimos solitarios; pedúnculo 2–4(–8) cm, terete, aparentemente liso, tomentoso con tricomas pardo-amarillentos; raquis floral 2.5–5(–8) cm, las flores esparcidas particularmente las proximales, las brácteas homomorfas 1.5–2 mm, gruesas, ligeramente cóncavas, ovadas a suborbiculares, caducas. Flores sésiles; botones florales con el cáliz abierto, obtusos; cáliz 9–13 mm, tubular, liso, cinéreo tomentoso, sin escotaduras, los lóbulos triangulares; corola 2.3–3.2 cm, tubular, blanco-

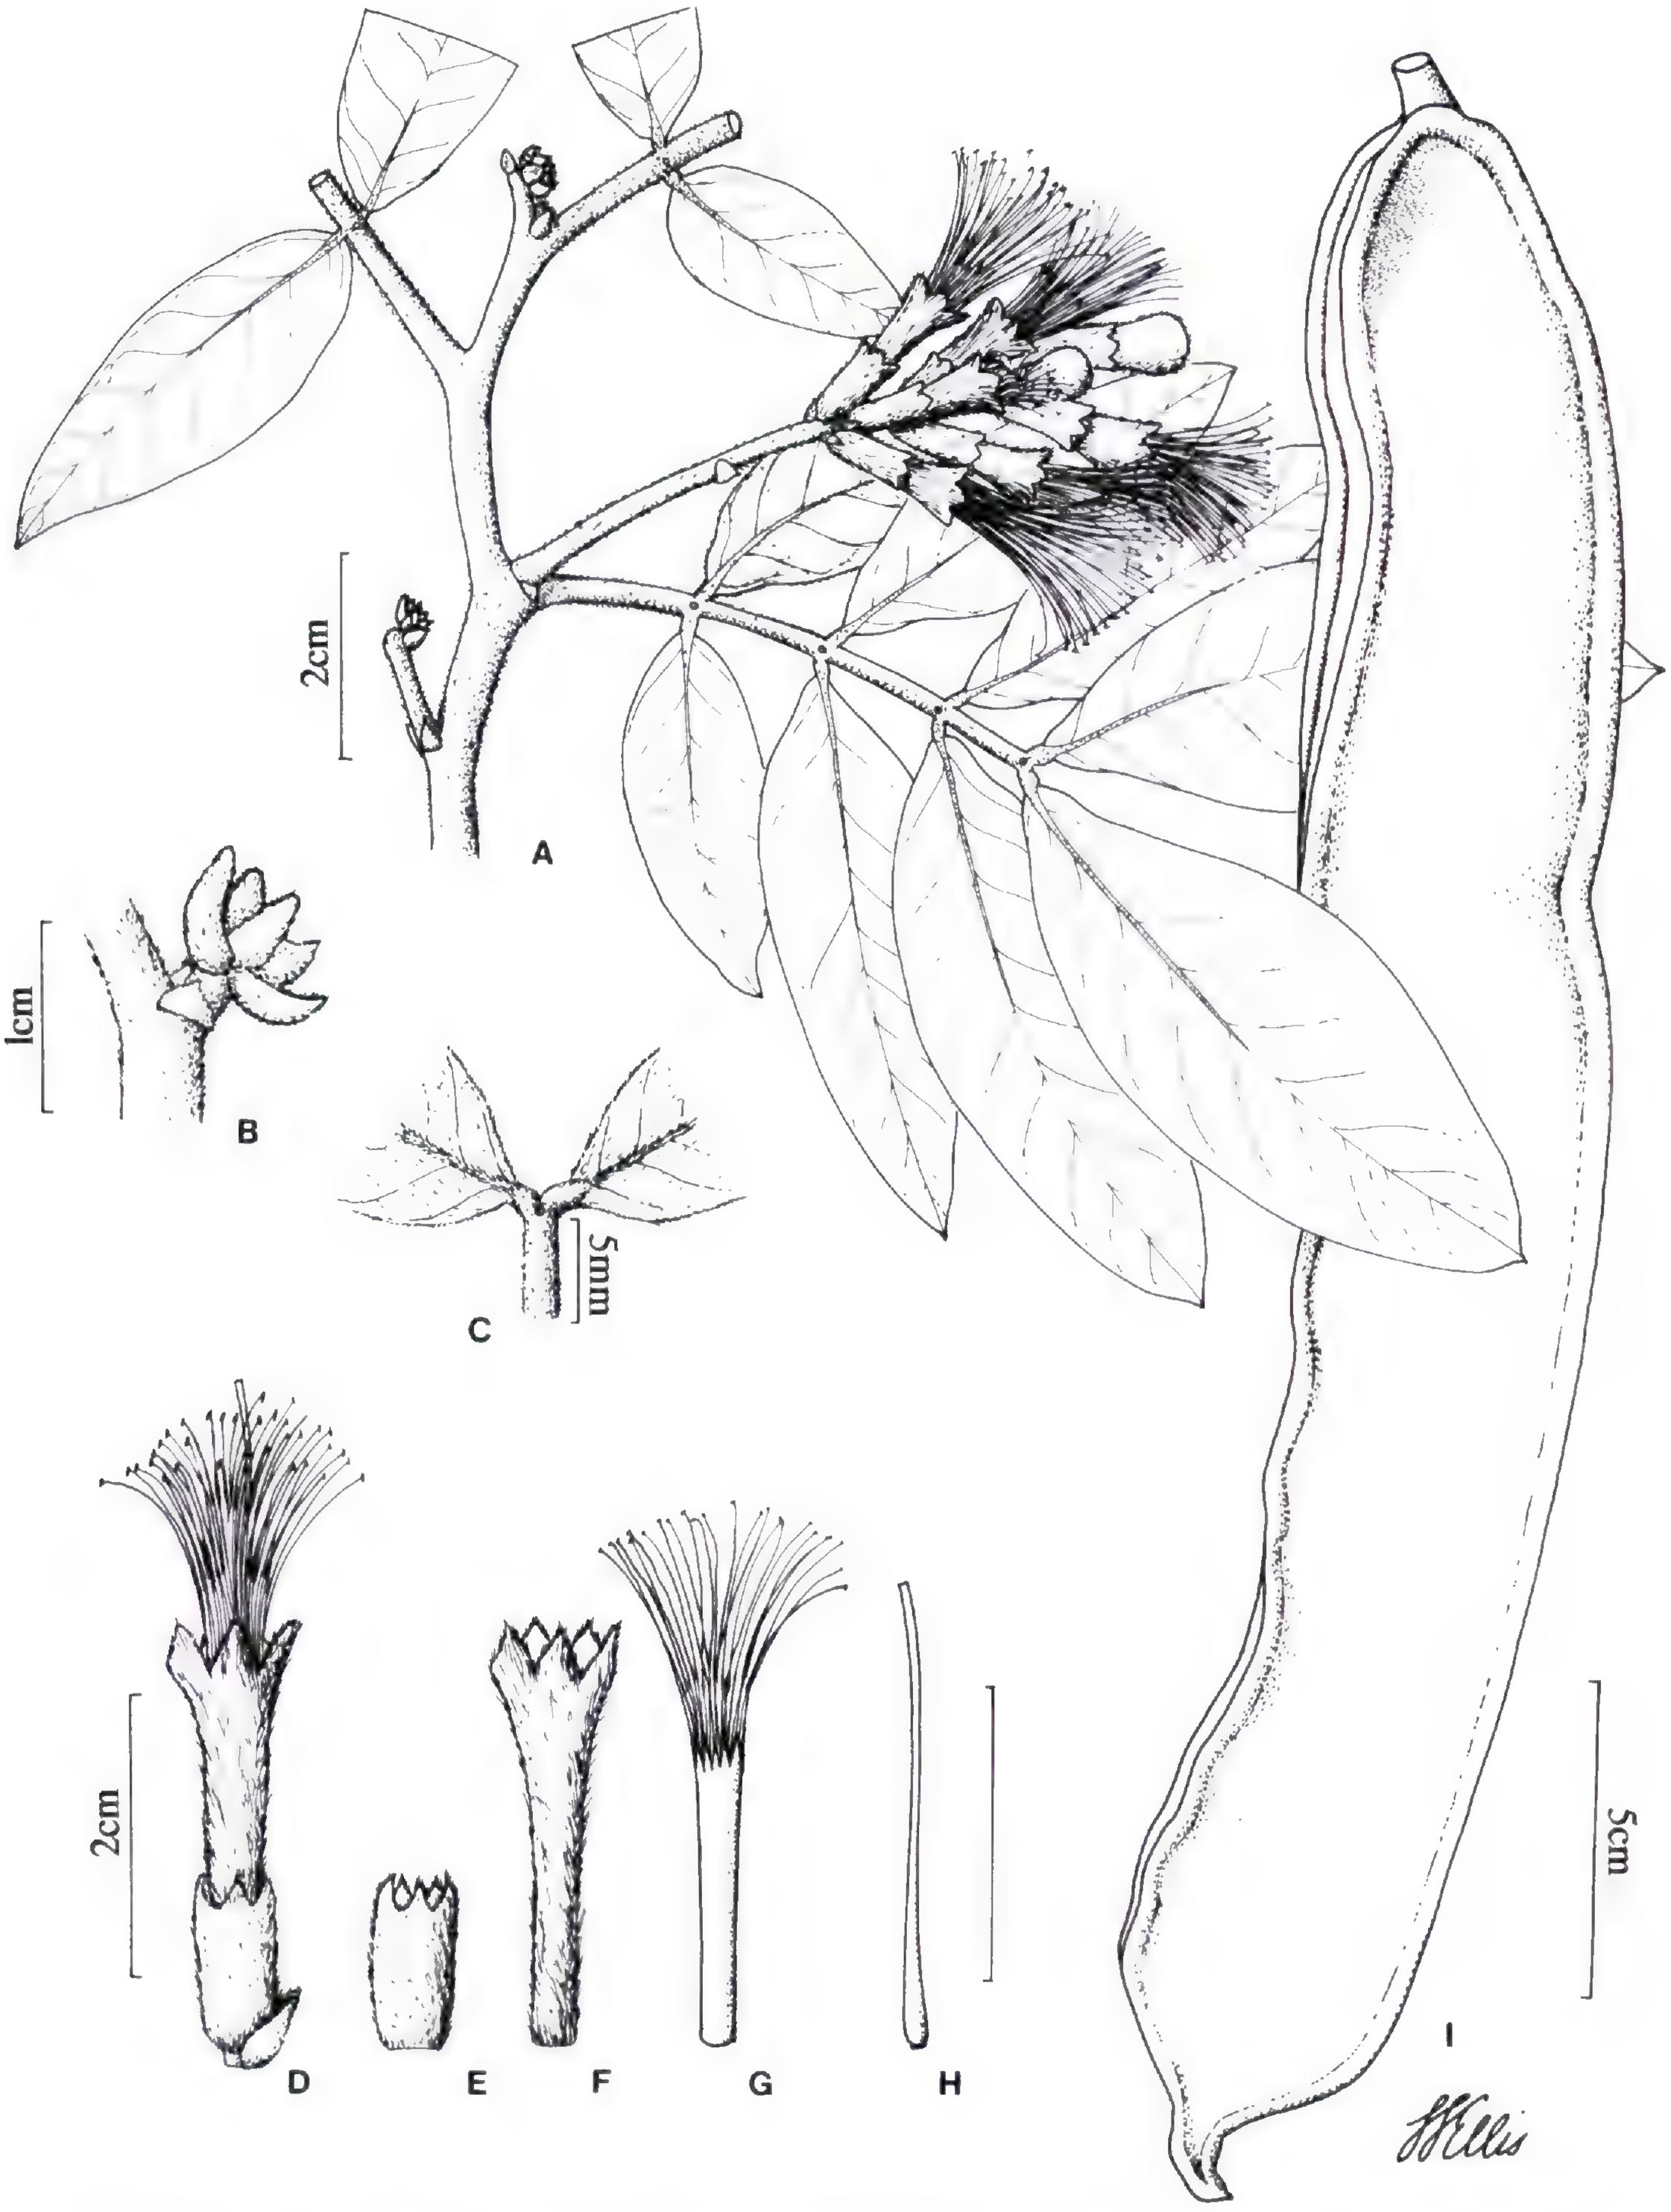

FIGURA 8. *Inga sinacae* M. Sousa et Ibarra-Manríquez.—A. Rama con inflorescencia. (Tomado de *G. Ibarra M. 1547.*)—B. Detalle de yema. (Tomado de *S. Sinaca C. 184.*)—C. Glándula interfoliolar. verdosa, densamente vellosa a lanosa con tricomas canescentes; tubo estaminal inserto, blanco, los estambres erectos en el crepúsculo. Legumbre 13–35 × (2.3–)3–5 × 0.8–1.5 cm, aplanada, derecha a curveada, oblonga, sésil en la base, apiculada a rostrada en el ápice, hirsuta con tricomas pardo-amarillentos, las valvas aplanadas, las suturas derechas, aplanadas a 1-sulcadas.

*Distribución y hábitat.* Hasta ahora sólo conocida de la región volcánica de Los Tuxtlas en el sur de Veracruz, México, en el estrato medio de selvas altas perennifolias y en encinares. En altitudes entre 200 y 650 m. Florece de abril a junio, fructifica de junio a agosto.

*Nombre vernáculo.* Vaina peluda.

*Usos.* Sombra de cafetos.

*Paratipos.* MEXICO. VERACRUZ: Mpio, Catemaco, Río Piso, a 3 km al N de La Palma, camino a Playa Escondida, *R. Cedillo T. 2761* (MEXU), *2762* (MEXU), *3600* (MEXU, MO), *3602* (MEXU, MO), *3624* (MEXU), *3626* (MEXU, MO); Mpio. San Andrés Tuxtla, Estación de Biología Tropical "Los Tuxtlas," *R. Cedillo T. 3647* (MEXU), *G. Ibarra M. 217* (MEXU), *1836* (MEXU, MO); Laguna Escondida, 3 km NO de la Estación de Biología Tropical "Los Tuxtlas," *S. Sinaca C. 184* (MEXU, MO), *893* (MEXU, MO); sin Mpio., Arriba de San Fernando, *A. Gómez-Pompa 4861* (MEXU).

*Inga sinacae* no parece tener un pariente tan cercano que permita comparación; sin embargo, tiene fuertes relaciones con la serie *Longiflorae* de Bentham. Con esta especie se ilustra muy bien lo variable del raquis foliar, el cual, aun en el mismo árbol, varía de terete a alado pasando por marginado.

Esta especie se dedica a Santiago Sinaca Colín (1959–), colector nativo de la región de Los Tuxtlas, quien ha contribuido grandemente al conocimiento florístico de la Estación de Biología Tropical Los Tuxtlas Veracruz, del Instituto de Biología, UNAM.

**Inga skutchii** Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 23: 11. 1943. TIPO: Costa Rica: *Skutch 4823* (holotipo, F; isotipos, A, MO, US).

Especie muy poco colectada que se relaciona estrechamente con *Inga stenophylla* Standley, pero esta última cuenta con una flor más pequeña.

*Material representativo.* COSTA RICA. PUNTARENAS: *Liesner 1989* (MO). SAN JOSE: *Skutch 4823* (MO).

**Inga spectabilis** (M. Vahl) Willd., Sp. Pl. ed. 4, 4: 1017. 1806. Basiónimo: *Mimosa spectabilis* M. Vahl, Skr. Naturhist.-Selsk. 2: 219, t. 10. 1792. TIPO: Colombia: *von Rohr s.n.* (holotipo, C no localizado).

El tipo de Vahl fue colectado en Santa Marta, Colombia, por J. von Rohr; sin embargo, en las microfichas del Herbario de Vahl en Copenhague (C), no se ha localizado, por lo que de no encontrarse otro duplicado de von Rohr, se debe lectotipificar con la lámina de Vahl.

Especie muy característica de la cual León le creó su serie propia: *Spectabiles* León (1966). Se trata de una especie que muestra cierta variabilidad sobre todo del raquis foliar que va de terete a francamente alado.

Respecto a la variedad *schimpfii* Little basada en *Inga schimpfii* Harms (Repert. Sp. Nov. Regni Veg. 43: 112. 1938) del Ecuador y Perú, los isotipos en MO y US, así como otros ejemplares, parecen sostener a esta variedad geográfica, fundamentalmente discernible por caracteres de la inflorescencia y de las flores.

**Inga spectabilis** var. **spectabilis**

**Inga spectabilis** var. **schimpfii** (Harms) Little, Phytologia 19: 268. 1970.

*Material representativo.* ECUADOR. ESMERALDAS: *Little & Dixon 21191* (US). PERU. HUANUCO: *D. Smith 1301* (MO).

**Inga spiralis** Liesner et D'Arcy, Ann. Missouri Bot. Gard. 75: 385, fig. 2. 1988. TIPO: Panamá: *Mori & Kallunki 5577* (isotipo, MO).

Esta magna especie de *Inga* tiene su símil en *I. bullata* Benth. sensu stricto (sin incluir a *I. campanulata* Benth., como Bentham sugirió en 1876 y Taubert hizo en 1892), de la provincia de Rio de Janeiro en Brasil, pero la mantengo aparte, fundamentalmente porque ignoramos la morfología del fruto de *I. bullata*, además del enorme espacio

geográfico entre ambas entidades. También muestra afinidades con *I. jaunechensis* A. H. Gentry del Ecuador, pero difiere porque esta última cuenta con el pecíolo alado, las flores en espigas cortas, y el fruto curvo, pero no leñoso y circinado-espiralado.

*Material representativo.* PANAMA. PANAMA: *Dressler 4325* (MO). SAN BLAS: *Liesner 1314* (MO).

**Inga stenophylla** Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 18: 499. 1937. TIPO: Costa Rica: *Brenes 6841* (holotipo, F; isotipo, CR).

*Inga barbourii* Standley, Publ. Field Mus. Nat. Hist., Bot. Ser. 23: 55. 1944. TIPO: Costa Rica: *Barbour 1008* (holotipo, F; isotipos, MO, US).

Especie muy relacionada a *Inga skutchii* Standley (véase ésta), también tiene grandes semejanzas con *I. tenuipedunculata* León, con la que se le ha confundido. Con esta última, *I. stenophylla* difiere por su corola en general más larga, el cáliz más pequeño y más peloso, el mayor número en promedio de folíolos por hoja y el hecho que habita en un piso altitudinal superior.

El ejemplar de Nicaragua está estéril, por lo que su identificación es tentativa.

*Material representativo.* NICARAGUA. CHONTALES: *Gentry et al. 43944* (MO). COSTA RICA. ALAJUELA: *Brenes 11574* (NY). PANAMA. COCLE: *Knapp 1153* (MO).

**Inga tenella** M. Sousa, sp. nov. TIPO: México. Chiapas: km 18 Colonia Cuauhtemoc, Mpio. La Trinitaria, 15 abr. 1985, *Alush S. Ton 8185* (holotipo, MEXU; isotipo, MO).

Arbores medianae, ramis juvenilibus dense ferrugineo-tomentosis praeditae. Folis 3–4-jugata; stipulae 2.5–5 longae, ex ligulatae subulatae; foliola ex membranacea chartacea; rhachis foliaris alata, glandulis ex sessilibus longe stipitatis. Inflorescentiae spiciformes; pedunculus 1.8–4 cm longus; rachis floralis brevis; bracteae ex oblongae lineares. Flores sessiles; calyx 5–7 mm longus, tubularis-conicus, striatus; corolla 8–14 mm longa. Legumen usque ed 4 cm latum, ex complanatum subtetragonale, oblongum, ferrugineo-hirsutum.

Arboles (3–)5–20 m; ramas subanguladas a teretes, densamente ferrugíneo tomentosas cuando jóvenes, posteriormente glabrescentes. Hojas 6–8-folioladas; estípulas 2.5–5 mm, liguladas a subuladas, caducas; pecíolo 1–2(–4) cm, terete a marginado; folíolos concoloros, en ocasiones ligeramente discoloros, membranáceos a cartáceos, la base simétrica a ligeramente asimétrica, obtusa a cuneada, el ápice agudo a acuminado, en ocasiones cuspidado, el haz ligeramente brillante, moderadamente a esparcidamente piloso, el envés opaco, moderadamente piloso, la nervadura primaria eglandular; par basal de folíolos (2.3–)4.5–7 × (1.3–)2.1–3.3 cm, ovados a lanceolados, el par apical 7–14 × 3.1–6.5 cm, ovados a obovados, elípticos; raquis foliar 5.5–7.5(–9) cm, alado, el ala hasta 7 mm de ancho, elíptica a oblanceolada; glándulas interfoliolares sésiles a largamente estipitadas, clavuliformes, el cuerpo glandular 0.5–0.8 × 0.5–0.8 mm; apéndice ausente. Inflorescencias en espigas, 1–2 fasciculadas; pedúnculo 1.8–4 cm, ferrugíneo tomentoso; raquis floral 1–1.3 cm, las flores congestas, las brácteas homomorfas, 1.5–5 mm, concavas, oblongo-lineares a oblanceoladas, caducas. Flores sésiles; botones florales con el cáliz abierto; cáliz 5–7 mm, tubular-cónico, estriado, esparcidamente estrigoso a tomentoso, con escotaduras, los lóbulos 1.5–2 mm, triangulares; corola 8–14 mm, infundibuliforme, blanca, canescente vellosa; tubo estaminal inserto, blanco. Legumbre 7–14 × 3–4 × 0.8–1.5(–1.8) cm, aplanada a ocasionalmente subtetragonal, derecha a subespiralada, oblonga, sésil, apiculada en el ápice, ferrugíneo hirsuta, las valvas aplanadas, las suturas más o menos derechas, marginadas, los margenes de las suturas aplanados a 1-sulcados.

*Distribución y hábitat.* De Chiapas, México a Comayagua, Honduras, en áreas montañosas, en bosques caducifolios con *Liquidambar* (Hamamelidaceae), bosques de neblina y pinares. En altitudes entre 1,170 y 1,800 m, en ocasiones hasta 2,000 m. Florece en marzo y abril e inicia la fructificación en mayo y junio, los frutos persistiendo en al suelo hasta abril del siguiente año.

*Nombre vernáculo.* Sakil kok (Chiapas); cosós, cosoz (Honduras).

*Paratipos.* MEXICO. CHIAPAS: Mpio. La Trinitaria, 10 km ENE of Dos Lagos above Santa Elena, *D. E. Breedlove 56196* (MEXU). GUATEMALA. *Inga tenella* M. Sousa pertenece al complejo de especies relacionadas con *I. villosissima* Benth. e *I. dasycarpa* M. Sousa (véase discusión de ésta); también se integra, en parte, con *I. cookii* Pittier (véase ésta). El epíteto se refiere a que dentro del grupo de especies a las que se relaciona, *I. tenella* es la que tiene la flor más chica, esbelta y frágil.

**Inga tenuipedunculata** León, Ann. Missouri Bot. Gard. 53: 308, fig. 3. 1966. TIPO: México. Veracruz: *Ll. Williams 9029* (holotipo, NY; isotipo, F).

Tanto en la clave como en la descripción de *Inga tenuipedunculata* León, la corola es citada como de 6–7 mm de largo; sin embargo, tanto en el tipo como en otras colecciones vistas por mí, la corola es más pequeña, de 4–6 mm de largo. Esto aunado a que en la clave León le da a la corola de *I. barbourii* Standley [= *I. stenophylla* Standley, véase ésta] como medida menos de 4 mm de largo, a pesar de que en el texto de la descripción él apunta como de 5–6 mm de largo, lo cual ha creado gran confusión en la determinación de estas especies.

*Inga tenuipedunculata* es una especie de las selvas altas perennifolias del sur de México a Costa Rica.

*Material representativo.* MEXICO. VERACRUZ: *Dorantes et al. 2956* (MEXU). NICARAGUA. MATAGALPA: *Neill 7258* (MO). COSTA RICA. ALAJUELA: *Herrera 1847* (MO).

**Inga tonduzii** J. D. Smith, Bot. Gaz. (Crawfordsville) 44: 112. 1907. TIPO: Costa Rica: *Tonduz 12928* (holotipo, US; isotipos, BM, K).

*Inga tonduzii* es cercana pero distinta de *I. barbata* Benth. de Brasil, la primera con brácteas, cáliz, y corola de mayor tamaño. Esta especie hasta hace poco era sólo conocida de Costa Rica, pero el ejemplar estéril de *Stevens 6886* de Nicaragua parece pertenecer a esta especie.

*Material representativo.* NICARAGUA. ZELAYA: *Stevens 6886* (MO). COSTA RICA. ALAJUELA: *Murphy 1363* (MO). CARTAGO: *Lent 1022* (MO). HEREDIA: *Chacón G. 986* (F). PUNTARENAS: *Utley & Utley 4913* (MO). SAN JOSE: *Burger & Stolze 5344* (NY).

**Inga umbellifera** (M. Vahl) Steudel, Nomencl. Bot. 1: 431. 1821. Basiónimo: *Mimosa umbellifera* M. Vahl, Ecolog. Amer. 3: 30. 1807. TIPO: América austral, *van Rohr s.n.* (holotipo, C, foto MO).

*Inga myriantha* Poeppig, Nov. Gen. Sp. Pl. 3: 77, t. 289. 1845. TIPO: Perú: *Poeppig 1097* (holotipo, W).

*Inga gracilipes* Standley, J. Wash. Acad. Sci. 15: 101.

1925. TIPO: Panamá: *Standley 30353* (holotipo, US).

*Inga lawranceana* Britton et Killip, Phytologia 1: 23. 1933. TIPO: Colombia: *Lawrance 260* (holotipo, US; isotipos, F, MO).

Aquí estoy considerando a *Inga umbellifera* en un sentido estricto sin incluir a *I. sciadion* Steudel, *I. umbratica* Poeppig, ni a *I. brevipes* Benth. (esta última no incluida en la sinonimia de León, 1966, ni por Poncy, 1985, para la Guayana Francesa), todas ellas con pedúnculos breves y otras combinaciones de caracteres que amplían el concepto de *I. umbellifera* a un punto de inmanejable; así que su delimitación requiere que se estudie con más cuidado el material sudamericano.

*Material representativo.* COSTA RICA. ALAJUELA: *Grayum 9052* (MO). HEREDIA: *Schubert & Holdridge 1302* (GH). LIMON: *Robles 2649* (MO). PUNTARENAS: *Gómez P. 22032* (MO). **Inga urabensis** L. Uribe, Caldasia 4: 406. 1947. TIPO: Colombia: *O. Haught 4716* (isotipo, K).

*Inga cyclocarpa* Ducke, Arch. Jard. Bot. Rio de Janeiro 4: 14. 1925, non *I. cyclocarpa* (Jacq.) Willd., Sp. Pl. ed. 4, 4: 1026. 1806 [= *Enterolobium cyclocarpum* (Jacq.) Griseb.]. TIPO: Brasil: *Ducke RB10031* (sintipo, RB; isosintipo, B, foto MO).

*Inga callicarpa* Zamora, Brenesia 33: 99. 1991. TIPO: Costa Rica: *Hammel 13081* (holotipo, CR).

Esta especie fue primero descrita por Ducke (1925) pero debido a que desafortunadamente usó un homónimo tardío, el nombre de L. Uribe lo reemplaza. Aunque él no tuvo tal intención, y consecuentemente designó tipo.

Su afinidad es muy estrecha con *Inga venusta* Standley, de la cual, no es fácil de separar; ésto es más crítico en Colombia donde *I. venusta* adquiere folíolos de gran talla. En Mesoamérica las diferencias son un poco más claras, y aquí *I. venusta* se encuentra en un piso altitudinal mayor que *I. urabensis*.

*Material representativo.* COSTA RICA. HEREDIA: *Hammel 11658* (DUKE). LIMON: *Stevens 23736* (MO). PANAMA. BOCAS DEL TORO: *McPherson & Aranda 10159* (MO). SAN BLAS: *Sugden 619* (MO). COLOMBIA. **Inga vera** Willd., Sp. Pl. ed. 4, 4: 1010. 1806. *Mimosa inga* L., Sp. Pl. 516. 1753, non. Vell. Conc. *Inga inga* (L.) Britton, Fl. Bermuda 170. 1918, nom. illeg. TIPO: Jamaica (lectotipo, Sloane, Voy. Jamaica 2: 58, t. 183, f. 1. 1725, designado aquí).

Para sinónimos véase León (1966) exceptuando a *Inga eriocarpa* Benth. e *I. xalapensis* Benth.

Con *Inga vera*, Willdenow creó un nombre dentro de *Inga* evitando el tautónomo que resultaría al usar el epíteto de Linneo, como lo hizo Britton posteriormente.

De *Mimosa inga* L. se ha reconocido desde Bentham (1845) que Linneo incluyó bajo este nombre a todas las especies relacionadas [serie *Inga*] que él conocía, incluyendo tres citas: Ray (Hist. Pl. 2: 1762. 1688), Sloane (Cat. Pl. Jamaica 153. 1696; Voy. Jamaica 2: 58, t. 183. fig. 1. 1725). Willdenow (1806) es el primero que la interpretó como lo que nosotros identificamos como *Inga edulis* C. Martius con material (P-H y B herb., B-W., IDC microficha no. 7440 microfoto 19020) y descripción que corresponden a dicha especie. Posteriormente Kunth (1824) adoptó esta determinación, la cual Bentham (1875) reconoció. El elemento de Linneo que podría caer bajo esta interpretación es la descripción de Ray (1688) por tratarse de una *Inga* del Brasil; sin embargo, en la descripción de la legumbre madura (la flor es desconocida) ésta es "compresa" y de 6.8–13.6

cm de largo, caracteres que no corresponden a *Inga edulis*. Por otro lado posteriormente Bentham (1875) estrechó los límites de *Mimosa inga* L. y de hecho pero no de forma la lectotipificó, apuntando que la "forma típica" es de Jamaica; así se reduce el problema a la segunda cita de Sloane. Linneo también citó al Hort. Cliff. 209, pero según F. Barrie (com. pers.) no existen ejemplares de herbario. Así, aquí se lectotipifica a *I. vera* con la lámina de Sloane, a pesar de que existen dos frutos en el herbario de Sloane, material del cual Linneo no tuvo acceso.

*Inga vera* es una especie muy polimorfa, que, muy problablemente agrupe a varias microespecies, que se han cruzado y ahora forman un complejo de híbridos, de los cuales no es posible delimitar taxa ni siquiera a nível infraespecífico. Sin embargo, los extremos de variación son reconocibles y en no pocos casos se presentan en las mismas áreas geográficas, haciendo difícil su separación en variedades geográficas o subespecies como León (1966) hizo. Así a guisa de ejemplo la muy característica variante de *Inga fissicalyx* Pittier, de cáliz grande con lóbulos largos y atenuados y corola cortamente exerta, es conocida principalmente del área de la vertiente del Golfo de México, de Veracruz al norte de Guatemala (área de *I. vera* subsp. *spuria*), pero aparece de nuevo (aunque con brácteas no tan largas) en el corazón de *Inga vera* subsp. *eriocarpa* (Benth.) León en Temascaltepec, Edo. de México (*Hinton 5572*, F) y en el área de *I. vera* Willd. subsp. *vera* en la República Dominicana (*Mejía & Zanoni 9062*, MO).

Es muy posible que el hombre haya ayudado grandemente a romper barreras entre las variantes originales, en vista que hoy en día se trata de un complejo con claras tendencias hacia "árboles maleza" de amplia distribución, particularmente en hábitats alterados.

La variación es muy notable en las flores así como las brácteas subyacentes, tanto en forma como en dimensiones y pelosidad; por otro lado las legumbres son bastante homogéneas.

Respecto a *Inga eriocarpa* Benth. (holotipo, *Coulter s.n.*, K) que León (1966) pasó a subespecie de *I. vera* Willd., el material más característico representativo (MEXICO. Colima: *Magallanes et al. 2815*, MEXU; Jalisco: *Mexía 1842*, BM, MO; Edo. México: *Hinton 5911*, F; Michoacán: *Emrick 22*, F; Morelos: *Muskus 20*, F; Nayarit: *Flores F. 1953*, MEXU) se parece más a *I. oerstediana* Benth. que a *I. vera*, tanto en hojas y glándulas interfoliolares como en pelosidad, pero con flores más robustas. Es muy posible que *I. eriocarpa* sea un híbrido entre *I. oerstediana* e *I. vera*. Ya Bentham (1875) consideró que *I. eriocarpa* podría ser la misma especie que *I. xalapensis* Benth. Sin embargo, *Inga eriocarpa* parece ser una buena especie que ha desarrollado una característica densa pelosidad lanuginosa en su cáliz y corola, diferente a la de sus postulados padres específicos, pero además *Inga eriocarpa* se está cruzando con *I. vera* produciendo todas las gradaciones tanto de glándulas interfoliolares como de tamaños de flores y formas de cáliz; un ejemplo de ello se muestra en los ejemplares del tipo de *I. oophylla* Riley (tipo, *González Ortega 250*, holotipo, K; isotipo, US).

Sobre la presencia de *I. eriocarpa* en Mesoamérica existen colecciones de Chiapas (*Goldman 858*, US; *Sousa et al. 11541*, MEXU) que tienen la pelosidad de *I. eriocarpa*, pero los demás caracteres se inclinan fuertemente hacia *I. vera*. Reconociendo que son posibles híbridos en donde dominan los caracteres de *I. vera*, por lo que no la estamos considerando para nuestra área.

Así *Inga vera* agrupa una gran variación no sólo por la cruza de sus variantes, sino también por cruzarse con *I. oerstediana* e *I. latibracteata* (véase *Inga* ×*xalapensis* Benth.), aumentando enormemente su variabilidad.

Con *Inga affinis* DC. (véase ésta) las similitudes también son grandes y sus diferencias son más bien de promedios que de calidad; sin embargo por el momento las mantengo separadas.

**Inga ×xalapensis** Benth. (pro sp.), London J. Bot. 4: 616. 1845. TIPO: México. Veracruz: *Linden 671* (holotipo, K).

*Inga ×zacuapanica* Harms (pro sp.), Repert. Spec. Nov. Regni Veg. 19: 63. 1923. TIPO: México. Veracruz: *Purpus 3684* (isotipos, F, MO, US).

Aquí se está postulando que *Inga xalapensis* Benth. y su sinónimo *I. zacuapanica* Harms son de origen híbrido entre *I. vera* Willd. e *I. latibracteata* Harms; se trata de una hibridización muy común que aún no se estabiliza, y por tanto hay ejemplares intermedios y otros más cercanos a uno u otro progenitor; sin embargo, los más comunes son con hojas similares a *I. vera*, pero con la bráctea floral grande y ancha de *I. latibracteata* y la flor de tamaño intermedio a chica y de las proporciones de *I. latibracteata*. La glándula interfoliolar varia de una a otra, predominando la de cavidad grande de *I. latibracteata*.

Estos híbridos se presentan a casi todo lo largo de la distribución de *Inga latibracteata*, extendiendose *I. ×xalapensis* más al sur hasta el oeste de Honduras.

# REVISION DEL GENERO *STYPHNOLOBIUM* (LEGUMINOSAE: PAPILIONOIDEAE: SOPHOREAE)[1]

*Mario Sousa S.*[2] *y Velva E. Rudd*[3]

## Resumen

Se confirma la segregación de *Styphnolobium* de *Sophora* en base a su hábitat, estipelas, bractéolas, legumbre y número cromosómico. Se amplian sus límites de cuatro a nueve especies, al describirse cinco nuevas especies para la ciencia: *Styphnolobium burseroides*, *S. monteviridis*, *S. parviflorum*, *S. protantherum*, y *S. sporadicum*. Se reconocen dos secciones, haciendose una nueva combinación: sección *Oresbios*. El género se centra en el área mexicano-mesoamericana. Se muestra su cercana afinidad con *Calia* en base a el hábito, bractéolas, y dehiscencia de la legumbre.

## Abstract

The genus *Styphnolobium* is recognized as a segregate from *Sophora* on the basis of habit, stipels, bracteoles, legume, and chromosome number. It is enlarged from four to nine species through the description of five species new to science: *Styphnolobium burseroides*, *S. monteviridis*, *S. parviflorum*, *S. protantherum*, and *S. sporadicum*. Two sections are recognized, one requiring the new combination section *Oresbios*. The genus is centered in the Mexican-Mesoamerican area. Through similarities in habit, bracteoles, and dehiscence of the legume, it is clearly most closely related to *Calia*.

El género *Styphnolobium* (Leguminosae: Papilionoideae: Sophoreae) fue creado por Schott (1830) a partir de *Sophora japonica* L., pero ha sido considerado frecuentemente como parte de *Sophora*, como en la última revisión del género por Tsoong & Ma (1981). Sin embargo Bentham (1837, 1839) y Burkart (1952) lo reconocen, aunque el primero posteriormente (1865) modificó radicalmente su criterio, o bien, existe el consenso de asignarle una categoría propia, así Yakovlev (1964) lo colocó como sección, que reconoce Rudd (1972) y como subgénero Tsoong en Tsoong & Ma (1981). Después Yakovlev (1967) cambió de opinión y lo reconoció como género aparte, reviviendo también a *Calia* Berlandier.

El concepto de este grupo como unidad, bajo las diferentes categorías que ya apuntamos, en realidad ha incluido solamente a dos especies *Sophora japonica* L. (*Styphnolobium japonicum*) del sureste de Asia y *S. affinis* Torrey et A. Gray (*Styphnolobium affine*) del sureste de los Estados Unidos, pero en los últimos años han empezado a aparecer nuevas especies para la ciencia en México y Centro América que corresponden a este grupo

[1] El trabajo de campo de esta revisión y una corta estancia del primer autor en el New York Botanical Garden fueron financiados en parte por la Organización de Estados Americanos, Proyecto: Estudios Biosistemáticos en algunos géneros de Leguminosas, Liliaceas, y Palmas de México: Citogénetica, bienio 88-89, PRDCyT-OEA. La finalización de este trabajo se realizó mientras el primer autor disfrutó de una beca del Missouri Botanical Garden con financiamiento de la Fundación Jessie Smith Noyer, así como de la ayuda de la Dirección General de Personal Académico, UNAM, durante mi año sabático. En el Missouri Botanical Garden mi trabajo fue agilizado grandemente por Enrique Forero y Gerrit Davidse. Agradezco a James Zarucchi por sus sugerencias al manuscrito; a Henk van der Werff por su traducción de las diagnosis al latín y revisión del manuscrito; a Linda Ellis por sus magníficas láminas botánicas; a mi esposa Gloria Andrade de Sousa por su gran ayuda, particularmente el haber pasado el manuscrito a un procesador de textos; y a los curadores de CR, HNMN, K, LINN, LL, MEXU, MO, NY, TEX, US por facilitar el material botánico para su estudio.

[3] Herbarium, Biology Department, California State University, 18111 Nordhoff Street, Northridge, California 91330, U.S.A.

(véase Sousa, 1990). Se totalizan hasta el momento nueve especies, que en conjunto permiten ahora evaluar mejor el problema al aumentar en varias veces la variabilidad conocida. Así decidimos estudiar el grupo desde diferentes puntos de vista, invitando a G. Palomino y a sus alumnas Patricia Martínez y Carmen Bernal (Bernal & Martínez, 1989), para ver el problema de los cariotipos y números cromosómicos, que a la vez ella logró que E. Martínez O. viera el polen, sus resultados son dados en el artículo que sigue a éste (Palomino et al., 1993).

Ya sea que la posición, sea dentro de *Sophora* o fuera, *Styphnolobium* mantiene varios caracteres propios distintivos y reconocibles, también es claro que está cercanamente relacionado a *Sophora* sensu lato particularmente a *Calia* como proponen en diferentes grados Yakovlev (1967, 1968), Tsoong & Ma (1981), y Polhill (1981).

Así podemos resumir sus diferencias con la siguiente clave:

1a. Herbaceas perennes, arbustos o árboles; flores ebracteoladas; legumbre dehiscente. ..... *Sophora*
1b. Arboles; flores bracteoladas; legumbre indehiscente.
2a. Hojas sin estipelas; cáliz bilabiado, el labio vexilar más largo que el carinal; legumbre con pericarpio seco; $2n = 18$. ..... *Calia*
2b. Hojas estipeladas; cáliz trunco o casi trunco, si bilabiado, el labio vexilar más corto que el carinal; legumbre con epicarpio coriáceo, mesocarpio y endocarpio carnosos; $2n = 28$. ..... *Styphnolobium*

Concordando en principio con Yakovlev (1967, 1968), separandolas en tres grupos, estando muy cercanamente relacionado a *Calia*, aunque no bajo la misma categoría como proponen Tsoong & Ma (1981), los que las incluyen bajo el subgénero *Styphnolobium*, incluyendo además a *Sophora pachycapa* Schrenk ex C. A. Meyer del Asia Menor, la cual es totalmente diferente en hábito además de que carece de estipelas y bractéolas, caracteres propios de *Sophora* sensu stricto.

Además de los caracteres morfológicos, los números cromosómicos de seis de las nueve especies conocidas de *Styphnolobium* presentan un número de $2n = 28$ (Palomino et al., 1993, artículo que sigue); contrastando con $2n = 18$ tanto para *Sophora* como para *Calia*. Resulta muy sugestivo el hecho que en las Sophoreae de Norte América existan dos géneros más con número diploíde de $2n = 28$, es decir *Cladrastis* y *Pickeringia* (véase Goldblatt, 1981) éste último considerado de posición incierta y frecuentemente colocado, aunque con reticencia, en las Thermopsidae por su similitud en las hojas (Turner, 1981).

Por otro lado, si comparamos morfológicamente a *Styphnolobium*, *Cladrastis*, y *Pickeringia* no resultan tan diferentes en cuanto a su tipo básico de inflorescencia (Fig. 1A–G). También muestran claras cercanias con *Calia*, asi tanto *Pickeringia* y varias especies de *Calia* presentan gradaciones de flores francamente solitarias en las axilas de las hojas a racimos, esto ya había sido observado por Nuttall (1840) en *Pickeringia*. La gradación va de hojas 3-folioladas cuyos folíolos laterales se reducen grandemente y constituyen las bractéolas y el folíolo terminal o central que funge como la bráctea floral subyacente al pedicelo. En cuanto a *Cladrastis* debido a lo efímero de sus diminutas bractéolas, no son descritas y en general se interpretan como carentes; su legumbre dehiscente, aplanada y delgada lo diferencia.

Dentro de las Sophoreae pero ya no en el grupo *Sophora* (Polhill, 1981), sino en el grupo *Dussia*, *Dussia*, en el único conteo reportado por Goldblatt (1981), presenta tambien $2n = 28$. Aquí se trata de un género con francas relaciones fitogeográficas hacia Sudamérica, que sin embargo comparte más caracteres con el grupo *Styphnolobium* que con *Sophora* sensu stricto.

Al aumentar dramáticamente el conocimiento de la variabilidad de *Styphnolobium* es posible sugerir tendencias evolutivas en el género (véase Tabla 1); así de su análisis *Styphnolobium affine* resultó la única especie que cuenta con todas las fases primitivas de los nueve caracteres tratados. Por otro lado ninguna posee todas las fases avanzadas de los caracteres usados: la que conjuntó más fue *S. burseroides* y en base a estos caracteres es que arreglamos las especies en el tratamiento sistemático, aunque con limitaciones, ya que en algunas especies faltó el conocimiento de estructuras o estadios como son las plántulas.

Sobre su fitogeografía Sousa y Delgado (en prensa) dan una relación que aquí modificamos en vista de la nueva información obtenida. Sus especies tienden a ser endémicos restringidos (Fig. 2), que actualmente habitan en climas templados a cálidos y de subdesérticos a húmedos.

Existen, afortunadamente, varios registros fósiles de frutos y folíolos asociados de la Formación Claiborne (Herendeen & Dilcher, 1986; Herendeen, 1990, 1992), fechados del Eoceno Medio del occidente de Kentucky y Tennessee y asociados a bosques que contaban con: Podocarpaceae, Theaceae, Anacardiaceae, Magnoliaceae, Hamamelidaceae, Moraceae, Sapotaceae, Annonaceae, Nys-

TABLA 1. Tendencias evolutivas en *Styphnolobium*.

| Primitivos | Avanzados |
|---|---|
| Estipelas bien desarrolladas | Estipelas muy reducidas a faltantes |
| Inflorescencia axilar, racemosa | Inflorescencia terminal, paniculada |
| Cáliz no giboso | Cáliz giboso |
| Cáliz 5-dentado | Cáliz trunco o casi trunco |
| Polen con la exina de retículo abierto | Polen con la exina de retículo cerrado |
| Ovario peloso | Ovario glabro |
| Legumbre homogenea | Legumbre con marcas |
| Germinación con los cotiledones epigeos | Germinación con los cotiledones hipogeos |
| Eófilos bien desarrollados | Eófilos reducidos a catáfilos |

saceae, Lauraceae, Fagaceae, Juglandaceae, Myricaceae, Rhamnaceae, Euphorbiaceae, y otras. Esta composición florística de la vegetación se acerca mucho a los bosques caducifolios o mesófilos de montaña que actualmente habitan las vertientes húmedas de las sierras del sur de México al norte de Nicaragua. Sin embargo, dada la abundancia, diversidad, y grupos de leguminosas conocidas (Herendeen, 1990, 1992) y considerando lo pobre en leguminosas que actualmente este tipo de vegetación posee, es posible que también habían otros tipos de vegetación menos húmedos y más cálidos, como selvas medianas a altas subperennifolias y aún más estacionales, francamente caducifolias con abundantes mimosoideas como los depositos atestiguan, y no necesariamente confinado a áreas templadas como Herendeen (1992) sugiere.

Por lo anterior, la naturaleza de endemismo en este género es de paleoendémicos, en los que el representante asiatico muestra ya caracteres avanzados y únicos en el género, como el polen y el tipo de inflorescencia; sus parientes americanos parecen ser sus predecesores, siendo *Styphnolobium affine* el posible puente entre la rama asiatica y la rama americana del género.

**Styphnolobium** Schott, Wiener Z. Kunst. 3: 844. 1830. Sinónimo: *Sophora* secc. *Styphnolobium* (Schott) Yakovlev, Trudy Leningradsk. Khim.-Farm. Inst. 17: 56. 1964. Homónimo tardío: Tsoong, Acta Phytotax. Sin. 19(2): 161. 1981. ESPECIE TIPO: *Styphnolobium japonicum* (L.) Schott.

Arboles; corteza lisa, fisurada a escamosa placoide irregular, en ocasiones exfoliante, con tonos metálicos; el crecimiento en brotes cortos y largos, frecuentemente ramifica en los cortos y las ramas tienden a parecer casi verticiladas. Hojas alternas, estipuladas, 1-pinnadas, imparipinnadas, los folíolos generalmente opuestos proximalmente y marcadamente alternos distalmente o todos opuestos o alternos, estipelados. Inflorescencias racemosas, axilares, raramente terminales y paniculadas; flores pediceladas, los pedicelos articulados basalmente, con una bráctea subyacente subamplexicaule en la base; bractéolas presentes, 2; hipantio desarrollado; cáliz lobado a truncado, giboso o no giboso; corola papilionoidea, polipétala, rosado pálido a blanquecina, glabra, pétalos unguiculados; lámina del estandarte suborbicular, reflexa, maculada; alas simétricas a asimétricas, sin rugosidades; pétalos de la quilla libres y ampliamente traslapados; estambres libres; anteras uniformes; ovario glabro a peloso, estilo glabro; estigma terminal, atenuado. Legumbre indehiscente, suculenta, moniliforme a torulosa, péndula, frecuentemente estipitada por aborción de las semillas proximales, homogénea o con marcas lisas en el margen vexilar, exocarpo coriáceo, mesocarpo y endocarpo carnoso y mucilaginoso; semillas oblongo-elipsoideas, lisas, negruzcas a negras, con el hilo lateral, con el endospermo cubriendo al embrión y la radícula incurvada. Plántulas con los cotiledones epigeos o raramente hipogeos, las primeras hojas por encima de los cotiledones (eófilos) alternas en ocasiones subopuestas, imparipinnadas o raramente reducidas a catáfilos. $2n = 28$.

líolos alternos a subopuestos, estipelados, las estipelas ca. 1 mm, aciculares, subpersistentes; láminas 1–6 × 0.5–2.5 cm, lanceoladas, la base obtusa en ocasiones aguda, el ápice acuminado a agudo, el haz glabrescente, el envés esparcidamente canescente seríceo, en ocasiones glauco. Inflorescencias terminales, en panículas; floración tardía; ejes secundarios 3.5–17 cm; bráctea 1–1.5 mm, triangular-atenuada, caduca; pedicelo 3 mm, articulado apicalmente, esparcidamente diminutamente canescente seríceo; bractéolas ca. 1 mm, triangular-atenuadas, cercanas al cáliz, pronto caducas; flores 12–15 mm; cáliz 3–4 mm, ciatiforme, no giboso, glabrescente excepto moderada a densamente canescente seríceo sobre los lóbulos y margen, 5-lobado, los lóbulos hasta 1.2 mm, redondeados; pétalos blancos a amarillo pálido; estandarte largamente unguiculado, la uña hasta 4 mm; ovario esparcidamente amarillento seríceo. Legumbre 3–12 × 0.7–1 cm, moniliforme, homogénea, glabrescente, excepto esparcidamente canescente serícea en el estípete, constricciones y rostro, estipitada, el estípite hasta 1.7 cm; semillas 0.8 × 0.4–0.5 cm, 1–8 por fruto. Plántulas con los cotiledones epigeos, los eófilos imparipinnados, en ocasiones 1-foliolados o 3-foliolados. $2n = 28$.

*Distribución y hábitat.* Esta especie aparentemente es sólo nativa de China, pero desde hace mucho se ha cultivado y naturalizado en Japón, de donde originalmente se describió, en la actualidad se le cultiva ampliamente en el mundo. Se trata de un árbol caducifolio que florece en agosto–septiembre y fructifica en octubre–noviembre en China.

*Material representativo.* CHINA. ANHUI: *K. Yao 8472* (MO). CHENGJIANG: *Yao & Kan 79360* (MO). HUBRI: *E. H. Wilson 2558* (MO). JIANGRI: *K. Yao 9113* (MO). XIZANG: *G. Forrest 24754* (MO). YUNNAN: *A. Henry 9871* (US).

El ejemplar anotado como *Sophora japonica* en el Herbario de Linneo LINN 522.9 no es *S. japonica*, y si es *Sophora* se parece más a *S. tomentosa* L.

Para fines de esta revisión no se estan considerando los taxa infraespecíficos descritos para esta especie, para ello véase el trabajo de *Sophora* de Tsoong & Ma (1981).

*Styphnolobium japonicum* muestra el carácter único en el género de inflorescencia terminal en panícula y sus relaciones más cercanas parecen ser con *S. affine*.

SECCION 2.

***Oresbios*** (Rudd) M. Sousa et Rudd, comb. nov. Basiónimo: *Sophora* secc. *Oresbios* Rudd, Phytologia 21(5): 327. 1971. ESPECIE TIPO: *Styphnolobium conzattii* (Standley) M. Sousa et Rudd.

Arboles; inflorescencia axilar, racemosa; polen con la exina de retículo abierto. Ocho especies de América del Norte y Mesoamérica, extendiéndose una a Colombia.

CLAVE PARA LAS ESPECIES DE *STYPHNOLOBIUM* SECC. *ORESBIOS*

1a. Legumbre moniliforme, 0.7–1 cm de diámetro, con 1–8 semillas. (Texas, Oklahoma, Arkansas, y Louisiana, Estados Unidos.) ..... 1. *S. affine*
1b. Legumbre torulosa a moniliforme 1.6 2.8 cm de diámetro, con 1–3(–4) semillas. (Centro de México al Norte de Sudamérica.)
2a. Legumbre ferrugíneo velutina o canescente-serícea al menos en el estípite; ovario canescente o pardo-amarillento seríceo.
3a. Legumbre homogénea sin marcas en el margen vexilar.
4a. Folíolos coriáceos; estipelas bien desarrolladas; folíolos redondeados a corto acuminados en el ápice; inflorescencias 2.5 6 cm, flores con cáliz 5–6 mm. (Oaxaca, México.) ..... 2. *S. conzattii*
4b. Folíolos cartáceos; estipelas poco desarrolladas; folíolos largamente acuminados a caudados en el ápice; inflorescencias 6.5 17 cm, flores con cáliz 3.5–4 mm. (Nicaragua.) ..... 3. *S. caudatum*
3b. Legumbre con marcas ocres (lisas al secarse) en el margen vexilar.
5a. Hojas 15–21-folioladas, folíolos 1.5–3 × 0.8–1.5 cm, canescente tomentoso en el envés; cáliz someramente 5-lobado. (S del Desierto de Tehuacán, Oaxaca, y Puebla, México.) 8. *S. burseroides*
5b. Hojas 7 11-folioladas, folíolos 5 6.5 × 2–3.3 cm, glabrescentes en el envés; cáliz casi trunco. (Costa de Jalisco, México.) ..... 6. *S. protantherum*
2b. Legumbre glabra; ovario glabro.
6a. Cáliz 5-lobado; hojas 13–17-folioladas. (Monteverde, Costa Rica.) ..... 4. *S. monteviridis*

**2. Styphnolobium conzattii** (Standley) M. Sousa et Rudd, Ann. Missouri Bot. Gard. 77(3): 575. 1990. Basiónimo: *Sophora conzattii* Standley, Contr. U.S. Natl. Herb. 23(2): 436. 1922. *Calia conzattii* (Standley) Yakovlev, Trudy Leningradsk. Khim.-Farm. Inst. 21(4): 45. 1967. TIPO: México. Oaxaca: *Conzatti et al. 3171* (holotipo, US; isotipo, MEXU herbario Conzatti). Figuras 1E, 2, y 3.

Arboles 22–25 m; corteza placoide; ramas canescente velutinas a tomentulosas cuando jóvenes, pronto glabrescentes, esparcidamente lenticeladas. Hojas 5–9-folioladas; estípulas ca. 0.8 mm, linear-aleznadas, pronto caducas; pecíolo 2–5 cm; raquis foliar 4–10.5 cm; folíolos opuestos a casi opuestos en ocasiones los distales alternos, estipelados, las estipelas 1–2 mm, recurvadas, crasas, persistentes; láminas 3.5–5.5(–7.5) × 2.2–3.5(–4.5) cm, coriáceas, ovadas, elíptico-ovadas a anchamente elípticas, la base obtusa a aguda, el ápice obtuso a agudo, el haz y envés glabros. Inflorescencias axilares; floración tardía; pedúnculo muy reducido hasta 0.8 cm, raquis floral 2.5–5.5 cm; bráctea ca. 1 mm, triangular-atenuada, pronto caduca; bractéolas ca. 0.6 mm, oblongas, pronto caducas; flores 20–25 mm; cáliz 5–6 mm, infundibuliforme, ligeramente giboso, ferrugíneo seríceo; casi trunco; pétalos violeta, glabros; estandarte largamente unguiculado, la uña hasta 4 mm; ovario canescente seríceo. Legumbre 6.5–14 × 2.2–2.5 cm, torulosa, homogénea, canescente sericea, densamente en el estípite, constricciones y rostro, esparcidamente a la altura de las semillas, estipitada, el estípite hasta 2.5 cm; semillas 2 × 1.4 cm, 1–3 semillas por fruto. $2n = 28$.

*Distribución y hábitat.* Especie endémica del Cerro Espino en la Sierra Madre del Sur, Oaxaca, México, en altitudes entre 1,150 y 1,200 m, poco común en selvas medianas perennifolias, en suelos rocosos. Florece de abril a mayo y cuenta con frutos maduros en abril del año siguiente.

*Nombres vernáculos.* Frijolillo, granadillo.

*Material representativo.* MEXICO. OAXACA: *Sousa 5598* (MEXU), *Torres C. 4901* (MEXU, MO), *5231* (MEXU, MO).

Esta especie es muy característica por sus hojas coriáceas; estipelas persistentes, crasas y recurvadas; y las flores grandes.

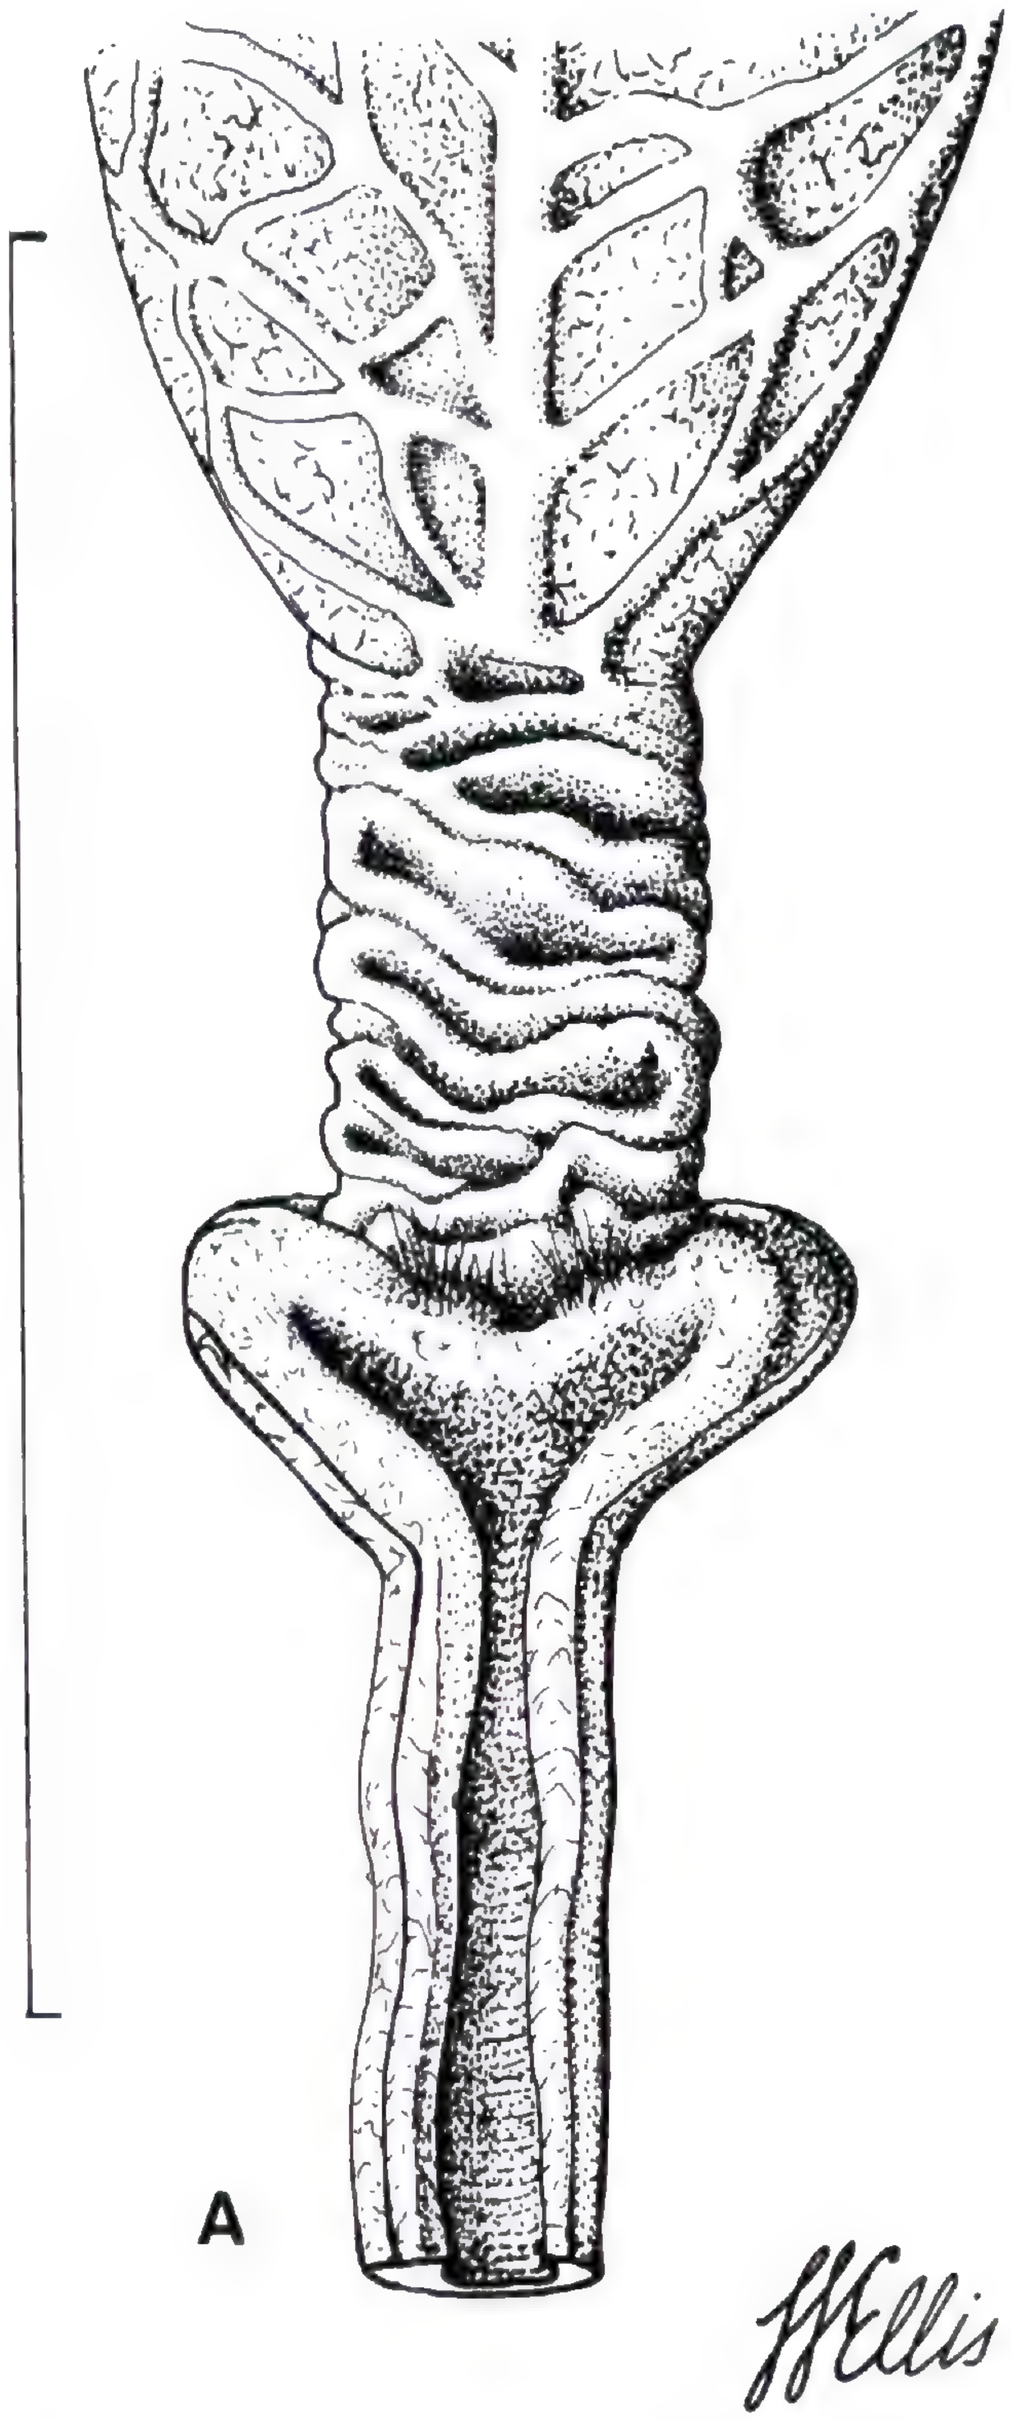

FIGURA 3. *Styphnolobium conzattii.*—A. Base de folíolo terminal, mostrando estipelas prominentes y pulvínulo. (Tomado de *R. Torres C. 5231.*)

**3. Styphnolobium caudatum** M. Sousa et Rudd, Ann. Missouri Bot. Gard. 77: 573, fig. 1. 1990. TIPO: Nicaragua: *Sousa et al. 12985* (holotipo, MEXU; isotipos, BM, HNMN, MO). Figura 2.

Arboles de más de 30 m; corteza escamosa placoide irregular, con tonos metálicos, con abundantes lenticelas prominentes; ramas diminutamente canescente seríceas cuando jóvenes, pronto esparcidamente, esparcida a moderadamente lenticela-

das. Hojas 9–13-folioladas; estípulas desconocidas; pecíolo 2.5–5.5 cm; raquis foliar 7–15 cm; folíolos alternos, estipelados, las estipelas hasta 0.8 mm, oblongas, pronto caducas; láminas 4–9 × (1.3–)2–2.7 cm, lanceoladas, la base redondeada ligeramente asimétrica, en ocasiones cuneada, el ápice largamente acuminado a caudado, el haz glabro, el envés esparcidamente seríceo. Inflorescencias axilares, en ocasiones algo paniculadas, 12–17 cm; pedicelo 5–9 mm; cáliz (en frutos inmaduros) 3.5–4 mm, giboso, pardo velutino, casi trunco. Legumbre 5–14 × 2.3–2.7 cm, torulosa, homogénea, densamente ferrugíneo velutina, estipitada, el estípite hasta 4 cm; 1–2(–4) semillas por fruto (semillas maduras no fueron vistas).

*Distribución y hábitat.* Sólo se conoce de la localidad tipo en Estelí, Nicaragua, de un sólo árbol, en una cañada húmeda, en la vega de un río, a 900 m de altitud. Con frutos inmaduros durante mayo.

*Material representativo.* NICARAGUA. ESTELI: *P. P. Moreno 25655* (MEXU, MO).

**4. Styphnolobium monteviridis** M. Sousa et Rudd, sp. nov. TIPO: Costa Rica. Puntarenas: Monteverde, Pacific slope, 10°18′N, 84°48′O, 1,450 m, *W. Haber 9118* (holotipo, MEXU; isotipo, MO). Figura 2.

Arbores magni, folia proterantha, 13–17 foliolata, foliolis lanceolatis vel ellipticis, glabris. Inflorescentiae axillares, pedunculi ad 1.2 cm longi, rhachides florales (3.5–)5–11 cm longae; bracteoli diminuti, decurrentes, caducei; flores mediani; calyx infundibuliformis, gibbosus, 5-lobatus; vexillum unguiculatum; ovarium glabrum. Legumina homogenea, glabra, 1–2(–4) seminibus onusta.

Arboles (15–)30–40 m; ramas esparcidamente canescente pilosas cuando jovenes, pronto glabras, moderado a densamente lenticelado-verrugosas. Hojas 13–17-folioladas; estípulas ca. 3 mm, linear-atenuadas, pronto caducas; pecíolo 2.5–6 cm; raquis foliar 9–15 cm; folíolos alternos a subopuestos proximalmente, estipelados, las estipelas ca. 1 mm, linear-liguladas, pronto caducas; láminas 3.2–6 × 2.2–2.5 cm, lanceoladas a elípticas, la base obtusa a aguda, el ápice acuminado, el haz y envés glabros. Inflorescencias axilares; floración tardía; pedúnculo muy reducido hasta 1.2 cm; raquis floral (3.5–)11 cm; bráctea 3–4 mm, linear-aleznada, pronto caduca; pedícelo 4–6 mm, pardo velutino; bractéolas ca. 0.2 mm, lineares, decurrentes por 1 mm, pronto caducas; flores ca. 20 mm; cáliz 7 mm, anchamente infundibuliforme, giboso, pardo seríceo a velutino, 5-lobado, los lóbulos ca. 1 mm, apiculados; pétalos lavanda con nervaciones oscuras; estandarte largamente unguiculado, la uña hasta 6 mm; ovario glabro. Legumbre (inmadura) 5.5–9(–13) × 2.2 cm, torulosa, homogénea, glabra, estipitada, el estípite hasta 2.5 cm, glabro; semillas (inmaduras) 2 × 1.7 cm, 1–2(–4) por fruto. Plántulas se desconocen.

*Distribución y hábitat.* Esta especie sólo se conoce del área de Monteverde, Costa Rica, en altitudes entre 1,400 y 1,550 m. Florece a mediados de febrero y a finales de julio, el período de fructificación aún se desconoce, pero a finales de agosto ya cuenta con frutos bastante desarrollados pero aún inmaduros.

*Paratipos.* COSTA RICA. PUNTARENAS: Monteverde, 10°47′N, 84°50′O, *A. Gentry & W. Haber 48728* (MO); 10°18′N, 84°43′O, *B. Hammel 17037* (MO); along road to Eston Rockwell farm, *G. S. Hartshorn 1898* (MO, NY).

Esta especie pertenece al grupo de *Styphnolobium* con ovario glabro, legumbre homogénea. El epíteto se refiere a Monteverde, área que es muy rica en endemismos.

**5. Styphnolobium parviflorum** M. Sousa et Rudd, sp. nov. TIPO: México. Veracruz: Estación de Biología Tropical Los Tuxtlas, U.N.A.M., Mpio. San Andrés Tuxtla, 150 m altitud, en selva alta perennifolia, suelo arcilloso, 9 enero 1974, *M. Sousa 4299* (holotipo, MEXU; isotipo, MO). Figuras 2 y 4.

Arbores magni; folia proterantha 5–7 foliolata, foliolis ovatis, oblongis vel late ellipties, glabris. Inflorescentiae axillares; pedunculi ad 1 cm longi, rhachides florales 1–4 cm longae; bracteoli parvi, ligulati, caducei; flores parvi; calyx infundibuliformis, agibbosum, truncatus; vexillum longe unguiculatum; ovarium glabrum. Legumina homogenea, glabra, 1(–2) seminibus onusta. Cotyledones epigaeae.

Arboles 22–35 m; ramas canescente seríceas cuando jóvenes, pronto glabras, moderadamente lenticelado-verrugosas. Hojas 5–7-folioladas; estípulas ca. 1.5 mm, lineares, pronto caducas; pecíolo 2.5–4 cm, raquis foliar 2.5–6.5 cm, folíolos opuestos a alternos, estipelados, las estipelas ca. 1.2 mm, lineares, pronto caducas; láminas 3.5–8.5 × (1.7–)2.2–4 cm, ovadas, oblongas a anchamente elípticas, la base obtusa, el ápice obtuso a apiculado en ocasiones acuminado, el haz y envés glabros. Inflorescencias axilares; floración tardía; pedúnculo muy reducido hasta 1 cm; raquis floral 1–4 cm; bráctea ca. 2.5 mm, angostamente triangular-atenuada, pronto caduca; pedicelo 2–4.5 mm, pardo seríceo, bractéolas ca. 0.5 mm, liguladas, pronto caducas; flores 11–13 mm; cáliz 3–4 mm, infundibuliforme, no giboso, pardo seríceo, trunco a casi trunco; pétalos blancos a rosado pálido; estandarte

FIGURA 4. *Styphnolobium parviflorum* M. Sousa et Rudd. A. Rama con inflorescencias.—B. Cáliz pedicelado con bráctea y bractéolas.—C. Estandarte. -D. Ala.—E. Pétalo de la quilla.—F. Gineceo y androceo. (Tomados de *Ponce y Cedillo T. 6.*)—G. Legumbre. (Tomado de *Calzada 994.*)—H. Semilla. (Tomada de *Sousa 4299.*)—I. Plántula. (Tomada de *Calzada 994.*)

largamente unguiculado, la uña hasta 4 mm; ovario glabro. Legumbre 4.5–11 × 3.5–4 cm, torulosa, homogénea, glabra, sésil a estipitada, el estípite hasta 3 cm; semillas 2.8 × 1.8–2 cm, 1(–2) por fruto. Plántulas con los cotilédones epigeos, los eófilos imparipinnados; 5–9(–10)-foliolados; $2n = 28$.

*Distribución y hábitat.* Conocida solamente de dos áreas del estado de Veracruz, la región de Los Tuxtlas y la zona de Uxpanapa, en vegetación

de selvas altas perennifolias a subperennifolias, formando parte del dosel de la selva con *Brosimum alicastrum* Sw., *Simira salvadorensis* (Standley) Steyerm. y *Pseudobombax* sp. en litosoles calizos y en suelos negros pedregosos de origen volcánico. En altitudes entre 100 y 250 m. Florece de principios de diciembre a la primera quincena de enero, la fructificación se inicia en febrero, habiendo frutos maduros hasta mayo.

*Nombres vernáculos.* Melaza, melcocha, palo de melcocha.

*Paratipos.* MEXICO. VERACRUZ: Mpio. Jesús Carranza: 0.5 km al N del Poblado 2, 17°15′30″N, 94°40′O, *T. Wendt et al. 5282* (MEXU); Mpio. San Andrés Tuxtla, Estación de Biología Tropical Los Tuxtlas, U.N.A.M., 18°34′–18°36′N, 95°09′O, *J. I. Calzada 994* (MEXU, MO), *1112* (MEXU), *1752* (MEXU), *G. Ibarra M. 615* (MEXU), *778* (MEXU), *1099* (MEXU), *1299* (MEXU, MO), *F. Ponce & R. Cedillo Trigos 6* (MEXU), *S. Sinaca C. & F. Chigo S. 729* (MEXU, MO); Laguna Escondida, a 3 km al NO de la Estación de Biología Tropical Los Tuxtlas, *Sinaca C. 708* (MEXU, MO).

Especie que cuenta con varios caracteres avanzados en el género, tales como cáliz trunco o casi trunco, ovario y legumbre glabras, reducción del número de folíolos, los cuales en plántula son más numerosos que en las hojas de los ejemplares arbóreos y flores pequeñas, por este último carácter se nombra a esta especie.

**6. Styphnolobium protantherum** M. Sousa et Rudd, sp. nov. TIPO: México. Jalisco: entrada a Cuenca 3, Estación de Investigación, Experimentación y Difusión Chamela, U.N.A.M., Mpio. La Huerta, 24 febrero 1984, *J. Arturo S. Magallanes 4159* (holotipo, MEXU). Figuras 2 y 5.

Arbores mediani vel magni; folia 9–11 foliolata, foliolis ovatis, late ellipticis, glabrescentibus vel glabris. Inflorescentiae axillares, interdum paniculatae; flores praecoces, mediani; pedunculi 1.4–3.5 cm longi; rhachides florales 7–13 cm longae; bracteoli parvi, lineari-attenuati; calyx infundibuliformis, paullo gibbosus, subtruncatus, ovarium sericeum. Legumina maculis ochraceis, laevibus praedita, 1–2(–4) seminibus onusta. Cotyledones epigaeae.

Arboles 12–25 m; corteza longitudinalmente fisurada que forma placas; ramas canescente seríceas cuando jóvenes, pronto glabras, esparcidamente lenticeladas. Hojas 9–11-folioladas; estípulas ca. 1.6 mm, linear-aleznadas, pronto caducas; pecíolo 1.8–4 cm; raquis foliar 8–11(–13) cm; folíolos opuestos a alternos, estipelados, las estipelas 0.4–0.6 mm, triangular-atenudas, pronto caducas; láminas 3–6.5 × 1.8–3.2 cm, ovadas, anchamente elípticas, en ocasiones elípticas u obovadas, la base obtusa, el ápice obtuso, apiculado a cortamente acuminado, el haz y envés esparcidamente canescente seríceos, pronto glabros. Inflorescencias axilares en ocasiones paniculadas; floración precoz; pedúnculo 1.4–3.5 cm, raquis floral 7–13 cm; bráctea ca. 1.5 mm, angostamente triangular-atenuada, pronto caduca; pedicelo 3–3.5 mm, pardo seríceo; bractéolas ca. 1 mm, linear-atenuadas, pronto caducas; flores 14–16 mm; cáliz 4–6 mm, infundibuliforme, algo giboso, pardo seríceo, casi trunco; pétalos rosados; estandarte largamente unguiculado, la uña hasta 5 mm; alas algo asimétricas; ovario densamente canescente seríceo. Legumbre 4–12.5(–15.5) × 2–2.5 cm, torulosa, con marcas ocres y lisas en el margen vexilar, glabra excepto serícea en el estípite, estipitada, el estípite hasta 2.6 cm; semillas 2.5 × 1.5 cm, 1–2(–4) por fruto. Plántulas con los cotiledones epigeos, los eófilos imparipinnados, 7–9-foliolados. $2n = 28$.

*Distribución y hábitat.* Sólo conocida de la costa de Jalisco en selvas medianas subperennifolias a subcaducifolias, en suelos metamórficos. En altitudes alrededor de los 800 m. En el período de sequía esta especie es caducifolia y florece sin hojas a finales de febrero a principios de marzo, fructifica a partir de marzo contando con frutos maduros en mayo.

*Paratipos.* MEXICO. JALISCO: Mpio. La Huerta, Estación de Biología, Chamela, U.N.A.M., E of Eje Central, *Bullock 1495* (MEXU, MO); Arroyo el Zarco, *J. A. S. Magallanes 990* (MEXU, MO); Estación de Biología, Chamela, *Magallanes 2177* (MEXU, MO); entrada a la Cuenca 3, *4179* (MEXU); Vereda Buho, *4237* (MEXU, MO).

*Styphnolobium protantherum* muestra ciertas afinidades con *S. burseroides*, pero es marcadamente diferente (véase clave); su epíteto hace énfasis en su floración previa a la producción de hojas en la estación seca.

**7. Styphnolobium sporadicum** M. Sousa et Rudd, sp. nov. TIPO: Colombia. Antioquia: Mpio. de Venecia: 4.2 km E of Bolombolo on road to Venecia, Hacienda La Plata, 06°01′N, 75°48′W, 920 m, *J. L. Zarucchi & B. Echeverry 4666* (holotipo, MO; isotipos, CR, HUA no vistos, K, MEXU, US). Figura 2.

Arbores mediani; vel magni. Folia proterantha, 9–13 foliolata, foliolis ovatis, ellipticis vel ovato-ellipticis. Inflorescenciae axillares, pedunculi ad 1 cm longi, rhachides florales 1.5–8(–11) cm longae; bracteoli parvi; flores mediani; calyx infundibuliformis, paullo gibbosus, fere truncatus; ovarium glabrum. Legumina homogenea, glabra, 1–2 seminibus onusta.

Arboles 18–30 m; ramas esparcidamente canescente seríceas cuando jóvenes, pronto glabras,

FIGURA 5. *Styphnolobium protantherum* M. Sousa et Rudd.—A. Ramas con hojas y flores. (Con hojas tomado de *Magallanes 2177*, con flores de *Bullock 1495*.)—B. Flor sin pétalos mostrando pedicelo, bractéolas, cáliz, gineceo, y androceo.—C. Estandarte.—D. Ala.—E. Pétalo de la quilla.—F. Legumbre mostrando las marcas vexilares.—G. Plántula. (Flor, frutos, y plántula tomados de *Bullock 1495*.)

esparcida a densamente lenticelado-verrugosas. Hojas 9–13-folioladas; estípulas ca. 1 mm, triangular-atenuadas a liguladas, pronto caducas; pecíolo 3.5–5.5 cm; raquis foliar 9 13 cm; folíolos alternos, estipelados, las estipelas 0.6–0.8 mm, liguladas, pronto caducas; láminas (4–)6–9.5(–11.5) × 3.5–4(–5) cm, ovadas, elípticas a ovado-lanceoladas, la base obtusa a aguda en ocasiones

cuneada, el ápice acuminado a cortamente acuminado, el haz y envés glabros. Inflorescencias axilares; floración tardía; pedúnculo muy reducido hasta 1 cm; raquis floral 1.5–8(–11) cm; bráctea 1–1.5 mm, triangular-aleznada a linear-aleznada; bractéolas muy reducidas, pronto caducas; flores 15–16 mm; cáliz 4–6 mm, infundibuliforme, algo giboso, pardo a cinéreo velutino, casi trunco; pétalos rosado pálido a purpúreos; estandarte largamente unguiculado, la uña hasta 4 mm; ovario glabro. Legumbre 4.2–10 × 2.2–2.7 cm, torulosa, homogénea, glabra, sésil a estipitada, el estípite hasta 2.5 cm; semillas (maduras se desconocen), 1–2 por fruto. Plántulas se desconocen.

*Distribución y hábitat.* Esta especie aparentemente tiene una distribución amplia y esporádica, en selvas altas subperennifolias con *Brosimum alicastrum* Sw. sobre litosoles calizos en altitudes entre 50 y 500 m, en el norte de Oaxaca, México; en altitudes entre 300 y 600 m en la reserva de El Imposible en El Salvador; en selvas medianas caducifolias a 920 m, en el Valle del Río Cauca, Antioquia, Colombia. Florece en marzo y fructifica en el norte de Oaxaca a finales de mayo y en El Salvador a finales de noviembre.

*Nombres vernáculos.* Almendrillo, almendrillo de montaña (en El Salvador).

*Paratipos.* MEXICO. OAXACA: Distr. Tuxtepec, Mpio. Santa María Jacatepec, camino a Cosolapa San Antonio, Ejido de San Felipe Tilpa, 13.3 km al SO de La Reforma, *R. Torres 12168* (MEXU); Mpio. Santa María Soyaltepec, lado sur del vertedor de la Presa Temazcal, *L. Cortés et al. 237* (MEXU, MO). EL SALVADOR. AHUACHAPAN: Hacienda El Imposible, *D. A. Cáceres 39* (MEXU), *J. A. Tablas s.n.* (MEXU).

Esta especie es la que tiene la distribución más amplia del género, y por lo incompleto del material (se desconocen sus flores) en su límite norte en Oaxaca, Mexico, es díficil precisar si en realidad estamos tratando solamente con una sola entidad taxonómica o dos; sin embargo, por los caracteres disponibles no nos es posible separarlas convincentemente. El epíteto hace referencia a la distribución esporádica de esta especie.

**8. Styphnolobium burseroides** M. Sousa, Rudd et Medrano, sp. nov. TIPO: México. Puebla: 7 km al sur de Molcaxac, 1,800 m altitud, en selva baja caducifolia sobre ladera caliza, 9 junio 1984, *F. González Medrano 14126* (holotipo, MEXU; isotipos, MEXU, MO). Figuras 1C, 2, y 6.

Arbores parvi; folia 15–21 foliolata, foliolis ovalis, oblongis, vel late ellipticis, subtus arachnoidei-canescentibus. Inflorescentiae axillares; flores coaetanei, mediani; calyx valde gibbosus, 5-lobatus; ovarium sericeum. Legumina maculis ochraceis, laevibus praedita, subra semina glabescentia. Plantulae hypogaeae, eophyllis cataphyllis reductis.

Arboles 4–10 m; corteza externa escamosa, exfoliante; ramas densamente canescente velutinas a tomentosas cuando jóvenes, pronto glabrescentes. Hojas 15–21-folioladas; estípulas 2–3 mm, angostamente triangular-atenuadas, pronto caducas; pecíolo 0.2–1 cm; raquis 6–10.5 cm; folíolos alternos a opuestos, en ocasiones estipelados, las estipelas 0.4–0.6 mm, liguladas, frecuentemente faltan; láminas 1.4–2.2 × 0.7–1.2 cm, ovadas, oblongas a anchamente elípticas, la base obtusa, el ápice obtuso, apiculado a mucronulato, el haz canescente velutino a piloso, el envés canescente aracnoideo. Inflorescencias axilares; floración coetánea; pedúnculo muy reducido a nulo; raquis floral 1.2–4 cm; bráctea ca. 2 mm, linear-oblanceolada; pedicelo 2–3 mm, densamente canescente velutino a piloso; bractéolas 0.5–0.6 mm, lineares, pronto caducas; flores 14–15 mm; cáliz 5–6 mm, ciatiforme, marcadamente giboso, esparcidamente canescente piloso, más densamente sobre los lóbulos, 5-lobado, los lóbulos hasta 1 mm, triangulares; pétalos rosados, excepto el estandarte que es blanco con máculas verde-amarillentas; estandarte largamente unguiculado, la uña hasta 4.5 mm; ovario densamente canescente seríceo. Legumbre 4–10.5 × 1.6–1.7 cm, torulosa, con marcas ocres y lisas en el margen vexilar, esparcidamente pilosa a glabrescente excepto sericea en el estípite, constricciones y rostro, estipitada, el estípite hasta 2 cm; semillas 2.3–2.5 × 1.4 cm, 1–2(–3) por fruto. Plántulas con los cotiledones hipogeos, los eófilos reducidos a catáfilos. $2n = 28$.

*Distribución y hábitat.* Endémico de la región sur del Desierto de Tehuacán, en los estados de Oaxaca y Puebla en México, en vegetación de selvas bajas caducifolias con *Cephalocereus* sp., *Bursera* spp., *Acacia coulteri*, *Actinocheita filicina* (Sessé et Mociño) Barkley, *Leucaena*, y *Wimmeria*, en matorrales esclerófilos con *Actinocheita*, *Rhus*, y *Brahea* siempre sobre suelos someros, negros, de origen calizo, en altitudes entre 1,520 y 1,900 m. Florece en marzo y junio y fructifica en julio y marzo.

*Paratipo.* MEXICO. OAXACA: Distr. Huajuapan de León, Yucumduchi, 10 km al N de Huajuapan en los límites de Puebla–Oaxaca, *A. García M. & R. Torres C. 1442* (MEXU); Distr. Teposcolula, a 3 km al NO de Tamazulapán, carr. Tamazulapán–Huajuapan de León, *E. Matuda 28424* (MEXU, MO). PUEBLA: Mpio. Huehuetlán, *P. Tenorio L. & A. Salinas 11539* (MEXU,

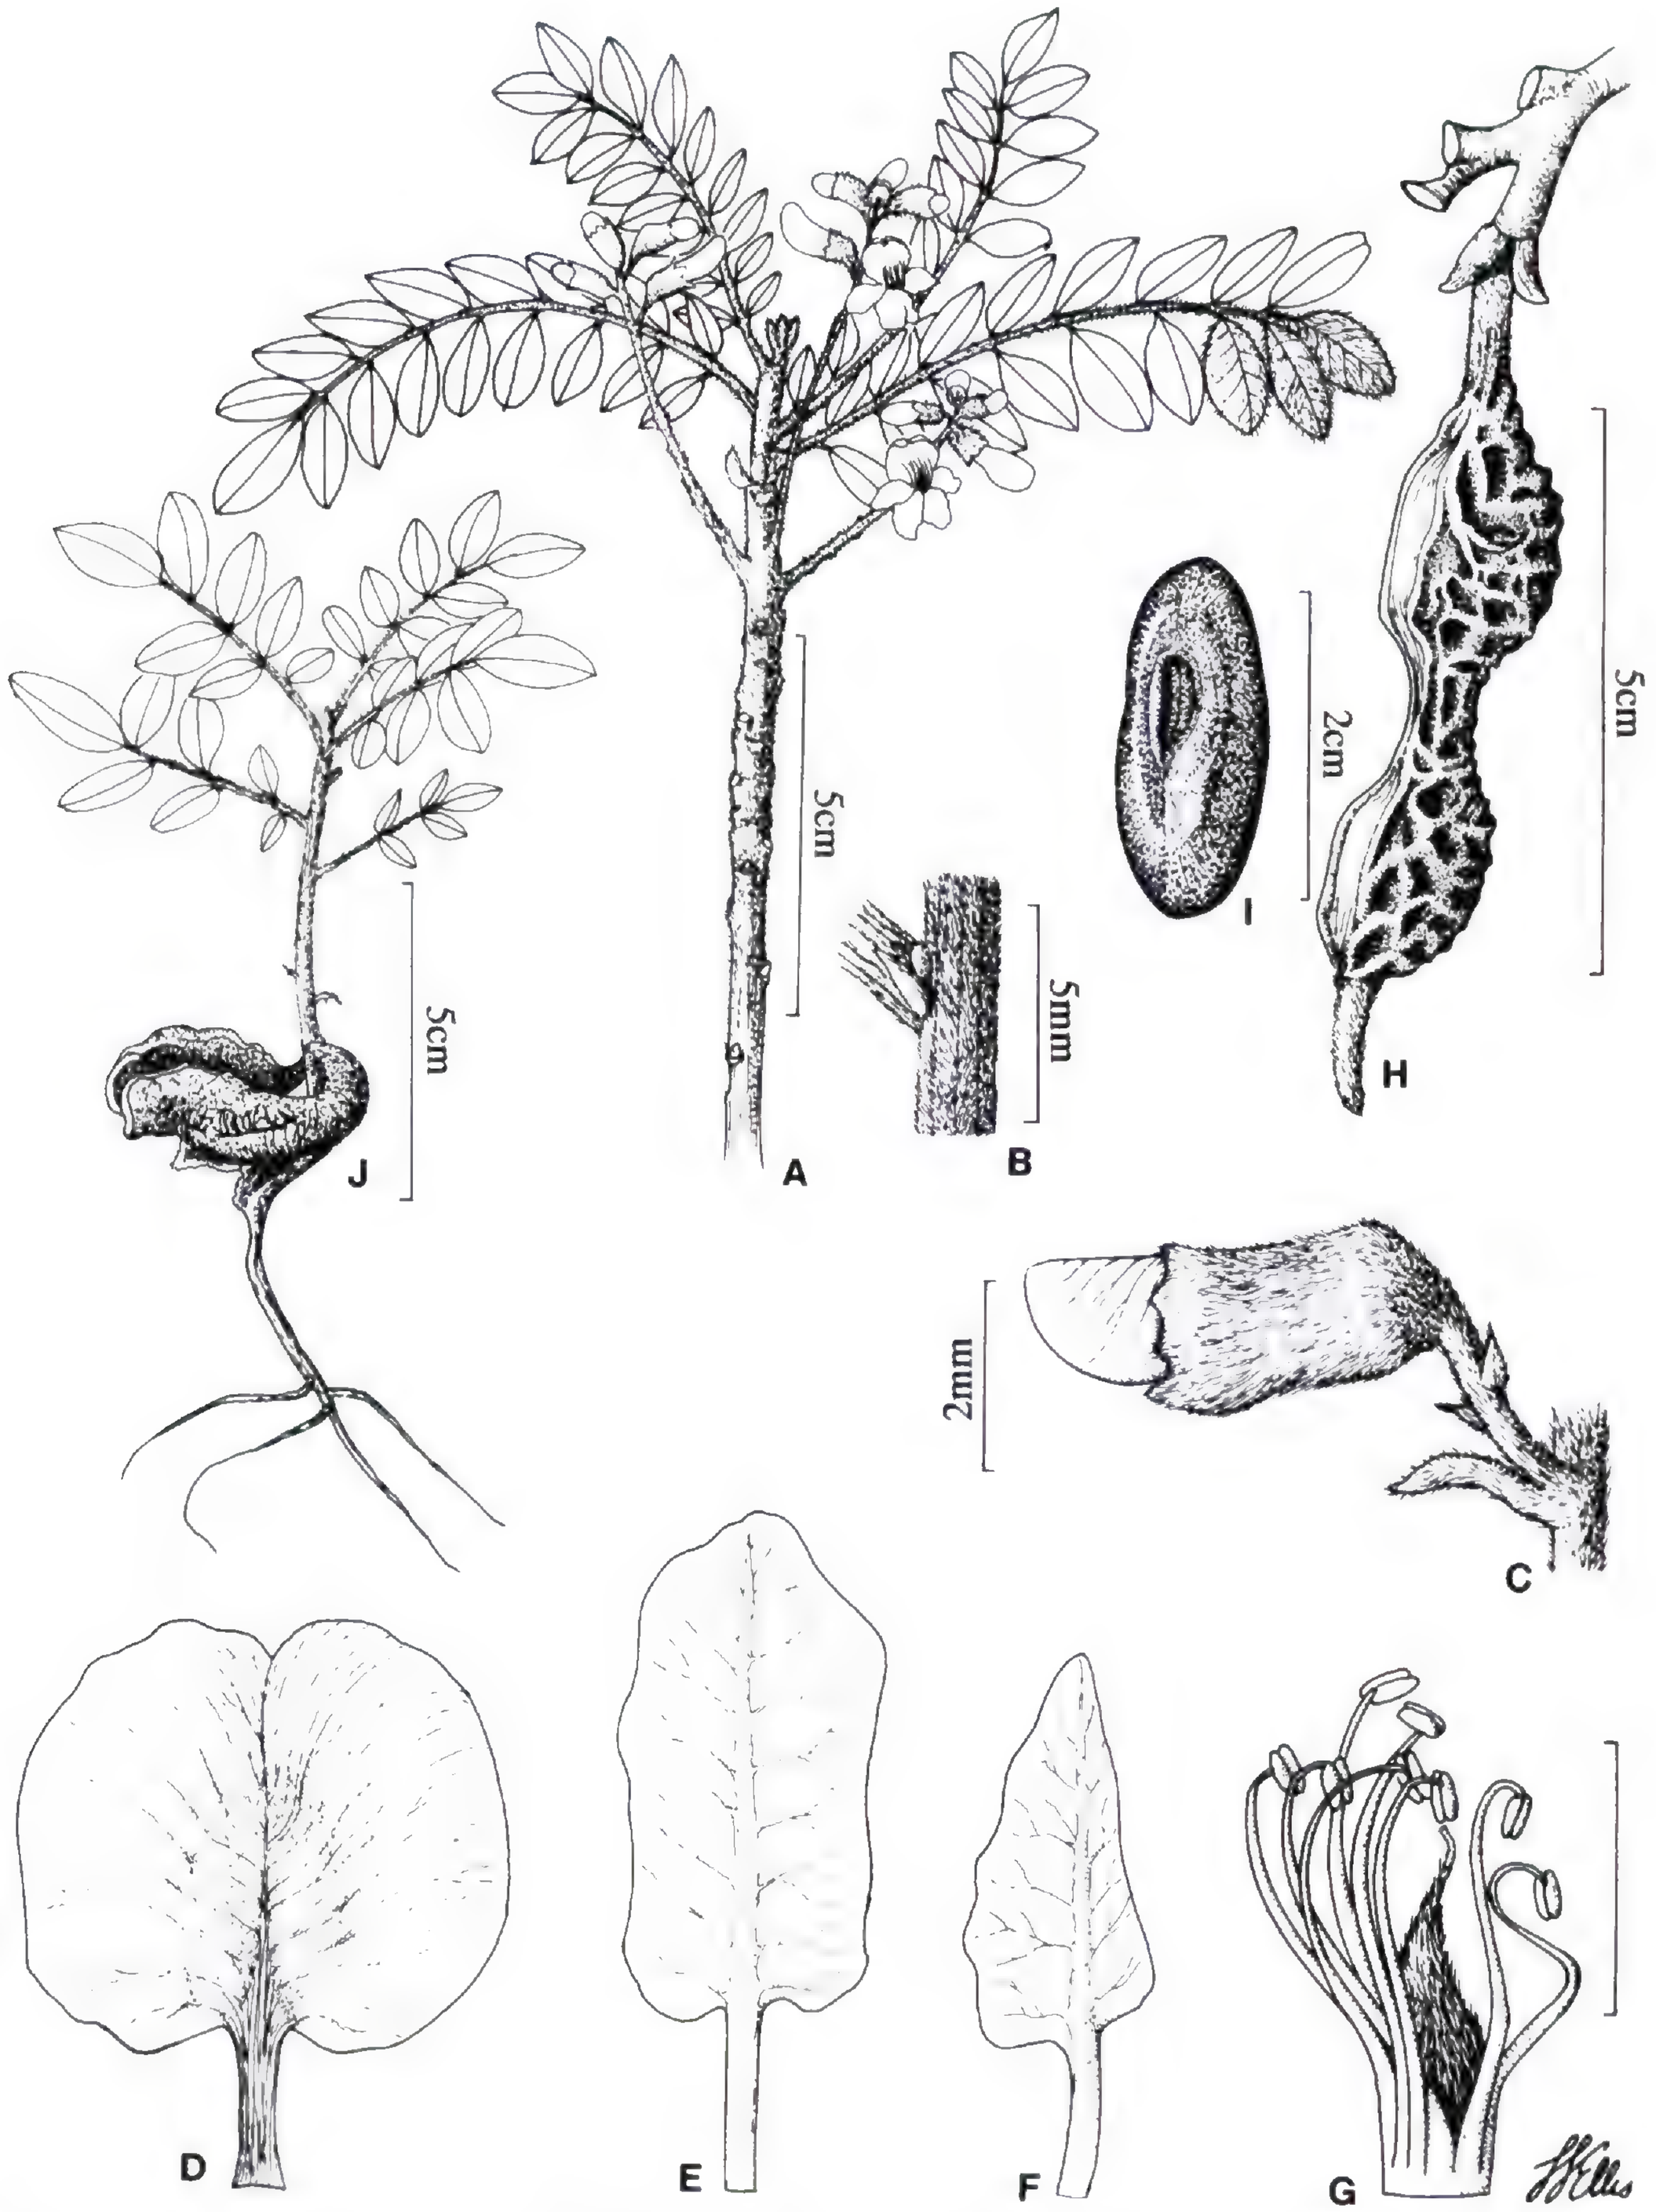

FIGURA 6. *Styphnolobium burseroides* M. Sousa, Rudd et Medrano.—A. Rama con inflorescencias.—B. Detalle de estípula.—C. Botón floral mostrando bráctea floral, bractéolas, y cáliz giboso, lobulado. (Tomadas de *González Medrano 14126.*)—D. Estandarte. —E. Ala. —F. Pétalo de la quilla. G. Gineceo y androceo. (Tomados de *Guízar N. 1343.*)—H. Legumbre mostrando las marcas vexilares. (Tomado de *Sousa 11952.*)—I. Semilla. (Tomada de *Guizar N. 1343.*)—J. Plántula. (Tomada de *Sousa 11959.*)

MO); Mpio. Izúcar de Matamoros, paraje Infiernillo, 12 km al SE de Raboso, dentro de la cuenca Vistahermosa, *E. Guizar N. 1343* (MEXU); Mpio. Molcaxac, 8–19 km al S de Molcaxac, carr. hacia San Juan Ixcaquixtla, *F. Chiang & A. Valiente 2005* (MEXU, MO), *Chiang et al. 2149* (MEXU), *F. González Medrano et al. 11727* (MEXU), *M. Sousa et al. 11952* (MEXU), *11959* (MEXU).

Especie muy característica tanto por la pelosidad en sus hojas, su cáliz fuertemente giboso y dentado, las contrastantes marcas de sus frutos, y las plántulas con cotiledones hipogeos y los eófilos reducidos. El nombre específico aduce a su superficial semejanza con el género *Bursera* tanto en sus hojas, como en su corteza que se exfolia.

# DIFERENCIAS CROMOSOMICAS ENTRE ALGUNAS ESPECIES DE LOS GENEROS *SOPHORA* L. Y *STYPHNOLOBIUM* SCHOTT[1]

*Guadalupe Palomino,*[2] *Patricia Martínez,*[2] *Carmen Bernal,*[2] *y Mario Sousa S.*[3]

## Resumen

En este estudio se determinó el número cromosómico ($2n$) y cariotipo de *Sophora secundiflora*, *S. velutina* var. *zimbabweensis*, *S. tomentosa*, *Styphnolobium japonicum*, *S. parviflorum*, *S. protantherum*, *S. burseroides*, y *S. conzattii*. Las tres primeras presentaron un $2n = 18$, un número básico $x = 9$, pequeñas variaciones en sus cariotipos, y un par de cromosomas con constricción secundaria. Las cinco especies restantes, mostraron $2n = 28$, $x = 14$; sus cariotipos fueron muy similares y presentaron tres pares de cromosomas con constricción secundaria. Los resultados apoyan la propuesta de Sousa y Rudd de incluir al grupo de especies con $2n = 28$ en el género *Styphnolobium*.

## Abstract

In this study chromosome numbers ($2n$) and karyotypes of *Sophora secundiflora*, *S. velutina* var. *zimbabweensis*, *S. tomentosa*, *Styphnolobium japonicum*, *S. parviflorum*, *S. protantherum*, *S. burseroides*, and *S. conzattii* were determined. The first three species presented $2n = 18$, with a basic chromosome number of $x = 9$. These species had small variations in their karyotypes and one chromosome pair with secondary constriction. The other five species presented $2n = 28$, $x = 14$ and their karyotypes were very similar, three pairs showing secondary constrictions. These results agree with Sousa and Rudd's proposal to include species with $2n = 28$ in the genus *Styphnolobium*.

El género *Sophora* L. pertenece a la familia Leguminosae (= Fabaceae) y a la tribu Sophoreae. Se encuentra distribuido en las regiones tropicales y templadas de ambos hemisferios, y es un género grande y variable. Rudd (1972) señala que ciertas especies podían tratarse en géneros diferentes. Polhill (1981) señala entre 45 a 50 especies para el género, Rudd (1968) señala 75, mientras que Yakovlev (1967) enlista 40.

Rudd (1968) coloca a *Styphnolobium* Schott en sinonimia bajo *Sophora*. A *Styphnolobium*, sin embargo, se le ha dado reconocimiento como categoría infragenérica, así Yakovlev (1964) y Rudd (1972) lo reconocen como sección en el género. Hasta hace poco sólo se había hecho la transferencia a *Styphnolobium* de *Sophora japonica* y *S. affinis* y recientemente Sousa y Rudd (en Sousa, 1990) hacen lo propio con *Sophora conzattii* y describen una nueva especie para Nicaragua: *Styphnolobium caudatum*.

Entre 1981 y 1984 personal del Herbario Nacional de México (MEXU) colectó ejemplares aún no registrados para la ciencia y cuyas características hacían pensar en plantas pertenecientes al género *Sophora*. Comparando estas nuevas especies con material de *Sophora japonica*, *S. affinis*, y *S. conzattii*, Sousa & Rudd (1993), observan diferencias entre estas especies con especies del género *Sophora*, ubicando estos autores a las primeras en el género *Styphnolobium*.

[1] Este trabajo fue financiado en parte por la OEA, Proyecto: Estudios Biosistemáticos en Algunos Géneros de Leguminosas, Liliaceas y Palmas de México: Citogenética, Bienio 88–89, PRDCyT-OEA y por el CONACyT CLAVE PCCNCNA-022645.

Se agradece al Herbario Nacional MEXU de la Universidad Autónoma de México el haber proporcionado las semillas de *Sophora secundiflora*, *Sophora tomentosa*, *Styphnolobium protantherum*, *Styphnolobium burseroides*, y *Styphnolobium conzattii*; al Herbario Nacional-Jardín Botánico de Zimbabwe, las semillas de *Sophora velutina* var. *zimbabweensis* y a la Universidad de Lisboa, las de *Styphnolobium japonicum*, para realizar esta investigación.

Agradecemos a Javier Martínez Ramón la obtención de las fotografías de este trabajo.

TABLA 1. Números cromosómicos ($2n$) y cariotipos de tres especies del género *Sophora* L. y cinco del género *Styphnolobium* Schott.

| Taxon | Localidad | Número cromosómico ($2n$) | Fórmula cariotípica | Constricción secundaria |
|---|---|---|---|---|
| *Sophora secundiflora* | México, Tamaulipas: Mpio. de Maquihuana, ej. La Peña, *Malda s.n.* México, Tamaulipas: Mpio. Bustamente, ej. Felipe Angeles, *Martínez s.n.* | 18 | 6m + 3m − sm | 1m |
| *Sophora velutina* var. *zimbabweensis* | Zimbabwe: semillas proporcionadas por el Herbario Nacional-Jardín Botánico de Zimbabwe | 18 | 6m + 3m − sm | 1m |
| *Sophora tomentosa* | México, Quintana Roo: Pto. Morelos, *Sousa 10995* | 18 | 4m + 4m − sm + 1sm | 1m − sm |
| *Styphnolobium japoicum* | Cultivada: semillas proporcionadas por el Jardín Botánico de la Universidad de Lisboa, Portugal | 28 | 13m + 1m − sm | 3m |
| *Styphnolobium parviflorum* | México, Veracruz: Mpio. Sn. Andres Tuxtla, *Ibarra s.n.* | 28 | 12m + 2m − sm | 3m |
| *Styphnolobium protantherum* | México, Jalisco: Mpio. La Huerta, Chamela, *Bullock 1495* | 28 | 11m + 3m − sm | 3m |
| *Styphnolobium burseroides* | México, Puebla: Mpio. Molcajac, *Sousa 11952, Sousa 11959* | 28 | 12m + 2m − sm | 3m |
| *Styphnolobium conzattii* | México, Oaxaca: Distrito de Pochutla, Cerro Espino, *Torres 4901* | 28 | 13m + 1m − m | 3m |

En un estudio palinológico de cuatro especies del género *Sophora* sensu stricto y seis del grupo *Styphnolobium*, Martínez (com. pers.) observó diferencias en relación a el tipo de retículo, tamaño y forma del grano de polen, estableciendo dos grupos. El primer grupo está formado por: *Sophora secundiflora*, *S. tomentosa*, *S. arizonica*, y *S. macrocarpa* y el segundo grupo está integrado por *Styphnolobium parviflorum*, *S. protantherum*, *S. burseroides*, y *S. conzattii*.

Revisando los estudios quimiotaxonómicos realizados por Izaddoost (1975, 1979) y Bailey (1974), se observa que *S. japonica* y *S. affinis* carecen de alcaloides (Izaddoost, 1975), ácido pipecólico y ácido 4-hidroxipipecólico (Izaddoost, 1979), a diferencia de las otras especies del género *Sophora* estudiadas por Izaddoost (1975, 1979). Además se aprecia que ambas especies contienen el polímero galactomanosa con composición similar (Anderson, 1949; Kooiman, 1971; Bailey, 1974), pero las demás especies del género *Sophora* estudiadas por Bailey (1974) no lo contienen. Reid & Meier (1970) y Bailey (1971), en base a sus investigaciones en la presencia o ausencia de galactomanosa en las semillas de leguminosas, suponen que estos compuestos pueden ser buenos indicadores genéricos. En relación al género *Sophora*, Bailey (1974) indica que aunque él sólo estudió ocho taxa en total, sus resultados parecen ser de considerable interés relativo a la revisión que hace Yakovlev (1967) del género, al colocar a *S. japonica* y *S. affinis* en el género *Styphnolobium*, ya que son las únicas especies que contienen galactomanosa.

Para las especies del género *Sophora* se han reportado números cromosómicos $n = 19$ y 11 y $2n = 16$, 18, 22, 28, y 36 (Federov, 1974; Goldblatt, 1981b, 1984, y 1988).

Goldblatt (1981a) consideró que la tribu Sophoreae tuvo un origen poliploide con $x = 14$, y posteriormente en su evolución ha habido una descendencia aneuploide con la diferenciación de líneas distintas en la tribu. Sólo se tiene conocimiento de $2n = 28$ para *Sophora japonica*, *S. affinis*, y *Cladrastis lutea* (Goldblatt, 1981a).

El objetivo de este trabajo fue obtener el número cromosómico $2n$ y el cariotipo de tres especies de *Sophora* pertenecientes a varias secciones y compararlas con el género *Styphnolobium* del cual se obtuvo información de cinco especies de las diez conocidas (ver Sousa & Rudd, 1993). *Sophora secundiflora* [sección *Calia* (Berlandier) Rudd], *S. velutina* var. *zimbabweensis* [sección *Disemaea* (Lindl.) Yakovlev], y *S. tomentosa* (sección *Aigialodes* Rudd). En *Styphnolobium* se determinaron cariotipos para *Styphnolobium japonicum*, *S. conzattii*, y tres especies nuevas para la ciencia: *Styphnolobium parviflorum*, *S. protantherum*, y *S. burseroides* (Sousa & Rudd, 1993).

## Materiales y Metodos

Las plántulas y las semillas utilizadas en esta investigación fueron proporcionadas por el MEXU, Index Seminum del Jardín Botánico del Instituto de Biología UNAM y Herbario Nacional-Jardín Botánico Nacional de Zimbabwe, Africa (Tabla 1). Todo el material fue determinado por el último autor y los ejemplares de respaldo se depositaron en el MEXU.

Las semillas de las distintas especies fueron sometidas a tratamientos previos a la germinación. Las semillas de *Sophora secundiflora* (Everitt, 1983), *S. velutina*, y *Styphnolobium japonicum* germinaron al ser tratadas con ácido sulfúrico concentrado durante 5–15 minutos, las de *Sophora tomentosa* al remojarlas en agua destilada durante 48 horas y finalmente las de *Styphnolobium protantherum*, *S. burseroides*, y *S. conzattii* con escarificación mecánica. Después de estos tratamientos, se sembraron en cajas Petri con algodón y papel filtro esterilizadas y mantenidas en una estufa a una temperatura de 30 ± 2°C.

Las semillas que germinaron se colocaron en vermiculita para su enraizamiento, regándose con solución nutritiva Hoogland. Posteriormente las plántulas se transplantaron a tierra preparada en una proporción de tres partes de tierra negra por una de tierra de hoja, y actualmente se mantienen vivas en los invernaderos del Jardín Botánico. Para *Styphnolobium parviflorum* se obtuvieron plántulas traídas de la Estación Biológica de Los Tuxtlas, del Instituto de Biología de la UNAM, las cuales fueron mantenidas en los invernaderos del Jardín Botánico UNAM.

Los meristemos radiculares seleccionados para la observación de las células en metafase se obtuvieron de raíces secundarias en división celular activa. Estas raíces tenían una longitud de 1–2 cm y fueron cortadas de 7:30 a 8:00 A.M., pretratadas con el mitostático 8-hidroxiquinoleína a una concentración 0.002 M, durante cinco horas a una temperatura de 18°C y en la obscuridad.

Al término de este tiempo, las raíces fueron lavadas con agua destilada y después se fijaron en solución Farmer (alcohol absoluto y ácido acético glacial, en una proporción de 3:1); en seguida fueron almacenadas en el refrigerador a 4°C, donde pudieron conservarse por tiempo indefinido.

Para realizar la tinción de los cromosomas, las raíces se hidrolizaron con ácido clorhídrico 1 N a 60°C durante 10 minutos y posteriormente se introdujeron en una solución de Feulgen preparada a base de fúcsina básica de acuerdo con García (1988) durante una hora y a temperature ambiente.

El meristemo radicular ya teñido fue cortado y colocado en un portaobjetos limpio, agregando una gota de aceto-orceína al 2%. Después se colocó el cubreobjetos dándole un ligero aplastamiento y golpeándolo con la punta de un lápiz para separar las células y poder observarse al microscopio. Enseguida se fijó la preparación por el método del hielo seco (Conger & Fairchield, 1953) y finalmente se montaron los preparados en bálsamo de Canadá.

Para la elaboración de los cariotipos se seleccionaron 20 células de cada individuo, considerando cinco plantas por población. Las mejores células fueron fotografiadas en un fotomicroscopio III Zeiss, con un objetivo 100× y un optobar 1.25.

Los cromosomas de las células seleccionadas se dibujaron en una cámara lúcida Zeiss. A partir de estos dibujos y de las fotografías obtenidas se elaboraron los cariotipos. La clasificación de los cromosomas se realizó de acuerdo a Naranjo et al. (1986) basado en Levan et al. (1964).

## Resultados

En la Tabla 1 y Figuras 1A–H y 2A–H, se indican los números cromosómicos ($2n$), las fórmulas cariotípicas, y los cromosomas con doble constricción de las ocho especies de los géneros *Sophora* y *Styphnolobium* analizadas.

## Discusion

En *Sophora secundiflora* se observó un $2n = 18$, el cual concuerda con los ya publicados por Atchison (1949), Darlington & Wylie (1955), y

Goldblatt (1981b, 1984). Un $2n = 18$ se determinó para *S. velutina* var. *zimbabweensis* y es la primera vez que este dato se informa, al igual que su cariotipo. El $2n = 18$ determinado para *S. tomentosa* en esta investigación confirma varios conteos previos informados para esta especie por Atchison (1951), Darlington & Wylie (1955), Federov (1974), y Goldblatt & Davidse (1977).

En *Styphnolobium japonicum* se observó un $2n = 28$, el cual está de acuerdo con los ya publicados por Darlington & Wylie (1955), Berger et al. (1958), Federov (1974), Fernandes et al. (1977), y Goldblatt (1981b, c, 1984). Para *S. parviflorum*, *S. protantherum*, *S. burseroides*, y *S. conzattii* se determinó por primera vez en este trabajo un $2n = 28$.

Sobre la base de los números cromosómicos de las ocho especies estudiadas, se encuentran dos grupos claramente definidos, un primer grupo con un número básico de $x = 9$ y un segundo grupo con un $x = 14$. El observar diferentes números básicos en especies relacionadas puede significar, según Löve & Löve (1974), que las mismas pertenecen a géneros distintos, siempre y cuando esta información se relacione con algunas características morfológicas (Moore, 1968), tal como ocurrió en *Hauya* y *Xylonagra* (Raven & Lewis, 1960). Esta situación es la presente en estos dos grupos de especies y los resultados citológicas son apoyados por los características morfológicas diferenciales mencionadas por Sousa & Rudd (1993), donde proponen la ubicación de las especies con $x = 14$ en el género *Styphnolobium*.

En *Sophora secundiflora* y *S. velutina* var. *zimbabweensis* se observó un cariotipo con seis pares de cromosomas metacéntricos y tres pares de cromosomos metacéntricos-submetacéntricos, un par de cromosomas metacéntricos en constricción secundaria. El cariotipo de *S. secundiflora* concuerda con el dibujo de los cromosomas de esta especie encontrado por Atchison (1949).

Kawakami (1930) reportó un $n = 9$ para *Sophora angustifolia* y el dibujo de los cromosomas de esta especie es semejante al cariotipo de *S. secundiflora* y *S. velutina* var. *zimbabweensis*. La única diferencia es que *S. angustifolia* no tiene un par de cromosomas con constricción secundaria.

Los cariotipos obtenidos para *Sophora secundiflora* y *S. velutina* var. *zimbabweensis* son ligeramente diferentes en relación a *S. tomentosa* en la proporción de metacéntricos, metacéntricos-submetacéntricos y submetacéntricos. Estas variaciones en los cariotipos pudieron haber sido causadas por inversiones pericéntricas y translocaciones desiguales (Stebbins, 1971).

Atchison (1949) obtiene para *Sophora tetraptera* y *S. microphylla* un $2n = 18$ y un par de cromosomas con constricción secundaria, concordande con lo que se encontró en las especies con un $2n = 18$ estudiadas en este trabajo.

Los cariotipos de *Styphnolobium japonicum*, *S. parviflorum*, *S. protantherum*, *S. burseroides*, y *S. conzattii* fueron muy parecidos, con tres pares de cromosomas metacéntricos con constricción secundaria. Se pudieron apreciar variaciones en la proporción de metacéntricos y metacéntricos-submetacéntricos, las que pudieron originarse por rearreglos cromosómicos llevados a cabo durante el proceso evolutivo de estas especies (Stebbins, 1971).

Las relaciones de brazos dentro de los cromosomas que comprenden el cariotipo son usualmente similares en poblaciones y especies relacionadas, así como el número básico de grupos de ligamiento génico (Kenton, 1986). Estas relaciones se mantienen en las especies analizadas en este estudio, el primer grupo con $x = 9$ y cariotipos similares entre sí, y son diferentes a las especies que muestran $x = 14$ donde los cariotipos de las cinco especies estudiadas son semejantes entre sí.

Considerando que la tribu Sophoreae probablemente tuvo un origen poliploide con un $x = 14$ y en su evolución posterior generó descendencia con números básicos menores, $x = 8, 9, 11$, por aneuploidías (Goldblatt, 1981a), se puede pensar que el género que se estableció primero fue *Styphnolobium* el que tiene un $x = 14$ y posteriormente por aneuploidías se estableció el género *Sophora* con un $x = 9$.

En base a los resultados obtenidos en este estudio se encontraron dos grupos citogenéticamente diferenciables, un primer grupo con un $x = 9$ y $2n = 18$ formado por: *Sophora secundiflora*, *S. velutina* var. *zimbabweensis*, y *S. tomentosa*, y un segundo grupo con un $x = 14$ y $2n = 28$ integrado

## Monographs in Systematic Botany from the Missouri Botanical Garden Number 43

# Comparative External Pollen Ultrastructure of the Araceae and Putatively Related Taxa

Michael H. Grayum

167 pp., illustrated, softcover, $30.00, plus postage.

This monograph presents the first extensive scanning electron microscope (SEM) survey of pollen of Araceae. Pollen of approximately 380 species of Araceae was studied, representing 99 of the 105 currently recognized genera. An effort was made to obtain material from all subgenera and sections distinguished in the most recent available taxonomic revisions (98 of 114 infrageneric taxa are represented in the study). Standardized, synoptic pollen descriptions are provided for all genera studied, and both whole-grain and high-magnification SEM micrographs are assembled in an atlas of 63 plates and 397 figures. An additional 12 plates and 92 figures summarizing the data accompany a detailed analysis of the polarity and evolution of pollen character states in Araceae. A discussion of the relationships of Araceae to other flowering plants features 15 plates and 104 figures depicting pollen of potential aroid relatives.

# KNOWLEDGE BROKERING: THE MECHANICS OF SYNTHESIS. INTRODUCTION[1]

*Nancy Morin*[2] *and*
*Theodore M. Barkley*[3]

Two items prompted us to propose this topic for the 38th Annual Systematics Symposium held at the Missouri Botanical Garden 4–5 October 1991. One is that scientific libraries have been growing rapidly, with the subsequent reduction in any one person's ability to remain current with his/her field. The other is that we systematists have an important element of synthesis in our work and are sensitive to the need to account for increasing amounts of information.

Systematists fall into two intergrading camps, monographers and students of the flora and fauna. The former study natural groups through a variety of techniques to provide new insights and to elucidate evolutionary relationships; the latter assess and synthesize information, particularly the works of monographers, and they prepare floras and manuals to account for all of the relevant organisms of a geographic region. These floras and manuals make the results of systematic research readily useable to a wider community, for they are a link between those who generate basic knowledge and the consumers of that knowledge. Floras and manuals are ever more important for wise stewardship as mankind becomes more obsessive at impacting the landscape. The Missouri Botanical Garden is engaged in several sizeable floristic projects, so it seemed appropriate to direct this symposium at the nature of information resources and their utilization.

A further factor in planning this symposium is the development of widely available computer capabilities for handling large amounts of information. We are the first generation of systematists to have the technical tools to evaluate the great amounts of information stored in our libraries and natural history collections.

The speakers were selected to present information and views of which systematists are not traditionally aware. We believe that we were fortunate to bring their unique expertise and breadth to this symposium.

The evening speaker, K. W. Bridges of the University of Hawaii, presented a dynamic, multimedia program that impressed those in attendance with innovative ways to consider information. Unfortunately, the program is not amenable to the printed page, and so it is not included here.

---

[1] This and the six articles that follow it are the proceedings of the 38th Annual Systematics Symposium of the Missouri Botanical Garden, *Knowledge Brokering: The Mechanics of Synthesis*. The symposium was held 4–5 Oct. 1991 at the Missouri Botanical Garden in St. Louis, Missouri, U.S.A.

This material is based upon work supported by the National Science Foundation under grant number DEB-8918138. We gratefully acknowledge their support.

# SYNTHESIS: A HISTORICAL PERSPECTIVE[1]

*Theodore M. Barkley*[2]

ABSTRACT

Biology and other scientific enterprises have generated an astonishing amount of information through the traditional techniques of experiment and observation. Little effort has been spent on the analysis or synthesis of the accumulated information, and there is both need and opportunity to do so. Some segment of future biologists must be trained in the emerging technologies for assessing literature and synthesizing information. The techniques of historiography may provide a model.

In 1955, I began graduate school, and in the course of events an advisory committee was formed, a thesis topic selected, the research methods agreed upon, and other routine matters were settled. Shortly thereafter, someone asked, "Have you exhausted all of the literature yet?" It was a perfectly reasonable question, and I set about finding and reading everything written on the topic. If difficult then, it would be all but impossible today. In the intervening years, the literature has "exploded," as they say, and access to it is both complex and incomplete. I cannot imagine asking a beginning graduate student in 1991 if he/she has exhausted the literature and then expecting an honest "yes" in response.

We all can agree that the enterprise of scientists has been productive, for libraries are bulging with the products of our efforts. The stunning success of the Soviets with their launch of the first space satellite, "Sputnik I," in 1957, prompted the U.S. government to increase greatly the amounts of federal support for basic research. Shortly after Sputnik I, generous support began for the whole spectrum of the sciences and technology, through the National Science Foundation, the National Institutes of Health, and various other agencies. We may be justly proud of our science, as we point to the libraries and note the long shelves of data and discussions and conclusions. However, we presume that the products of our science have a utility and significance greater than those we have been finding in them, if we could just synthesize the knowledge that is in hand.

## LITERATURE RESOURCES

The libraries of North American academic institutions are diverse; they were reviewed and ranked recently in the *Chronicle of Higher Education* (1991). There are a few giants, e.g., Harvard, University of California at Los Angeles and at Berkeley, University of Texas, and Yale, which have huge holdings and acquisitions programs. Harvard has nearly 12 million volumes and added 261,846 volumes in the academic year 1989–1990. Most of the major university libraries fall in the range of 1.5–3 million volumes and add about 40–60 thousand volumes per year. My home institution, Kansas State University (KSU), has a bit smaller library, with some 1.2 million volumes and an annual acquisition approaching 40,000 volumes. The KSU library has been growing at 4–6% per year, as have other academic libraries. The implication is clear. The KSU library is currently adding 564,000 inches of new shelf space (= 14,450 m) just to make the holdings accessible, and other libraries can tell of similar additions. The factors affecting the inescapable growth of libraries are treated by Okerson & Stibbs (1991) in a paper titled "The Library 'Doomsday Machine'." Librarians worry about budgetary problems and shelf space. The former can be handled, at least in theory, by appropriating more money; the latter is not so easy. The point is: How can we continue to store and access the accumulating literature?

We systematists are as committed to scribbling as anyone, and we have produced a wonderful trail of literature. Tod Stuessy (1990) has written a fine textbook on the topic, *Plant Taxonomy, the Systematic Evaluation of Comparative Data*, wherein he summarizes the practices and goals of taxonomy in its broadest sense, as seen by one of this generation's notable practitioners of the science.

[1] This paper is contribution No. 92-231-A from the Kansas Agricultural Experiment Station, Manhattan.
[2] Herbarium, Division of Biology, Kansas State University, Manhattan, Kansas 66506, U.S.A.

It is a fine text for beginning graduate students to view the "state of the art," and it is deemed a worthy successor to *Principles of Angiosperm Taxonomy* by P. H. Davis & V. H. Heywood (1963). Both Stuessy and Davis & Heywood draw on wide bases of references, and both have extensive bibliographies.

Davis & Heywood is a tome of 532 pages, of which 44 pages are references, i.e., 8% or 1 page out of 12. Davis & Heywood cite 1,286 references, all published before 1963. On the other hand, Stuessy has 514 pages, of which 83 are references, i.e., 16% or 1 page out of 6. Stuessy cites 2,862 references, of which 1,919, or ⅔ of them, are from between 1970 and 1 July 1988 (the cut-off date in the preparation of the book), or a period of 18½ years. There are some interesting comparisons. Like his predecessors, Stuessy was selective. He gathered information and cited sources to illustrate how taxonomy is practiced, and he was not attempting to be comprehensive. Moreover, some authors and topics were given different degrees of importance by Stuessy than by his predecessors, e.g., H. J. Lam, a theoretician of floral structure, has one work cited by Stuessy and six cited by Davis & Heywood; I. W. Bailey, the comparative anatomist, has one work cited by Stuessy and ten cited by Davis & Heywood; H. G. Baker, the ecological systematist, has three works cited by Stuessy and thirteen cited by Davis & Heywood. Even when we allow for the differences in the predilections of the authors and the different times when they were writing, it is evident that a notable portion of what is published has a certain "shelf life," i.e., it is most relevant for a period of time after it is published, and eventually falls into respectable neglect. Note that the older literature is not wrong merely because it is old, rather, it is just politely forgotten. I wonder how often we have "reinvented the wheel" because of our inability to grasp what is hidden in the literature. E. S. Deevy, a geologist of Yale University, reviewed the relevant literature for his 1949 landmark paper "Biogeography of the Pleistocene," and even at that date he regarded the literature resources as "terrifying."

## Sources of Our Literature

The learning of antiquity has been admired by historians since the Renaissance, and much has been written about the great stores of information in the ancient world. The library at Alexandria surely was a justly fabled treasure of fact and philosophy. However, the literature from antiquity must be read with a different mindset than we moderns have, for books that were handwritten by scribes (rather than printed on a printing press) were written with the notion that they were merely permanent records and were not especially concerned with making a point, i.e., ancient books largely reflected conventional wisdom and were not polemics. Students of Hellenic scholarship note that Theophrastus wrote some rather obscure and elliptic sentences. Probably what has survived are his lecture notes; he had no idea that posterity would hang on his every written word.

The advent of printing from moveable type in the mid-1400s changed forever the ways we record and disseminate information. These changes and their impact are related most interestingly in *From Script to Print*, by H. J. Chaytor (1945). The author was a man of letters at Cambridge University, and he detailed how literate mankind of Europe was apprehensive about the impact of printing. Medieval schooling included a prodigious memory as a component, which printing later obviated. The ability to read had meant previously that a person could read aloud from manuscript texts. Printed books meant that the literate public would learn to read silently and rapidly, and books could be written to argue a case or to be read for personal entertainment. Chaytor was not aware of the irony in his book when he discussed the degradation of the medieval values of learning that were brought about by a new technology. Today, we are uneasy about the revolution of electronic information transfer, and we complain that kids spend too much time watching television. In 1500, people worried that the younger generation was getting hooked on reading.

About 50 years passed before the impact of printing and the realities of mass communication settled onto the literate communities of Europe. It happened nearly concurrently with the start of commercial exploitation of the New World, the rise of nationalism, and the great theological upheavals. Printing meant that Everyman could have a piece of learning and could write about it with the expectation that someone would read what he had written. Printing was essential to put learning into the public domain and, therefore, to the making of modern science.

Written publication was early done in books and in the Latin language of medieval scholarship. By the late 1600s, scientific publication was usually through journal articles in the colloquial languages. The development of scientific publication is detailed by Daniel Boorstin (1983) in *The Discoverers*. The shift of scientific pre-eminence from Italy to north-

western Europe through the 1600s saw, among other things, the rise of the Royal Society of London. Henry Oldenburg, a German who had immigrated to England, became the Secretary of the Royal Society and, in effect, was the general editor of publications. In this capacity, he designed the notion of the journal paper and initiated the *Philosophical Transactions*, which is the type specimen of the scientific journal. We here in St. Louis in 1991 should tip our hats in passing to Henry Oldenburg, for he was the most influential editor in the history of science.

Journals are published by scientific societies, commercial firms, governmental agencies, and rarely today but formerly even by individuals. Journals have two purposes: (1) to communicate information among those who are interested and (2) to record information (i.e., to communicate to later generations). I have no idea how many journals there are, or have been, in botany. Counting the entries in the B-P-H (*Botanico-Periodicum-Huntianum*) or in the *Union List of Serials*, used by librarians, would reveal many thousands.

## The Uses of the Literature

The advent of available modalities (e.g., inexpensive laboratory equipment, easy travel, relatively easy publication) moved the natural sciences from contemplative activity to increased observation and experiment. The 20th century has been the preeminent time for sophisticated observational and experimental methods. The graduate students of this century are trained with the presumption that good science means the addition of new data, derived from observation or experiment. Critical analyses and syntheses of previously published information have rarely been stressed in graduate training. Thus, review papers and state-of-the-art works have not been esteemed quite so highly as publications derived from fresh experiment and/or new observation.

Synthesis and interpretation of information already at hand, however, have always been a part of scholarship. Synthesizers may be recognized as four species, and like many species with which I am familiar, the boundaries among them are not sharp.

*1. Compilers and catalogers* write dictionaries, bibliographies, nomenclatural compendia, etc., with the goal of accounting for everything available on a particular topic. The approach and mindset of a dedicated compiler was described by K. M. Elisabeth Murray (1977) in *Caught in the Web of Words*, a biography of her grandfather, James Murray, whose passion was words and who organized and compiled the *Oxford English Dictionary*.

*2. Integraters* produce expanded catalogs that are edited to conform to a point of view, e.g., an encyclopedia that carries a particular view of mankind, or a regional or continental flora that implies a certain uniformity of taxonomic interpretation. Integration involves scientific judgment on the part of the integraters. A lucid but lengthy apologia for integration was presented by Jean Le Rond d'Alembert in 1751 as an introductory essay to the magnum opus of the French Philosophes, the *Encyclopédie* of Denis Diderot (d'Alembert, 1963).

*3. Digesters* selectively seek data and ideas from the literature and derive a comprehensive treatment to tell a story or instruct novices. Digesters write textbooks and state-of-the-art compendia. The aforementioned works of Stuessy and Davis & Heywood are examples of the works of digesters.

*4. Assimilators* are those who compile, integrate, and digest the works at hand. Assimilators produce expanded insights and new conceptual schemes. Among the great examples are the works of James Hutton and Charles Lyell, who assimilated the available information into the theory of Uniformitarianism and created modern historical geology. The Russian chemist D. Mendeleev likewise created the periodic table of the atoms through insightful assimilation. And so, too, with Charles Darwin and Alfred Russell Wallace, inter alia, who made the theory of evolution scientifically respectable. A notable current venture of assimilation in systematic botany is the preparation of a refined general system of classification to account for the present level of understanding in a justifiable phylogenetic scheme. Those engaged in this project include Armen Takhtajan (1980, 1991) in St. Petersburg, the late Arthur Cronquist (1981, 1988) in New York, and Robert Thorne (1976, 1983) in Claremont. Another contemporary assimilator of considerable influence is Lynn Margulis, who has developed the notion that the eukaryotic cell is derived from a prokaryotic ancestor that co-opted other prokaryotes, which, in turn, evolved into the intra-cellular organelles that are typical of the eukaryotes (Margulis, 1981). The elucidation of the genetic code rested upon some elegant experimental research, but the "central dogma" of molecular biology is an example of assimilation of data from disparate sources (Watson, 1968).

Some great works have elements of all four of these items, e.g., *Die natürlichen Pflanzenfamilien* of A. Engler & K. Prantl (1887–1915) is

largely an integration and digest of what was known, but the approach had an element of assimilation in that the editorial policy sought to use the work as a platform to support a particular understanding of plant evolution.

In recent years, our colleagues in ecology have found it necessary to synthesize their information into a whole that exceeds the sum of the parts, and they have done so by engaging mathematical concepts and computer technology. The resultant efforts are a subspecies of assimilation called "modelling," by which means it is hoped to create a precise depiction of the dynamics of the ecosystem or some part of it.

## A Model for Synthesis

Rather little is written on the methods of synthesizing great amounts of information, or at least little that is current among us biologists. Our colleagues the historians, however, might give us a clue from their methodology. Historians work on a subject for which there is neither experimental nor observational research, by our reckoning. Rather, historians are in the business of organizing and synthesizing diverse sorts of information about people, places, and events, and then composing possible conclusions. Historians note what has happened and then suggest interpretations as to how and why. Histories are written with different ends in mind, and distinctions among historical approaches are as old as written history. Herodotus,"the father of history," told the story of the Athenians' rebuff of the Persians so as to make it a timeless event of cosmic significance, but in the telling, he allowed inaccuracies of fact and some fanciful interpretations. Thucydides, on the other hand, recounted the Peloponnesian Wars with precise accuracy, but with no suggestion of a relevance that transcended the affairs of Greece. Needless to note, both historians have been read and respected through the ages.

The craft of writing history is called "historiography" and is often taught in history departments as a class for beginning graduate students. There are textbooks and workbooks in historiography, often with titles suggesting methods or techniques (e.g., Stoffle & Karter, 1979). Much effort is given to locating and evaluating sources of historical information, and some effort to the matter of integration of information. Historiographers usually assume an "angle" or a point of view about what is being studied, e.g., a Marxist historian could interpret the Reformation as a struggle among the social classes, whereas a theological worldview would offer a different explanation of events. Alteration of the point of view is termed "revisionism" by historians.

We biologists already share some procedures with historians, for we draw up hypotheses and test them, and we have our own ideologies and methods that are subject to re-evaluation. The point, however, is that historiographers have made a profession of learning to compile and evaluate information from the written record, and we biologists may certainly look to our colleagues in history for guidance and methodologies.

## A Modest Proposal

The time has clearly come to seek the "Broader Synthesis" from the information that is accumulating in the libraries. Most of us are established as practitioners in our professions; we are biologists or librarians or information manipulators, etc., and it is unlikely that many of us are seeking new avenues for our lives. However, please consider the following:

1. As noted earlier, we biologists believe that the products of our research have a value that transcends the miserly accumulation of facts in a library, i.e., our research collectively "means something." We do not often ask to whom it means something, or how it is meaningful. We simply assume that our research is part of a grander scheme, if we could but make the connections. By extension, the proverbial "answer to cancer" is likely to be elucidated by a synthesizer of information sitting at a computer terminal, rather than by a wet-bench researcher.

2. We are the first generation to see the opportunities of widely available electronic syntheses of information. The advent of printing changed the ways we handled information, and now the advent of inexpensive computer technology is assuring new and profound changes in the handling of information.

3. The techniques and mindsets of compilation and synthesis are hardly new—historians have been compiling and synthesizing for centuries.

Thus, we have the motive, the means, and the opportunity to tackle the treasure trove of information in our libraries. I propose:

Let us prepare a new subspecies of biologist, whose primary domain is not the field or laboratory (we have done *very well* at training field-and-lab researchers), but rather whose activity is mining the data in hand, and who is versed in the techniques of historiography as well as the approaches of traditional, observational, and experimental bi-

ology. The new biologist would not be a "historian," i.e., not a student of the history of science, but rather a biologist who addresses the Big Picture, asking new questions and testing hypotheses with the abundant and diverse information in hand. Think of the kinds of topics that such biologists could address, e.g., (a) changes in the structures of the biotic communities of North America since the melting of the Wisconsin ice sheet, (b) the impact of vegetation dynamics on air pollution and climate change, (c) an integration of paleobotanical evidence into the general system of angiosperm taxonomy.

Approaching these synthetic studies would require being well versed in all of the resources, plus having linguistic ability in more than English. Likewise, our newly trained synthesizer would require competence in electronic data management, where, I am told, the capabilities of the hardware far exceed the uses to which it is presently put.

Can we train a generation of biologists to regard the libraries as their sources of information? We will surely do so. But how long will we still have stick-in-the-muds, who assume that measuring a plant in the field or pouring from a test tube in the lab is worth more than asking new questions of data already in hand?

As we plan for our new subspecies of biologists, we would do well to co-opt the librarians early in the scheming. I imagine that they should be prepared for an eager group of biologists who have recently discovered The Library and who will treat it as we now treat our laboratories.

What will make Synthetic Biology a viable field for the future? Certainly two things: (1) some tangible resources to entice academia to engage these people and (2) thoughtful consciousness-raising among biologists to convince our colleagues that The Time Has Come. But the ultimate and compelling reason to study the accumulated body of information is simply because we have built it, and it is there.

## Note

Charles Darwin, Herodotus, James Hutton, Charles Lyell, D. Mendeleev, Thucydides, and Alfred Russel Wallace are noted in the text, but specific citations are not given here. All are historical figures, whose works are widely available, and for whom the abundant secondary literature is most accessible. The connections among Darwin, Hutton, Lyell, and Wallace are well noted by Eiseley (1958).

# THE FUTURE OF SCIENTIFIC COMMUNICATIONS: MORE QUESTIONS THAN ANSWERS[1]

*Arlene E. Luchsinger*[2]

ABSTRACT

The paradigm of scientific literature has been the paper journal for the past 300 years. An economical design is needed for future information acquisition and storage, and the electronic journal may be the model for the future. Four issues seem to drive the production and dissemination of future scientific literature: the development of an acceptable standardized format; the copyright of intellectual property; the use and preservation of the literature; and funding for access to the literature. Today's electronic journals are characterized as being from the not-for-profit sector, originating with faculty members in universities. They are text only, they are not expensive, and they are relatively unknown. Electronic publishing will not supplant paper journals in the near future, but we are in the early stages of electronic communication.

For more than 300 years, scientific journals have been the medium for communicating new ideas and a stable means to chronicle scientific achievement. Before the first journal, correspondence to other intellectuals provided a method to distribute speculations, theories, and philosophies. The exchange of these letters was encouraged by the formation of official scientific academies, and the letters were read to the members who attended the meetings. The secretary of the society often assumed the role of soliciting, receiving, and responding to the letters of the correspondents. The secretary was also responsible for advising those who could not attend the meetings. The monotonous hand copying of the news and ideas for each of the absent correspondents was laborious and time-consuming (Kronick, 1976).

The printing press, Gutenberg's contribution in the mid-15th century, was one of the greatest innovations of history. The printing press had been most successful in producing books and was used in 1665 to produce the first scientific journal, the *Philosophical Transactions* of the Royal Society of London. As scholarly correspondence increased, the character of the scientific journal changed to include original research, reviews of research, book reviews, and news reports. The letters have continued as letters to the editor (Chappell, 1970; Kronick, 1976).

From ancient clay tablets to manuscripts to printed books and journals, microforms, and computer files, libraries over the centuries have obtained, preserved, and organized these sources of information. Before the end of this century, another format will be common in most libraries: information of an electronic design.

Library subscriptions to journals involve a commitment to continue their purchase and preservation on an annual basis. Debate and concern has been growing over the escalating cost of scientific journals and the increasing number of new journals. This expansion of journal literature has provided not only more titles than ever before, but more specialized titles in every discipline. The proliferation of journals (the number doubles every 10 to 15 years) and the shrinking acquisitions budgets of most academic libraries will force the focus of academic libraries from acquiring resources for teaching and research to providing access to information (Broad, 1988; Smith, 1991).

Librarians need to make decisions about how to utilize their resources. Should they acquire paper copies of the information, or provide access to information using electronic means? Will the ability to access other collections be more expensive than continuing to subscribe to the paper copies? Will libraries rely on cooperative borrowing, or shift to purchasing journal articles from commercial

[1] Discussions with William Gray Potter contributed to my understanding of and interest in this evolving field. I thank my colleague, Virginia Benjamin, who read the manuscript and made helpful comments.

[2] Science Library, University of Georgia, Athens, Georgia 30602, U.S.A.

sources? Several commercial providers exist now, and more are projecting entry into the marketplace (Jackson, 1992; Lenzini & Shaw, 1992). What level of staff interface will be needed for the various modes of access? The cost for delivery of an article may depend on the urgency of the requestor and the mode of delivery. That is, articles may be sent by mail, overnight courier, electronic mail, or fax. Who will decide whether a library user needs information immediately or if documents can be delivered after a brief wait by conventional interlibrary loan? Some librarians believe that the institutions that can provide ready access to necessary materials will recruit the brightest faculty and students; those that cannot provide this access will lose the competitive edge (Mitchell & Saunders, 1991).

Four issues seem to be driving the production and dissemination of future scientific literature: format, the copyright of intellectual property, how the literature is used and preserved, and funding for the access to the literature.

## New Approach to Packaging Information

The current paradigm of scientific literature is the paper journal. To change this paradigm, we must approach the current publication dilemmas with innovative mental restructuring, fresh approaches, and renewed imaginations. Because one impetus for change is the increasing cost of paper journals, the change to electronic formats will not happen if the costs are more than the users are willing to pay.

Electronic publishing may be defined as publishing that encompasses all computer-assisted methods for the production, manipulation, and dissemination of information (Brailsford & Beach, 1989). Electronic publishing encompasses on-demand publishing, bibliographic databases, desktop publishing, documents on optical disks, etc., but the electronic scientific journal is a major concern to the academic community. What is the future of the electronic journal? What are the technical problems of production? What are the implications for libraries? How will access to the electronic journal be provided?

The characteristics of today's electronic journal are outlined by Okerson (1990). These journals are from the not-for-profit sector; they originate with faculty members in universities; they are text only; they are free or inexpensive; they have generous copying statements; the circulation or subscription lists are rapidly growing; and they are relatively unknown. A recent publication, *Directory of Electronic Journals and Newsletters* (Strangelove & Kovacs, 1991), lists 30 journals and more than 60 newsletters that are available over electronic networks.

More typical of electronic information implementations are electronic indexes such as *Biological Abstracts* and *Agricola*, which correspond to their paper counterparts. Most college and university libraries have or are planning an on-line catalog of their holdings with author, title, subject, and keyword searching (Burke, 1991; Sitts, 1988). Some libraries have installed journal indexes such as *Medline* and *Current Contents* that are accessed through the on-line catalog. These electronic on-line indexes are available not only to users in the library but also to remote users through dial-up access. On-line journals exist now that are versions of the same title published in paper. The American Chemical Society in the early 1980s made its primary journals available on-line. They are accessible through the on-line database service, STN. Electronic journals could conceivably be archived on a mainframe computer and linked to on-line catalogs.

Rather than subscribing to an entire journal, a profile of a consumer's subject interest could be matched electronically against articles in a wide range of journals. Much more information would be made available than if one subscribed only to those journals that could be supported financially; the cost would be for the articles that were selected. The consumer could be the individual scientist, or a library that serves a scientific community (Lancaster, 1989).

There are some obstacles to the use of electronic media or formats. Illustrations are not a part of current electronic communications. Many scientists lack or do not want to use electronic communications. The medium may appear to be difficult and inaccessible. Most people are accustomed to a paper format for journals, and paper products are readily available through conventional and uncomplicated means (Loken et al., 1991; Okerson, 1990).

Standards are lacking for the format used to convey electronic data. These standards include, but are not limited to, the coding for specific instructions to the computer such as what designates underlining, italics, or paragraph spacing. Standards are absent for encoding and distributing texts and accompanying images. Standardization of symbols and graphics and the rules for their use must

be developed, and there must be interfaces for text and images (Gould & Pearce, 1991; Weber, 1990).

The problem of moving textual material among different types of computers with incompatible operating systems and differing applications software was solved by the American Standard Code for Information Interchange (ASCII). ASCII is a binary code used in all personal computers. However, ASCII lacks the codes for such things as editorial and critical comments, book formatting instructions, printer commands, and other features that add worth to the idea of electronic publications. ASCII text files prevent the use of different fonts such as foreign character sets, mathematical symbols and scientific notation, illustrations, and color. There are other text files that might solve the problem, but may not be practical for users who do not have the necessary software to use those files (Bailey, 1991; Basch, 1991; Kaufman & LeClercq, 1990).

Today's scientific paper publications have high-quality color illustrations. We do not know the limitations of monitor and printer displays, but to be successful, microcomputer hardware must be inexpensive and improved so that the quality of the data reception on screens and printers is high and is as acceptable as paper copy (Bailey, 1991; Weber, 1990).

Another challenge is the establishment of high-speed research networks and their integration into a national networking infrastructure. These networks must have the speed and bandwidth to accommodate an increasing data transmission requirement.

Legislation to establish the National Research and Education Network (NREN) was first introduced by Senator Albert Gore, Jr., in 1988. Each year since then, revised versions of this act have been introduced in both the U.S. House and Senate. The proposal is to connect supercomputer centers and to accommodate the massive amounts of data produced by high-performance computer projects. NREN would expand and improve the existing interconnected group of research networks such as NSFNET, MIDNET, and SURANET that are collectively known as Internet. It is expected to be completed by the year 2000. Federal agencies will be expected to work with state and local agencies, libraries, educational institutions, and private network services to provide access to electronic information resources held by publishers, research facilities, and libraries. The creation of the NREN will expedite the publication of electronic journals (Henderson, 1991; Brownrigg, 1990).

## Copyright

With the invention of the photocopier came the concern that these machines would put some journals out of business. The photocopier removed a section of readers who might have subscribed to a journal if that was the only way they could have acquired the papers they needed. The publishers normally do not receive revenue from these readers (Brailsford & Beach, 1989).

Copyright is not intended as a permanent monopoly, but software vendors have been known to use technical strategies to thwart attempts to copy a program into a user's computer memory (Pool, 1985).

Photocopies may be made of today's paper journals and mailed to a colleague or borrowing library. Fax machines may be used to transport that same copy faster. An article in digital form may be sent from a computer workstation and arrive at one or more distant workstations almost instantaneously. What will keep the receivers of the document from redistributing the material (Weber, 1990)?

Sharing or even reselling books has never been prohibited, and such prohibition would not be enforceable. Colleagues may read information from your computer terminal or ask for a copy of a copyrighted electronic publication you have ordered, paid for, read, and stored in your computer's memory. It is easy to do this; press a couple of keys, and the information is sent to an electronic mailbox. If you comply, you may be disregarding the copyright laws (Pool, 1985; Solomon, 1985).

Enforcement of copyright laws from the commercial publisher's view is an economic, not an intellectual, issue. If copyright cannot be enforced, that is, if the reader does not have to pay to read an electronic document, there would be little incentive for a commercial publisher to distribute merchandise in an electronic format. Will publishers permit storage of their electronic publications in a central site? If copyright is not necessary for commercial publishers to collect revenues, and if a charge is collected for each use of the electronic publications, will copyright be obsolete (Smith, 1991)?

## Using and Preserving Electronic Literature

According to Dillon (1991), scholarly journals are read for several reasons: for work purposes, to keep up with the literature, for reference, or for learning. Her study indicated that readers of academic journals scanned the tables of contents first,

and then rapidly browsed and turned pages quickly back and forth through an article. Electronic versions must have the capability to scroll through pages as well as skip forward and backward through a document. Users of electronic journals will want to perform tasks other than full reading of a text. Paper is more adaptable than a video screen; the white paper and black ink format will not transfer easily to screens.

There is a rush by the scientific community to get information into print. Today the lag time between submitting a paper and seeing it in print is usually from 4 to 18 months. Full-text electronic journals could be printed in any location and forwarded to users, thus dramatically shortening the time lag.

Informal use of electronic mail (e-mail) systems is increasing in academia (Loken et al., 1991; Smith, 1991). Ideas are exchanged, but this communication form has met resistance when it threatens the more formal channels, that is, the refereed journal (Piternick, 1989). The role of the scientific journal today is to provide a mechanism to notify others of the results of research. Publishing is also done for scholarly prestige and the academic reward system. Will electronic publications be acceptable for promotion, tenure, academic honors, author recognition, and increases in salary? If articles published in peer-reviewed electronic journals are not accepted for promotion or tenure, will researchers be kept from fully exploring the possibility of publication in the format? Who will be on the editorial board—only those who are skilled enough to handle the manipulation of electronic text? Will the part of the publication process that is not automated be the editorial work by referees and editors? Will the contributions of scientists who are uneasy about the integrity of scientific data be jeopardized (Eisner, 1991; Gould & Pearce, 1991; Smith, 1991)?

Invasion of privacy may be an issue if publishers of the electronic information systems collect data about subscribers' proprietary interests and sell this information to a third party. Some publishers today sell the subscription lists of their paper publications.

Haywood (1988) described the "electronic aristocracy." They consume, enjoy, and digest electronic information in private without having to share with others. They work in an information-rich environment and can afford the up-front connect and search charges, or they work for an organization that pays these charges. These users could also be termed the "information elite."

A significant portion of the world's population will be the "information poor." These people will not have access to electronic publications. This will be true not only of third-world scholars, but also those in some developed countries. Until language translation systems are available, English will continue to dominate the databases, and those who cannot read English will be "information poor." Inefficient communication and transportation networks, inadequate telephone and mailing services, and a dearth of technical expertise will challenge the development of electronic information delivery in the third world (Haywood, 1988).

Libraries subscribe to and maintain journals that only a few people read or consult when first published. Those journals, however, may build readership in later years as certain papers begin to be cited. Preservation of printed volumes, films, photographs, and slides has been a task of librarians. The paper format has been successful and has endured through the centuries. The librarians of the future dealing with electronic publications may not have the preservation problem—there simply may not be anything to save.

There are several nontrivial obstacles to the preserving of electronic data files. Magnetic media degenerate due to heat, sunlight, humidity, dryness, magnetism, dust, and unintentional erasure. How long will an electronic media exist without self-destructing? Data tapes, hard and floppy disks, and digital optical storage have a lifetime of a few decades (Kaufman & LeClercq, 1990). Who is and who will be doing the archiving of intellectual content of electronic publications?

Soon the technology of today may be obsolete. Will we be able to continuously move stored data from one technology to another? Electronic standards will be more important than ever. It will also be essential that archives of electronic serials be maintained by libraries or other organizations (Bailey, 1991).

## The Economics of Electronic Publishing

Information acquisition and publishing is becoming increasingly centralized. Users of inexpensive packages of information (e.g., books) should not be disenfranchised by the sudden disappearance of information if that information becomes accessible only by electronic means. Users must be able to access the electronic networks at a reasonable cost. Government funding will be needed to bring modern, fast, and relevant information networks to the majority of the population (Bailey, 1991; Haywood, 1988).

The level of university support for networked

publishing ventures is a concern. Endorsement by scholars and publishers is essential. A charge for use could accommodate those for-profit publishers. The noncommercial presses, such as universities and societies, might not be threatened as long as the editorial and review processes remain within their purview (Okerson, 1990; Smith, 1991). Most revenue will come from subscriptions, fees for connect time, royalties for viewing and printing pages, charges from users downloading information, and rental of compatible equipment. There will be less revenue, and nearly all of it will be delayed in coming because most use will be "on demand." Advertising income will be lost. Publishers worry about the revenues they will expend and what the profits will be. They need to know how to make money on this technology (Standera, 1987; Eisner, 1991).

The publishing process for scholarly print journals is financially underwritten by the scholarly community either from page charges or library subscriptions. Government grants may provide funding for the research for new data. This new information is forwarded to a journal publisher, and frequently grants provide the resources for page charges. State and federal governments provide the money for libraries to purchase the information that was formulated by the researchers.

Rogers & Hurt (1990) described a scenario for a Scholarly Communication System. Briefly, scholars could publish and read other publications on this electronic network. The system could also be used as a communication device to seek data from current and archival files. Those with valid passwords could leave signed statements related to the articles they have read in a comments field. An article that had been in the system for six months would be flagged for review. The author would have several weeks to use the responses from the comments section and prepare a final, revised version to submit to a review board. The boards would perform the reviews now undertaken by editors of scholarly journals. If the article was approved by the board, it would become a permanent part of the communication system.

Grants from the participating universities, foundations, and government agencies would provide the capital for establishing the system. Annual fees paid by each academic institution would pay for selection and training of reviewers, honoraria for reviewers, and administrative costs. Operation costs and hourly usage charges would be paid by a membership fee from each institution. Authors whose articles were printed out by the system would be provided with royalty payments. Libraries would have access to the system and could print files using sophisticated printers (Rogers & Hurt, 1990).

This new communication system would provide numerous advantages to colleges and universities. The amount of money spent for subscriptions to publications would be significantly decreased. The need for additional library space would be reduced. The hours spent by library personnel processing, shelving, and reshelving journals could be better spent on helping users find the information they want. The system would establish and enforce the format standards to be used for storing information. Universities would regain control over the review and publication of research. That is, rather than having publishers and their referees decide who gets published, the universities would have a role in choosing the members of review and management boards. The system thus could provide better information for universities to make hiring, promotion, tenure, and salary decisions. In addition universities would regain copyright control (Okerson, 1991; Rogers & Hurt, 1990).

## One Society's Vision

In 1988 the president of the American Physical Society (APS) formed a six-person Task Force on Electronic Information Systems. The extensive report of the Task Force was published in the *Bulletin of the American Physical Society* (Loken et al., 1991). While the report concerns the physics community, the findings and visions may apply to all disciplines.

Some of the findings were: (1) those who have otherwise avoided the use of computers for research are utilizing word-processing on desktop personal computers; (2) many have personal computers that are linked to electronic services and on-line databases; (3) the use of electronic mail (e-mail) through BITNET or Internet has increased in frequency and scope; and (4) e-mail is used for short communications, nonlocal collaborations, and submission of papers (Loken et al., 1991).

The APS vision is for the year 2020, but it may be reached by 2010 or even 2000. Workstations with color-graphic resolution comparable with today's best on-paper printing may be used by the majority of scientists. These workstations may be connected and have access to local or remote servers within seconds. A single, worldwide, fiber-optic network with a structure that is analogous to a highway system with superhighways, state and regional highways, local roads, and driveways is planned. Storage of information will be $10^{-4}$ less

than the cost of storing documents on paper. Software standards will be in place to deal with text, equations, graphics, illustrations, and multimedia output (Loken et al., 1991).

Computerized scientific literature delivered to graphic terminals may have output that is three-dimensional, dynamic, and that can be viewed in arbitrary orientation, with arbitrary magnification, and at variable speeds—all selected by the individual viewer. The user may be able to request documents, sections of documents, or texts to which the original document refers. The user may be able to make comments on the document. The capacity of computers to perform translation of natural languages will be developed. This will permit an author to submit a paper in one language and have it read in the languages of the readers' choice. Authors may submit their manuscripts by electronic submission to publishers using a form that follows an international standard. Messages between referees and editors and between editors and authors may be electronic (Loken et al., 1991).

The APS Task Force felt that there could be separate databases supporting broad subjects. The individual databases could form a central database that would be accessible. Managers of the databases would be responsible for the physical operations such as maintaining the hardware, software, and networking, as well as making and implementing the policy decisions of the supporting organization. This organization could be a government or private enterprise (Loken et al., 1991).

Search strategies will be efficient and easy to use. Entire documents may be indexed by bibliographic information, descriptors, symbols, and perhaps diagrams. Searches will be more interactive; computers will be used as expert systems to lead an investigator through a search. Today, the results of on-line searches are downloaded to paper or floppy diskette. In 2020, downloading will be over the network into computer files (Loken et al., 1991).

Most scientists have a set group of journals they read and use as vehicles for publishing their papers. What impact will the electronic publication and retrieval of documents have on the journal in which it is published? Will journals as we know them exist? Today, many scientific journals are only sold to libraries. The cost to the libraries is the same whether the journal has a large or small readership. In 2020, the use of the electronic publication could be monitored. These observations could be used to determine the number, kind, and extent of any use (Loken et al., 1991).

## Conclusion

Print journals will probably continue as the primary method of scholarly communication in the near future. However, we are in the beginning stages of the development of electronic communication. Paper will not disappear, and the new media will not threaten the future of the printed book. Electronic journals may be read on-line, but most scientists will want a printed copy. Publishing in both print and electronic formats may be necessary, and this will increase the cost to the publisher. Long-term storage will be in electronic formats rather than microfilm and microfiche.

The promise of successful technology alone will not force the acceptance of electronic publishing. The real concerns may be fiscal, legal, regulatory, social, and political factors rather than technological issues. However, as computer technology becomes a central force in scientific dialogue, electronic publishing may supplant the printing press as a comparable force in communication among readers.

# OWNERSHIP AND OUTREACH: A MODEL FOR ADMINISTRATION OF SHARED DATA

*Jean E. Nash*[1]

ABSTRACT

Sharing data is a common practice among researchers in all fields. In most, however, sharing is limited to data passed among a few researchers known to each other. In this paper, issues raised by larger scale, multiple use of data are discussed. The two major issues that arise are ownership of data and access to data generated by others. Ownership is both a legal and a behavioral issue, as yet unresolved. Even without clear consensus on ownership, however, means for promoting multiple use of data that accommodate researchers' concerns can be found. Access issues include which data should be retained, the costs associated with retention and maintenance, and how access to others' data is managed. The Utah Resource for Genetic and Epidemiologic Research (RGE) has developed from a committee of data contributors and data users into a program for management of multiple-use data. Examination of its history and operations gives some insight into how issues of ownership can be managed. From that example, five general components of a multiple-use data management system are generated. Finally, throughout the paper an argument is made for institutional consideration of data management issues at the policy level prior to development of formal data sharing mechanisms.

The concept of multiple-use data in scientific research is not a new one; in fact, sharing data is common among researchers. However, the context of sharing data for most researchers is that of Researcher A sending a data disk or a copy of lab results to Researcher B. This form of data sharing appears to raise no eyebrows within our current research culture. It is when a larger scale is proposed that support for the concept of shared, multiple-use data falters. At that point, promotion of data sharing seems to run into some perceptual roadblocks that, if not addressed, will continue to impede the development of multiple-use data on a large scale. The evolution of the Utah Resource for Genetic and Epidemiologic Research (RGE) has included the development of a certain focus, albeit fuzzy, to the apprehensions that the idea of multiple use of data generally raises. It is my purpose here to delineate the issues involved and then use the experience of RGE to demonstrate how those apprehensions may be addressed. That in turn will serve as the basis from which to generate a model for management of effective data sharing.

I begin with two caveats: first, as the experience of RGE is solely with human subjects data, the issues raised and the model outlined will at times be unique to research with human subjects. However, many of the principles involved should be applicable to other areas of biological research. Second, in the interests of simplicity, I use the following definition of data, which summarizes the lack of consensus on a single definition among researchers and administrators considering data sharing: Data are whatever the researcher designates as such (derived from remarks, U.S. Public Health Service, 1990).

## OWNERSHIP

Perhaps the pivotal concern raised in any discussion of data sharing is that of data ownership. Who owns the data generated in the course of scientific research? As demonstrated by the results of a workshop on "Data Management in Biomedical Research" convened by the Public Health Service in April 1990, consensus on this issue does not exist. Investigators who have generated data in their research regard those data as "theirs." The PHS stated that "When PHS awards a research grant, the data developed by the grantee institution are owned by the grantee institution . . . ." Institutions that receive grants and support investigators (many of whom wrote the grant proposals in the first place) are caught in the middle.

Ownership, in a legal sense, deals with property and one's rights to use of that property. Ownership

[1] RGE, School of Medicine, University of Utah, Salt Lake City, Utah 84132, U.S.A.

ANN. MISSOURI BOT. GARD. 80: 304–308. 1993.

is important, as Fishbein (1991) pointed out, because ". . . whoever owns also controls dissemination, especially the timing of dissemination, publication and proprietary rights. Moreover, whoever owns data also has the ultimate ability to control their preservation and destruction." Basing her argument about data ownership on the principle of "works-for-hire," Fishbein agrees with the position taken by the Public Health Service that institutions are the owners of data generated in the course of federally supported research. It is her assertion that "this basic principle regarding ownership of data is [not] open to debate as a legal matter." In her opinion, the problems raised by the question of ownership are, in fact, ethical problems of appropriate conduct, rather than legal ones.

In legal terms, the Public Health Service and Fishbein are correct about ownership of data. I differ, however, with Fishbein on the roots of the actual issues with which we deal. Issues of what is, or is not, ethical conduct in the sciences are secondary consequences of the important aspect of human behavior just noted: scientists who have generated data regard them as "theirs." It may be a logical argument that, since most university policies and procedures manuals exempt certain products of scholarly work from university ownership, those products not exempted are indeed owned by the university. Viewing the exempted scholarly works from another perspective, however, a different logic appears.

The book or article or review is owned by the author, who generated it. On this, we all can agree. Moving backward, the book or article or review is usually based on data generated by the author.

If the product is owned by the person who generated it, how can it be that some of the pieces of the product, generated by the same person, are not "owned" by that person also? In behavioral terms, although not perhaps in strictly legal terms, data and product seem inextricably intertwined. Ownership of one appears to confer ownership of the other. Any resolution of the issue of ownership must accommodate this perspective.

## Ownership: Responsibility and Stewardship

Resolution of this disagreement between human and legal realities will take many forms. The concept of stewardship mentioned by Fishbein is one that maximizes the utility of the data, while minimizing friction over ownership. No matter who owns data in a strict legal sense, all parties benefit from appropriate management of those data. In policies regarding data being developed at the University of Utah, it is proposed that a fundamental relationship to data be that of responsibility. Differing parties in the university community have differing responsibilities to each other and to the data generated there. As examples: The university has a responsibility to protect the research interests of all members of its community. To do so, it may be necessary to require that an investigator who moves to another university take responsibility to ensure that data generated by his/her team are available to all members of the original research team. Or: For a researcher to enjoy the benefit of the university's responsibility to deal appropriately with allegations of research misconduct, the researcher must take responsibility to maintain data in a form that facilitates resolution of those allegations. Focus on the various responsibilities for data acknowledges their value for both individual and collaborative work and encourages productive use of data while protecting the interests of all parties. Final resolution of the issues of ownership will probably occur with the evolution of the scientific culture. During that process, however, specific institutional policies regarding data provide mechanisms by which work can proceed without undue constraint. However, as noted in the 1989 Institute of Medicine report, "The Responsible Conduct of Research in the Health Sciences," "few academic institutions have established explicit standards for responsible research practices . . . ." Without such policies, Fishbein's conclusion that ". . . if the academy does not come to a consensus—preferably in some formal way—about the ethical and professional obligations of researchers in stewardship of their research data, the courts or the government may do it for them" is unfortunately logical and predictable.

## Access

The other major category of concerns usually raised about data sharing is access. In order for data to be shared (that is, used by someone other than the generating researcher) they must be retained, maintained and accessible. The volume of research data, enormous in the biomedical arena alone, limits the feasibility of this. Even in large, well-funded programs that rely on sharing of data, such as the Human Genome Project, problems of size and access have arisen (Aldous, 1991). We will have to make some difficult decisions as to which data are kept for shared use. Prospective utility of data will have to be evaluated relative to the costs of retention, maintenance, and accessi-

bility, preferably on an institutional level, so that resources may be allocated in the most effective manner. What is effective will vary from institution to institution, and from one college or department to another within a given institution. If we wish to encourage sharing of data, problems associated with retention, maintenance, and accessability must be identified so that practical solutions can be found.

### Access: Retention

Which data justify retention? At the 1990 PHS data management workshop, substantial agreement was reached on retention of certain types of data. The first type of data were those that were expensive to generate. Epidemiological data were cited in this category, as were data from longitudinal studies. The sheer scale of most such research makes the data generated very expensive. Making such data available for multiple use reduces the cost of future work in those areas, as well as in areas not yet foreseen. The second kind of data to be retained were those that are no longer replicable (or that would be extremely difficult to replicate). The major example noted here was studies on species that are no longer available for research purposes. The final category of data to be kept, and the one for which there was much less agreement than the above two, was data that had significant public policy implications. Keeping these data ensures that the foundations of the policies are as open to review as the policies themselves. Within a given institution, other types of data may be deemed worthy of retention; these are mentioned here only as examples of some data retention recommendations.

The benefits of retaining certain data for multiple use can be agreed upon. There are, however, other factors in the decision to make data available for multiple use. Chief among these are the costs of retaining/maintaining the data and costs associated with providing access to them.

### Access: Storage Costs

The first set of costs associated with data sharing are those incurred in storing data. Data may be stored as hard copy (such as lab notebooks, X-rays, photographs, printouts) or electronically. Either form of storage entails space costs. Space, on computers or in filing cabinets, is a valuable commodity in most institutions. Its costs may be onetime, such as purchase of filing cabinets, or ongoing, as in monthly charges for electronic data storage. In the case of most epidemiological data, for example, size is a significant factor in space calculations. Furthermore, how data are stored may be a factor in accessibility. For example, data on a tape in archives are not as accessible as data present online and may thus not be as valuable to another researcher. Minimizing storage costs may also minimize utility, thus subverting the purpose of storing the data.

### Access: Confidentiality

A second element in decisions about the cost of some data retention is confidentiality. Maintenance of human subjects data requires strict protections for the privacy of the subjects and the data about them. Locking file cabinets, appropriate computer security procedures, and staff training in appropriate data handling methods are necessary. Personnel and personnel training are necessary appropriate maintenance of confidential data. Costs are both onetime and ongoing.

### Access: Cataloging Costs

Another major factor in the costs of maintaining data for multiple use is cataloging. A prospective data user needs to know exactly what the data are, where they reside, in what format they are available, and what the access procedures are. While oversight by the generating researcher is absolutely necessary to the cataloging process, creation and upkeep of data descriptions is not an appropriate use of researchers' time. Personnel becomes a significant cost determinant here.

### Access: Management

The final area of questions raised about access is who will have access to the data and for what purposes. At this point, the human logic about ownership is significant. Researchers have concerns about what others will do with "their" data. Will it be used to further scientific inquiry or perhaps for purposes of discrediting the generating researcher? Will it be used to do work the researcher has planned to do? Will it be used in research that is not sound? These are legitimate concerns. Allowing the generating researcher to control access to his/her data resolves them. However, requiring a scientist to manage use of the types of data identified as valuable for multiple use would add an intolerable burden of administrative work. Appropriate management of access requires development and administration of mechanisms that allow reasonable control by generating researchers yet promote maximum use by others. As in retention/maintenance, costs here are associated with personnel and the media in which data are stored.

Costs of data retention, maintenance and access for multiple use clearly exceed the capacity of single researchers or even of most research groups. Thus, in order to promote data sharing in the biological sciences, the costs must be accepted on an institutional level. RGE is an example of one such institutionally supported data sharing program.

## History of RGE

RGE is a data administration program supported at the University of Utah. Its primary responsibility is a large electronic database of records on past and present residents of the state, which is used in genetic, epidemiologic, and demographic research. It began the the mid-1970s when University of Utah researchers interested in genetic epidemiology obtained family history records from the Genealogical Society of Utah and received permission from the Church of Jesus Christ of Latter-Day Saints (LDS or Mormon) to compile family history records (three-generation genealogies) into a computerized genealogical database. At the same time, the growing group of researchers began to computerize death certificates from the Utah Department of Health and cancer records from the Utah Cancer Registry. Both of those data sets, along with the 1880 U.S. census of Utah, were linked to the genealogical records. By the early 1980s, research uses of these data were extremely varied: cancer epidemiology, historical demography, cancer genetics, genetics of autism, epidemiological research into the effects of nuclear fallout, and genetics of early coronary disease were the major areas of research. The management needs occasioned by the diversity of research projects using an aggregate of private, public and research data were the impetus behind the creation of RGE.

## RGE Operations

Perhaps the single most important facet of RGE is that it functions as an intermediary between data contributors and data users. RGE "owns" neither data nor research. Data contributors own their data and negotiate agreements with RGE regarding how those data may be used. Data users own their research projects and work with RGE to complete projects within the constraints of the data agreements. RGE has custody of the data and the responsibility to ensure that the agreements are upheld.

With this structure, many of the ownership issues that impede data sharing fade from importance. Dissemination and publication, issues of ownership identified by Fishbein, are but insignificantly different from other research practices. While publications using RGE-held data are reviewed, the reviews are limited to ensuring that certain agreed-upon protocols are used. Control over preservation and/or destruction of new information (data) created by the data user is retained by the user. Control over preservation and/or destruction of data created by the data contributor is, as defined in the agreements described above, retained by the contributor.

The issue of the constraints on the use of data placed by the data contributor is a more thorny one. Where data ownership is absolutely clear, as with the LDS Church family history records, the data contributor may impose whatever restraints on usage desired. Publicly held records, such as those from the Utah Health Department, are subject to state law and regulation, with which few would argue. Our experience with data generated solely by researchers and then given to RGE custody is limited. That limited experience leads me to propose, however, that if agreement can be reached on the need for retention of certain data, agreement can be reached on appropriate use, as well as on protections for the data contributor. However, such agreements are considerably easier to reach if the institution has already defined its policies regarding management of data. In those circumstances, the outlines of a culture of multiple-use data have already been traced.

The data within RGE's custody fit the criteria for retention described above—they are data that would be very difficult and expensive to duplicate. Support for storage and maintenance of these data includes an administrator, a database manager, and a dedicated computer with both hardware and software support. User fees are charged and used to augment institutional support. Past experience has shown that reliance solely on research grants, without providing a "floor" of institutional support, allows data to deteriorate. The funding fluctuations inherent to American research grants result in support that can be insufficient to maintain data quality, particularly over time. In addition, without institutional support, institutional memory about the data can easily be lost. In both cases, the utility of the data diminishes.

Confidentiality of data and management of access are the responsibilities of the RGE administrator. Confidentiality protections are central to the access procedures; both electronic and personnel protection measures must be defined. Extensive guidelines about use requirements are provided to all researchers prior to application for access. Before access to data is granted, a research protocol specifying confidentiality protections must be ap-

proved. All users must sign confidentiality pledges accepting their responsibility to protect the confidentiality of the data. These protocols are required in addition to the more general protocols required by Institutional Review Boards. IRB approval is required for any projects requiring access to individually identifying information.

Applications for access are reviewed by a committee that includes representatives of data contributors, computer personnel, and other scientists in the field. The review is not a peer review of the proposed science, but a review of the procedures for management of confidentiality and specific data. As most users are familiar with the data and the procedures, the review is not a tortuous process. The RGE administrator is responsible for working with prospective users to acquaint them sufficiently with the procedures so that reviews proceed smoothly. The data manager also works with prospective users to ensure that proposals that are submitted can be accomplished with RGE-held data.

## Components of a Multiple-Use Data Management Program

Over the past decade or so, RGE has developed to provide a group of users with a shared data management program. Although the user group is not large, it is diverse. Applying RGE's experience to the apprehensions outlined earlier gives a picture of a multiple-use data management system grounded in the following components:

1. Some characteristic of the data makes them valuable yet not easily available elsewhere.
2. Ownership is managed in such a way as to protect the interests of all parties. Written agreements, review authority, and appeal proceedings are integral parts of the system.
3. Detailed guidelines, procedures, etc., are developed by data contributors and data users in concert. These are provided to any researcher prior to application, along with consultation with staff who are familiar with the data and the guidelines.
4. Administration is handled by a non-research third party, whose function is defined as accommodating the constraints of data contributors while promoting scientific use of the data.
5. An adequate "floor" of support is guaranteed so that data do not deteriorate, information about the data is retained and available, and there is sufficient staff support to data contributors and data users.

While development of a multiple-use data management program will likely proceed more smoothly in an institution with already defined data management policies and practices, such definition is not a requirement in the creation of a data sharing program.

## Summary

The particular constellation into which these components are grouped will be determined by the data, its contributors, users and research environment. RGE is one such constellation that works at the University of Utah. Evolving from the specific to the general, operation of RGE has served as a basis from which institutional policies regarding data are being developed at Utah. Creating a locally effective constellation of the above components will proceed more smoothly if such policies are developed prior to designing any shared data management program. The combination of institutional data policies and a well-designed data management program provides a strong basis for the promotion of sharing of data in the biological sciences.

# EMERGING TECHNOLOGY FOR BIOLOGICAL DATA COLLECTION AND ANALYSIS[1]

*Stanley A. Morain*[2]

ABSTRACT

Increasing concern for Earth's biological resources—their inventory, protection, and use—has prompted efforts to modernize practices and procedures for botanical data collection, storage, and retrieval. America's Global Change Research Program, the International Geosphere/Biosphere Program, the International Space Year, and related multinational efforts are already requiring massive species databases and analyses of plant species information, much of which is either not readily available, or locked in herbaria on specimen sheets. One of the first orders of business for botanists and taxonomists should be to explore new and emerging technologies that can reduce the time, expense, and human resource requirements for automating existing herbarium data, optimizing field data collection, and analyzing massive, computerized biophysical data sets. A few of these prospects are described here in context of my research on the flora of the Rocky Mountains.

It is estimated that Earth's flora and fauna represent somewhere between 10 and 30 million lifeforms, of which a scant 1.7 million have been named scientifically (Wilson, 1989). Human impact on the global environment is rapidly altering and destroying whole ecosystems, and untold numbers of species are becoming extinct before they have been discovered, named, and assessed for their beneficial properties. There is an on-going demand to complete a worldwide species inventory, but this cannot be realized without using new and emerging technologies. In the early 1980s it was hoped that new computer technology would permit scientists access to data and images from herbarium specimens, allowing them to compare and identify the large number of new collections being made. Our vision of what that technology can do for botanical and taxonomic research has vastly broadened as the technology has become more sophisticated and more generally available.

In this report, I review the potential for new taxonomic data collection and processing techniques, ranging from electronic notepads and microminiature, digitally compatible cameras to database development and management systems applicable to herbarium inventories and research laboratories. For example, an on-line image database that permitted botanists to retrieve pictures of type specimens, rotate them in 3-D, and zoom in on key structural elements would significantly reduce the time and personnel required to manage herbarium collections. Field camps and herbaria equipped with a portable imaging system could communicate with a centralized image database to compare specimens located in other collections, or to those freshly collected in the field. Finally, the availability of interactive databases designed for specimen attributes, landscape analysis, and human imprints contributing to landscape changes would permit a new genre of research hypotheses and modeling. Already in the 1990s, significant strides have been made in imaging, database management, telecommunications, miniaturization, global positioning, and computing technology that will allow rapid modernization in field and herbarium practices. Moreover, there are major new capabilities evolving in the general tool kit of Earth-observing technologies that will enhance not only the collection of taxonomic, ecophysiological, and distributional data about species, but will also reduce the time and expense of analyzing the data and disseminating the information.

The Rocky Mountains represent an exciting regional laboratory for adopting new data collection and management technology for plant species information, and will be used here to illustrate the potential. The origin and development of the Rocky Mountain flora throughout the Tertiary Period, the shifting and sifting of elements and communities during the glacial Quaternary Period, and the manifest changes and imprints superimposed by human cultural systems in the past millennium (especially in the past half-century) all contribute to our understanding of the area as an ancient but constantly

changing and increasingly vulnerable set of environments. The region stretches for more than 25° latitude, from northern New Mexico to the Laird River in British Columbia, and rises at its highest peaks to over 4,000 m from a general elevational base of 1,600 m.

## Rocky Mountain Data Sets

Activities are underway that enhance the Rockies as a technological test bed. The Flora of North America (FNA) Project (Morin et al., 1989), the revision of the *Flora of the Rocky Mountains*, the Greater Yellowstone Ecosystems Project, and the Global Environmental Monitoring System/Global Resources Information Database (GEMS/GRID) are all efforts aimed at the development of plant species databases. Likewise, they have all shown a compelling need to address global change issues on a regional basis.

The FNA project will result in a 13-volume synoptic flora of the plants of North America and a computerized database derived from this information. In one design (Morin & Tomlinson, 1988), 13 data files were envisioned: taxonomic placement, scientific and vernacular name(s), authorities, synonyms, type specimen(s), literature, morphology, breeding system(s), chromosome numbers, flowering time, elevation, habitat, and distribution. At the Floristics for the 21st Century workshop (Morin et al., 1989) it became clear that the database would also need to contain an image file, data on relative abundance or rarity, status as threatened or endangered, economic significance, plant–animal associations, ethnobotanical uses, and accurate locality data. Such data sets, when merged with other biophysical parameters, define a geographic information system. In sum, the data universe should consist of both taxon data and spectral/spatial data from satellite and/or aircraft remote sensors, and geographic information systems (GIS). These data sets need not be co-housed, but they must be accessible through networks, and their files must be compatible to address management questions being raised by environmentalists and global change scientists.

The revision of the *Flora of the Rocky Mountains* began in earnest in 1989, spearheaded by Ronald L. Hartman, curator of the Rocky Mountain herbarium at the University of Wyoming. The chapter describing the origin and development of the flora of the Rocky Mountains (Morain, in review) to be included in this publication contains a section on human impacts since European settlement. It is in this context that the development of a species information system compatible with a GIS seems most urgent. Habitat fragmentation (and outright loss of some habitats), environmental changes induced by acid rain and the rise in concentration of greenhouse gases, fire management practices, economic activities (both extractive and recreational), and alterations due to plant introductions are all human imprints that affect the pace and direction of floristic and vegetational change. Today, only a few areas of pristine wilderness remain in the Rocky Mountains in an expanse of logged, mined, grazed, and farmed land. There is an extensive network of national forests, national parks, state forests, wilderness areas, national monuments, and other "protected" or multiple-use areas, but even these suffer from overuse and general environmental degradation. The species they harbor already represent isolated, and in some cases peripheral, populations about which we know very little. Worse, the boundaries on these civil and political units become evident on the landscape as economic development and land use changes outside the units evolve, thus fragmenting any avenues for plant migration that may someday be necessary.

The Greater Yellowstone Ecosystem has emerged in these concerns as a specific area of interest. The range of local climates, elevations, lithologies, and soils results in a natural fragmentation of the landscape and striking vegetation dynamics. It is the largest ecosystem remaining in the Rockies that has been relatively untouched, and as a consequence there are many questions about the ecosystem that should be addressed on behalf of the region's general history and development. There are disjunct elements of California, Great Basin, and boreal vegetation that contribute to the ecosystem's uniqueness. It has long been recognized that management questions of such intricacy require joint and collaborative research and the use of modern technologies to coordinate the programs of many state and federal agencies. The Greater Yellowstone Ecosystem Coalition is a step in that direction. Agencies meet periodically with the Nature Conservancy to discuss problems within the National Park area and to coordinate their various management programs. A geographic information system is being created to catalog and explain the interactions between plant and animal species, especially the rare or endangered forms stranded by their environmental history.

The United Nations Environment Programme (UNEP) has established a Global Environmental Monitoring System (GEMS) as a means for assessing environmental conditions, the quality of life,

and the changing conditions of life around the world. The United Nations Environment Programme GEMS/GRID database has been developed to assist these efforts. As of 1990, GRID consisted of some 15 global data sets (such as soil, topography, climate, vegetation) representing the first-order physical environmental parameters affecting human welfare. They are largely compiled from sets created at national and smaller scales, but private sector efforts are also gaining importance, as are those contributed by institutional (e.g., environmental, university, and other not-for-profit) groups. At the national and regional levels, mission-oriented government agencies have contributed a wide array of information coverages. What is clear, however, is that many GRID coverages are at too coarse a resolution for regional application. Their utility is greatest at continental, hemispherical, and global scales. Nevertheless, they provide a stimulus for refinement and the basis for initial model building. A companion effort, focused on the Rocky Mountains, is the Land Cover Pilot Project undertaken through the International Geosphere/Biosphere Program (IGBP), which is designed to collect transect data across the region.

## Global Change Modeling

Global change modeling will impact the course of research in the Rocky Mountains and could serve as a driver for modernizing taxonomic data collection. Morain (1990) has summarized the main arguments. If the concentration of $CO_2$ and other greenhouse gases doubles by the middle of the 21st century, some climate models show that by the mid-2000s the Earth's temperature could rise between 1.5°C and 4.5°C (UNEP/GEMS, 1987). A 3°C increase would emulate the global temperature of 13 million years ago (Mathews, 1987), roughly analogous to the Middle Miocene. While the actual rate, cause, and magnitude of increase is debatable, it is generally agreed that there will be an increase, and that as a result, there will be northward and altitudinal redistributions of species, plant communities, and whole vegetational zones toward cooler regimes.

Concomitant with global warming, a change in precipitation regimes up to 5% is predicted by climate models (Mathews, 1987). Some areas would gain, while others would become more xeric. Several models suggest that there would be a decrease in total annual precipitation in the Rockies. Clearly, the flora will respond to these temperature and moisture stimuli differently. Predictive modeling and visualization based on a modern species information database, and an environmentally oriented image-based GIS that contains detailed ecophysiological data on a species-by-species basis, will be required to: (1) know which new assemblages could possibly populate habitats of the future; (2) predict how long it would take them to adjust by natural means; and (3) determine whether there is sufficient land area at higher elevations to sustain them.

At present, there is almost no evidence by which to assess the rates and directions of biotic adjustment in the Rocky Mountains, but we do know that existing communities and distributions are in disequilibrium with today's environments (Habeck, 1987). Becker (1961) suggested that the Oligocene Florissant flora of Colorado expanded into Montana at a rate of 1 m every 30 years. If the anticipated rate of global warming actually occurs, some studies have suggested that vegetation in the Rockies will have to migrate 300 km poleward, which at Becker's rate would take 9 million years, or hundreds of meters upslope (perhaps as many as 500). Although many species of plants might possess the ecophysiological tolerance to adjust to these migrations, others with slower rates of migration, or those that lack access to new habitats will either require human intervention to ensure the introduction of suitable genetic stocks into new localities or they will necessarily become rare, endangered, or regionally extinct. In any case, the need to migrate upslope will be ecologically impossible for alpine tundra forms, and may be very restrictive to numerous other species, since land area will physically diminish. As Lewin (1989) indicated, the depth of biological knowledge required to manipulate species' geography is extraordinarily complex. But such manipulation will undoubtedly be required because natural migrations will be stymied by existing and evolving land use restrictions. To achieve this in-depth knowledge will require analysis using GIS technology, an ability to model changes through time, and to then animate the rates and directions of predicted change for better long-term planning.

## Mechanics of Synthesis

Existing data sets are so diverse in their origin and structures that a prerequisite exists to assemble and convert these assets into a body of regional data. The compatibility of GIS databases operating in a multitude of computer hardware/software configurations is essential if economy of operation is to be achieved and duplication avoided.

In addition to the GEMS/GRID coverages that are available in both raster and vector format, there

are several databases under development at the federal level. NPFLORA is a module in the National Park Service database called COMMON (G. Waggoner, pers. comm.). It contains almost 80,000 records on some 14,300 taxa in the National Park system, including 12 areas in the Rocky Mountains. Although the module is not specimen based, it is a documented floristic list of species present in each of the park areas. It currently contains information to the subspecies level including regional distribution, status, habitat descriptors, and citations. It will soon include synonyms as set forth in the National List of Scientific Plant Names (NLSPL) prepared by the U.S. Department of Agriculture–SCS (Soil Conservation Service, 1982).

Yellowstone National Park has been developing a GIS for management purposes. At present, the system consists of two vegetation layers: habitat types, as defined by Daubenmire (1966); and cover types, as defined by dominant emergents. In addition, there are coverages (some only partial for the 2.2 million acres) for bedrock geology, precipitation, and hydrology. Digital line graph (DLG) and elevation models (DEM) are also included. The system is running on a Masscomp computer using Earth Resources Laboratory Analysis (ELAS) and Geographic Resources Analysis and Statistical System (GRASS) software and operates in both raster and vector modes. NPFLORA is available for Yellowstone but has not yet been merged into the GIS. A specimen-based electronic catalog is also being created by the Park museum curators, but its relation to the Yellowstone GIS has not been addressed.

There are several other databases under construction, or already operating, for management areas within the Rockies. Many of these are housed in universities or federal agencies (e.g., DEM and DLG files) and contain coverages captured for different reasons. For example, the Technology Application Center (TAC) at the University of New Mexico is compiling a checklist of Rocky Mountain species, as developed by John T. Kartesz at the University of North Carolina. This represents the first time that a modern checklist has been constructed for the region and from which we can research the phytogeography of species. In a companion effort the TAC team is retrieving the lists of rare and endangered species from the Nature Conservancy's Heritage Programs in each state for each of the mountain ranges within the Rockies. We are plotting these data onto 1 : 250,000 scale maps and loading the results into ELAS image processing software to create a region-wide database. The data are then plotted onto Digital Elevation Models and will eventually be superimposed onto NOAA Advanced Very High Resolution Radiometer and Landsat Thematic Mapper (TM) data.

## Enabling Technologies

As the elements of an initial operating system are being configured, it clearly will be necessary to develop the means for rapid and efficient species data collection in the field, and for rapid information retrieval and dissemination in herbaria. Among the obvious candidates for this modernization are global positioning systems (GPS), pen-equipped computers, microminiature cameras, new satellite data collection systems, and advanced visualization technology.

### Global Positioning Systems

Global positioning system (GPS) technology, like GIS, has already reached commercial status and has numerous technical and scientific applications. Compact and low-cost, hand-held GPS devices are already available. Magellan Systems Corporation, for example, has produced a battery-powered unit called the NAV1000 PRO, which weighs only 0.85 kg and measures 21.5 × 9.0 × 5.0 cm. It has an operating temperature between −40°C and 70°C and operates on six AA alkaline batteries. It provides two-dimensional, single-fix, autonomous positioning accuracies of 25 m, or three-dimensional accuracies of 30 m in 2.5–3 minutes. Using two receivers, accuracies improve to 5 m in 2-D, and 10 m in 3-D. Data can be downloaded directly into a data logger or personal computer. Its display is a 4-line, 16-character alphanumeric liquid crystal display (LCD).

Gilman et al. (1989) have also described a hand-held system, called TRIMPACK, that has been designed to address applications where the GPS equipment must function independently of external power, mechanical support, or antenna. By using LCD technology, they keep power consumption under 3 watts and capture 20 hours of continuous use. Industry leaders are expecting the price per unit to decrease rapidly from about $3,000 to perhaps $500. Other references on hand-held GPS technology include McDonald (1989), Smith et al. (1989), Baker (1987), and Smith (1985).

Regarding taxonomic data collection specifically, Wilkie (1989) has described his use of a portable GPS in the Ituri rainforest of Zaire. He used a 12-volt gel cell battery-powered Magnavox 4400 backpack receiver with a detachable 0.6 m aluminum antenna. The system was solar-recharged with an ARCO G100 solar panel. With it, he was

able to obtain 3 hours of receiver time per recharge, during which he captured three-dimensional geographic locations in forest openings as small as 0.125 ha.

Hand-held GPS technology represents an essential link in creating a species information system for the Rocky Mountains. When in place, the full complement of 21 NAVSTAR satellites will permit continuous data collection in remote areas, thus freeing taxonomists from interpolating or, worse, guessing at the location of their collection sites. Environmental attributes such as aspect and elevation will also be much more accurate and consistent, especially if field crews are correlating data from several receivers.

## PEN-EQUIPPED COMPUTERS

An exciting new development in computing is the pen-equipped electronic clipboard. This genre of devices is expected by the industry to sweep the marketplace for applications where traditional clipboards are already used to record data. One company, Grid Systems, has produced a 2-kg "Gridpad" containing the power of a hand-held (not laptop) personal computer. It looks essentially like an "etch-a-sketch" tablet, but one that derives its electronic utility from recognizing block characters and storing them in battery-backed RAM cards. It quickly recognizes characters in nine different languages and has a "fill-in-the-blanks" graphics form that could be ideal for recording specimen data in the field. Gridpad is a DOS machine, but other manufacturers are planning to use ROM-based DOS and Windows environments. An essential ingredient in this evolving capability, of course, is to ensure that data are transferrable to office PCs and workstations—the objective being to avoid data reentry and transcribing errors. Pen-equipped technology is so new, and potentially so large, that several American and Japanese manufacturers have entered the market and are currently posturing for software companies to develop applications.

In an article titled "Computers Without Keys," Normile & Johnson (1989) described Canon's "Ai Note" and Sony's "PalmTop." These, too, use an electronic pen to allow users to take notes, do word processing, calculate printed formulas, and create graphics. The PalmTop is 21 × 16 × 5 cm with a 10 × 15 cm LCD display, and weighs 1.5 kg (battery included). It uses a 68HC000 microprocessor and has 2MB ROM for programs and 320KB RAM for temporary data storage.

In support of modernizing field taxonomy, now is the time to ensure that adequately robust pen-equipped computers and software are developed for botanists' needs. Those elements in the design of the global species information system that require accurate field data could form the basis for the requisite software, and could even include 2-dimensional or 3-dimensional positional data obtained from hand-held GPS observations. For management of herbarium specimen data, an ability to hand-scan information quickly and download it simultaneously into a database is essential.

## MICROMINIATURE CAMERAS

A new generation of video imaging cameras is available for field and herbarium use. These are described in product literature as microminiature color charge-coupled device (CCD) cameras that record images in digital format. The cameras are about the size of a person's thumb, the imaging element of which is about one-half inch consisting of as many as 420,000 CCD sensing elements. Together with their accessories, these cameras could be ideal tools for recording field specimens using power from a field vehicle (current technology would permit ranging distances up to 30 m from the vehicle), or in converting herbarium specimens to CD-ROM formats. Resolution of these systems also permits close-range imaging of plant morphologies. Among the other specifications attractive to field and laboratory taxonomy are: (1) electronic shutter speeds ranging from 1/60th to 1/10,000th of a second; (2) low (10 lux) subject illumination requirements; (3) wide range of operating temperatures (−10°C to 40°C); (4) 12-volt DC or 120-volt AC power source; and (5) an array of interchangeable lenses from 3 mm to 24 mm.

## SATELLITE DATA COLLECTION SYSTEMS

The Earth Observing System (EOS) is a major element in the National Aeronautics and Space Administration's "Mission to Planet Earth," but it is also a major international cooperative element in the International Geosphere/Biosphere Program, the U.S. Global Change Research Program, and the World Climate Research Program (Morain, 1991; Thompson, 1991). It has a profound potential for impacting the ways and means for collecting, storing, disseminating, and analyzing biological data of the future. Currently it is designed as a 15-year program to commence with a series of EOS-A satellites in 1998. Its three primary components include a Space Measurement System (EOSSMS), consisting of a wide variety of sensors; the Data and Information System (EOSDIS), designed to archive and disseminate data, and to

supply products to the science and research communities; and the Scientific Research Program (EOSSRP) consisting of institutionally supported individuals and collective research efforts.

*Space Measurement System (EOSSMS)*

The needs of the Earth-observing and Earth System Science research communities encompass the ionosphere, atmosphere, hydrosphere, lithosphere, and biosphere. Past and present satellites are already collecting data from these realms using imaging and nonimaging (sounding and profiling) systems, and many of these data sets will be readied for general access as part of a pre-EOS dissemination system. The EOSSMS sensors are divided into two categories representing a plethora of experiments and applications in the earth sciences. The first category consists of facility instruments, so called because they represent the core NASA instruments for EOS, and will be managed mainly by NASA facilities or other closely related non-NASA laboratories. The second category is referred to as Principal Investigator Instruments because they represent more narrowly defined, special purpose experiments. Data captured by both sets of instruments will be divided into three categories to ensure their widest use and analysis: (1) facility investigations; (2) principal investigator investigations; and (3) interdisciplinary investigations.

Each of the facility sensors has numerous measurement and integration functions as well as scientific applications. The Moderate Resolution Imaging Spectrometer (MODIS), for example, will be collecting data for at least two dozen experiments, including: (1) the dynamics of snow and ice over large areas; (2) studies of primary production in the world's oceans; (3) species variability and improved carbon and nitrogen cycling determinations; (4) monitoring global vegetation dynamics; (5) global aerosols monitoring; and (6) land surface temperature measurements. MODIS-N (nadir) will have 36 channels for data capture ranging from 0.4 to 14.2 $\mu$m in 10- to 360-nm bandwidths. MODIS-T (tilt) will have 32 channels between 0.4 and 0.88 $\mu$m in 10- to 15-nm bandwidths. Such fine resolution spectral data are expected to provide insights into ecosystem dynamics, global change research models, and general vegetation monitoring.

*Data and Information System (EOSDIS)*

EOSDIS represents the means by which data processing and analysis are to be made available to the scientific community. At the heart of all EOS activities is the EOS Operations Center located at Goddard Space Flight Center in Greenbelt, Maryland. It will serve as a communication link between EOSSMS and EOSDIS to ensure sensor operations and raw data capture. Working together with the System Management Center, the Instrument Control Facility, and the International Partner Operations Center, raw data and level-0 data will be distributed to a network of centers called Distributed Active Archive Centers (DAACs). Level-0 data will be released to these centers to be further refined by their internal Product Generation Systems into level 1 or higher products, or stored for later use in their Data Archive and Distribution Systems. This initial operating structure and management plan for EOSDIS is referred to as Version 0, because ultimately several versions will succeed this design. Version 0's focus is on science data processing, but is designed to be flexible and evolutionary as subsequent technologies, expertise, experience, and infrastructure come into play (Taylor et al., 1991).

An integral part of EOSDIS is represented by data that have been, and are now being, collected. These pre-EOS data sets are divided into a "Pathfinder" series having global extent (e.g., NOAA AVHRR/Global Area Coverage, Total Ozone Vertical Sounder, and Geostationary Operational Environmental Satellite—GOES); a "Precursor" series of important, but not necessarily global, data sets (e.g., NOAA AVHRR/Local Area Coverage, Airborne Visible and Infrared Imaging Spectrometer, and Thermal Infrared Multispectral Scanner); and "non-EOS" data (e.g., Landsat Thematic Mapper and Multispectral Scanner). The DAAC at EROS Data Center has recently inaugurated the Global Land Information System as a prototype in Version 0 to provide access to some of these data: namely, AVHRR, Landsat, 1-degree USGS Digital Elevation Models, Matthews Global Vegetation Data Set, and Major World Ecosystems, among others. These are accessible for searching, browsing, and interrogating through Internet and direct-dial using IBM-compatible terminals.

## ADVANCED VISUALIZATION TECHNOLOGY

Three-dimensional image processing technology and 3-dimensional GIS modeling techniques are in the forefront of new earth science applications, especially those in meteorology, oceanography, hydrology, and geology, where depth sounding and profiling have been long-term 2-dimensional tools. In terrain analysis, the availability of digital elevational models (DEMs) has enabled ecologists to

superimpose computer classified land cover types onto a static representation of relief, and to even quantify the elevational ranges, aspects, and total area occupied by each type. At a higher level of sophistication, and requiring massive computer processing, techniques are available for moving the terrain past an observer. Several videos have been produced by the Visualization Laboratory at the Jet Propulsion Laboratory in Pasadena, California, to illustrate how static terrain and weather conditions might appear to someone "flying around and through the landscape." These are indeed impressive and instructive, but they do not animate "change." Visualizing temporal changes in landscape ecology requires a static observation point while animating a time series as viewed from that perspective. Research is now beginning that will add the time dimension (in the form of multiple-image dates) to this capability.

What has not been attempted yet is to adapt the technology for 3-D modeling of vegetation cover—that is, to assess the structure of plant communities in the spatial domain. Data sets that would permit this kind of analysis are not available either. Unlike geologic, atmospheric, and oceanographic applications where vertical profiles are standard measurement attributes (i.e., well logs, depth soundings, balloon soundings), vertical structural profiles are not a common measurement in botanical and ecological studies. Certainly they are not acquired systematically, although one economic means for getting them would be to use low-altitude aerial mapping photography. The needs of the global species information system, and the GISs that will interface with it, will surely impact future data types and their collection strategies. But, as Ellefson & Kaiser (1990) have suggested, it is not just for the species information system or GIS modeling that such developments are emerging. They cite global change issues and improved forest planning and management as driving forces behind the need to develop new methods in forest research.

## Summary

Accurate locational and ecophysiological data for most dominant species may be relatively easy to incorporate into image-based and object-oriented databases, even today. Similar data for rare and endangered species and even dominant species at the periphery of their ranges, however, still require data collection, and this must be done by using less time-consuming and less costly means. It is not unreasonable to imagine that in our drive to collect massive amounts of environmental data and make measurements of current earth resources, we will design "new-age" botanists who are equipped with more than plant press, hand lens, ruler, and knapsack. New-age botanists will have voice, data, and video links to their home institutions, as well as to the world's major herbaria and centralized data repositories. In the future, they will be able to predict and visualize the impact of environmental changes on flora and vegetation, assess the potential impacts of varying economic development scenarios, and better manage ecosystems and communities at risk. Emerging technologies that will foster these improvements include 256 MB processing chips; seamless integration of spatial and nonspatial data sets; pedabyte storage capabilities; advanced computer networks, local area networks, and client servers; advanced visualization capabilities; advanced telecommunications systems; and miniaturization of electronic field and herbarium equipment.

# DATA BANKING AND THE ROLE OF NATURAL HISTORY COLLECTIONS[1]

*Nancy R. Morin*[2] *and Janet Gomon*[3]

## Abstract

A variety of strategies is being used to capture information from natural history specimens and to develop new research databases containing information on taxonomic groups. Consortia of institutions are being formed for the purpose of capturing data and making them available through centralized or dispersed databases. Geographical information, when analyzed using Geographical Information Systems, provides information useful in management and conservation of taxa and habitats. Images, when analyzed using such techniques as X-ray computed tomography and three-dimensional image processing, can reduce the need to examine actual specimens. Image, sound, and text data are being combined into research and instructional programs. Information on characteristics, distributions, and relationships of taxa are being linked to other data sources, from both collections and non-collections databases. Efforts are underway to develop data standards and data-sharing protocols in order to facilitate sharing of these data among institutions and across disciplines.

Natural history collections provide a rich information resource about our natural world. The past several years have seen administrators of systematics collections and systematists placing greater emphasis on providing improved access to collections data and supporting the synthesis of information from collections. New directions in research, a broadening of users of systematics information (from environmentalists and natural resource managers to science educators), coupled with relatively recent advances in computer technology, have been the driving forces. The result is a significant shift in purpose and expansion of collections-related databases, from the traditional databases serving primarily as indexes to the physical collections, to ones that are capable of being used as true research and educational tools.

The traditional catalog or database (for example, specimens in a herbarium) contained a relatively small core of text information about a single museum's collections. Within the botanical community, core information entities are usually contained in the specimen "label" and have included specimen identity, locality and date of collection, collector, field number, and for some organisms, substrate. When only parts of a plant are collected, some morphological features (e.g., overall size) have been noted. Additional data, such as the habitat in which the organism occurred, or other organisms with which it occurred, have often been included. Other information may also be placed on the label, e.g., chromosome counts or ethnological information, or a reference to a publication or repository. The place and method of storage for each item have also been recorded.

Unless computerized, or otherwise cross-indexed in some way, none of this information is readily available from the stored collections themselves. To find specimens from a specific locality, the entire collection must be searched manually. Similarly, to re-create an itinerary for a collector whose field book is not extant, it is necessary to comb the holdings for collections made by that collector.

These traditional catalogs or databases, if automated at all, often cover only a small portion of an institution's collection, making them minimally useful as research tools. So, although the collections were considered an extremely rich information resource, their utility was largely a potential yet to be realized. The adage, "data rich but information poor," seemed to apply.

## Current Data Banking Strategies and Projects

Today, the picture looks quite different with regard to data banking. The systematics community has undertaken multiple strategies to expand specimen-based databases and develop new research databases containing derived, rather than primary, collections data (e.g., taxon-based databases). In addition, collections data have been in-

[1] We thank T. Duncan, R. Haynes, J. Humphries, and W. Brigham for providing information for this paper.
[2] Missouri Botanical Garden, P.O. Box 299, St. Louis, Missouri 63166, U.S.A.
[3] National Museum of Natural History, Smithsonian Institution, Washington, D.C. 20560, U.S.A.

tegrated with non-collections data sources to provide a richer information resource. One can summarize the community's current, primary strategies in data banking efforts as follows:

1. Rapid automation strategies for specimen-based data in order to bring entire collections into an automated database.
2. Coalescing of a single discipline's specimen data from multiple institutions into a centralized, easily accessed database.
3. Employing a variety of new tools, from analytical tools to authoring (software) tools.
4. Incorporation of new data types (e.g., image and sound samples) with traditional text data.
5. Expansion of collections-related databases by including new data elements, both primary and derived, or by linking these databases with non-collections-related data sources (e.g., chemical databases).
6. Integration of collections data across disciplines.
7. Integration of system architectures across departments within an institution and across institutions.

Three current projects exemplify the first two strategies of rapid computerization of collections data and coalescing of that data into centralized databases.

The Southeastern Regional Floral Information System (SERFIS) has as its objectives: (1) to develop a centralized database composed of label data of specimens in herbaria of the southeastern United States; (2) to provide data management and storage for these data; (3) to provide technical assistance and support to these herbaria; and (4) to participate in national and international attempts to establish computerized access to specimen label data (Macrander & Haynes, 1990). Label images are captured at each herbarium, stored in digital form, then entered into the database at the University of Alabama. Each herbarium receives its data back in computerized form, and each has access to the central database via a network connection. About 100–120 herbaria are involved, covering ca. 6 million specimens, approximately 10% of the botanical specimens held in U.S. and Canadian institutions.

The Specimen Management System for California Herbaria (SMASCH) has objectives similar to those of SERFIS, but its strategy for data collection is different (Duncan, 1991). The Association of California Herbaria has devised a plan whereby its three largest members, the California Academy of Sciences, the University of California, Berkeley, and Rancho Santa Ana Botanical Garden, each have responsibility for entering data from about one-third of the largest California families. Once this phase is completed, coordinated data entry of the remaining families for each institution and for the remaining institutions will be undertaken.

About 53 institutions and 6.5 million specimens (10.8% of the total U.S. and Canadian holdings) will be involved. Data entry and access will take place over NSFNet between institutions and local area networks within institutions. Images primarily from a collection of photographic slides will begin to be scanned as part of the project.

The Inter-Institutional Database of Fish Biodiversity in the Neotropics is a major effort to build an international database bringing together information from all major collections of neotropical fishes, initiated by the Academy of Natural Sciences of Philadelphia, the University of Michigan Museum of Zoology, and Cornell University. It will make available systematic and geographic data from specimens deposited in collections in North, Central, and South America and in Europe. It includes a Geographic Information Systems interface, an electronic atlas of neotropical type localities, and remote access features. This effort uses the software MUSE for its central database. MUSE has been developed for and used by the ichthyological community at many institutions. MUSE recommends adherence to a "primary" data set and structure but is flexible in how the "secondary" data, which are less likely to be exchanged, are handled.

These three examples all provide access to collections data from more than one institution, and thus they each require integration of data across institutions.

The third and fourth strategies, employing new tools and expanding the traditional catalog with new types of data such as images and sound samples, are particularly well-exemplified by the following projects.

Geographical Information Systems (GIS) when linked with collections databases offer powerful analytical capabilities. They provide new information about the locality from which a specimen was collected, and they can be used to analyze complex relationships between the distributions of taxa, their characteristics, and their relationships with other taxa. Various current projects analyze precise locality information from systematics collections using GIS (1) to manage and conserve individual taxa and (2) to manage geographical areas and habitats. The Illinois Natural History Survey combines data on natural features, man-made features (roads,

pipelines, etc.), and distributions of individual collections, to make recommendations about planned land use in light of its impact on the environment. The survey can use the same data to determine the physical and ecological requirements of individual taxa for either research or management applications. Information on the location of organisms was used to suggest locations for the Superconducting Super Collider (SSC), a high-energy physics research facility under the auspices of the U.S. Department of Energy. The extensive database maintained by the Natural History Survey on the wildlife and plants of Illinois, including their distribution and abundance, their habitats, and their life histories and status within the state, was supplemented with computerized databases on wetlands, natural areas, soils, property boundaries, and other information necessary for siting the SSC and evaluating its potential environmental impacts (Joselyn, 1988). The Survey uses similar data to predict distributions of taxa. For example, county records for a water beetle, *Haliplus tortilipenis*, were compared with such information as average January temperature, annual precipitation, and percentage forest cover. GIS was used to determine which other counties have ecological parameters similar to those of counties within which the beetle is known to occur. That is, to determine which counties have the same combination of temperature, precipitation, and forest cover as the counties where collections of the beetle have been made. Based on this information, a hypothetical distribution range can be mapped showing areas where the species might be expected to occur.

The Illinois Natural History Survey also uses knowledge of habitats and collecting patterns to help "clean up" locality and mapping data. For example, fish can be assumed to have been collected in water, so collection sites that do not fall within a water body can be "snapped" to the nearest stream. Unfortunately, when more than one stream is nearby, the correct choice may not be made. Collections are often made at bridges or near roads, and that information can be used to influence which stream site is chosen by the computer. The best solution, according to Warren Brigham at the Survey, is to sit down with the collector in front of a terminal on which streams, bridges, and roads can be displayed and ask the collector to show where the collection was actually made.

Similar, but even more sophisticated GIS methods are used by the Environmental Resources Information Network (ERIN) in Australia to increase the accuracy of computerized collections information (Slater & Noble, 1991). Australian natural history institutions are collaborating among themselves and with the ERIN Unit, a part of the Australian National Parks and Wildlife Service, to computerize their collections following community-adopted standards and protocols. Data are transferred from the institutions into the central ERIN database and can be used in GIS and other applications. ERIN uses a climatic file, called BioClim, that incorporates data from thousands of data-gathering locations for 16 climatic parameters such as wet season rainfall maximum, wet season rainfall minimum, and wet season maximum temperature. By mapping reported localities for a taxon, a statistical analysis can be used to identify specimens that fall outside the typical climatic range for the taxon in any one or a combination of parameters. Those specimens can then be checked to see that they have been correctly identified and that the locality was recorded correctly. BioClim data can be used as a modeling tool by adjusting any one of the 16 parameters, which results in associated dependent changes in the rest of the parameters. The current climatic requirements of species can be inferred from the species' current distributions; thus, if the distribution of a given climatic type is changed the concomitant change in species distribution can be predicted. This information can be used to determine whether natural area preserves are available in the predicted future climatic zones to provide refuge for sensitive taxa.

A new tool of the medical profession, and one that a number of researchers at the Washington University School of Medicine (St. Louis) have employed and studied, is X-ray computed tomography combined with three-dimensional image processing (Hildebolt et al., 1990). This technology enables scientists to conduct research without physically damaging specimens. It also improves the ability to make new measurements and preserves images of objects that must be returned to their places of origins. Physical anthropologists at the National Museum of Natural History (Smithsonian Institution) recently completed a prototype in which two-dimensional image slices were produced, then used to produce three-dimensional reconstructions that show both the exterior and interior surfaces of specimens and objects. In the future, one may find these types of images commonly associated with museum collection databases and available by network to other researchers.

The relatively new authoring tools that enable creation of interactive monographs and tutorials have been used in several recent projects aimed at science education and the identification of specimens. As part of the Biological Curriculum In-

novation Study (BioCIS) led by Chad McDaniel of the University of Maryland, Smithsonian Institution researchers have been working on the development of introductory college-level biology courses through the production of hypertext multimedia databases that document aspects of biological diversity. These applications combine text, image, and sound from a variety of museum information sources. Projects being undertaken include a database of information on mammal species of the world, an application documenting collection and processing of botanical specimens, an identification manual for crocodiles and their products, and an application that allows the user to "deforest" the Amazonian rainforest while learning what species can or cannot live in the remaining forest fragments.

A botanical project similar to BioCIS has been envisioned by Arturo Gómez-Pompa of the University of California, Riverside. His prototype, Q-Taxa, incorporates images of specimens, living plants, drawings, maps, plus specimen information and taxonomic information in an environment that invites exploration by both layman and researcher (Gómez-Pompa & Plummer, 1990).

Programs for producing descriptions and interactive keys from sets of characters and character states, DELTA, have been written by Michael Dallwitz and Les Watson of CSIRO (Australia). An interactive key to cultivated plants in North America using hypertext is being developed by Larry Ragan at Pennsylvania State University. Interactive keys to families or to taxa within individual families are also available, e.g., a family key from T. Duncan, a key to Australian rainforest trees by B. Hyland, and a key to the orchids of Great Britain by R. Pankhurst. Although such files are not derived directly from specimen data, they are a product of the expert staff associated with natural history collections and are important tools in curation and education.

The fifth strategy supports information synthesis in two ways: (1) by broadening collections-related databases beyond the traditional specimen "label" database to include both primary and derived data, and (2) by linking collections-related databases with other, non-collections-derived sources.

The first of these two ways is exemplified by the Hymenoptera Database System (HDS) and Flora of North America (FNA). They are taxon-based online databases. HDS is maintained by systematists at the U.S. Department of Agriculture and National Museum of Natural History, and FNA is maintained by the Flora of North America project at the Missouri Botanical Garden.

The Hymenoptera Database System contains systematic and biological information on about 18,000 species of saw flies, parasitic wasps, true wasps, ants, and bees (see Krombein et al., 1974, for a description of earlier phases of this project). The project has integrated data from both entomological and botanical sources, one botanical source being Index Nominum Genericorum, a database of all validly published generic names for plants (Farr et al., 1979, 1986). The HDS contains literature references on taxonomy, biology, and morphology for described taxa. Information is provided on geographic range, ecology, whether introduced or adventive (accidently introduced), plant or animal hosts, parasites, predators and prey, pollen preferences, and flowers visited. A wide variety of queries can be made from this database, e.g., a biological control specialist could ascertain the names of parasitic Hymenoptera introduced from other parts of the world and successfully established in the United States, and obtain information on their known distributions.

Flora of North America is a binational, multiinstitutional project to produce a floristic treatment of the vascular plants and bryophytes growing outside of cultivation north of Mexico. In addition to 14 published volumes, the project will produce a taxonomic database containing information on the relationships, characteristics, and distributions of the plants. A key feature of the FNA project, as with most floristic and faunistic projects, is that it provides authoritative data on the plants. Flora of North America, while accumulating morphological data in a traditional manner, captures that morphological data in a database (TROPICOS, developed at the Missouri Botanical Garden) that allows analysis of correlations among taxa, and among characteristics. Moreover, Flora of North America, by integrating morphological data with collections-based, mappable distribution data, can provide a tool for studying the relationship between morphological characteristics and the physical parameters within which the plants occur (Morin, 1991).

Furthermore, taxonomic databases like HDS and FNA can serve as connecting points to link disparate data using a taxonomic framework. An independent query might ask for the chemicals produced by plants that occur on a certain soil type. Specimen information mapped using GIS against soils gives the names of plants that occur on the soil type in question, and those names can be used in turn to query a remote phytochemical database to get a list of the chemicals they are reported to produce. The number of databases that can be linked through the taxonomic framework is unlim-

ited but includes ethnological, reproductive, anatomical, genetic, specimen-based, and bibliographic data.

Researchers in the Evolution of Terrestrial Ecosystems Program (ETE) (University of California, Santa Barbara, and National Museum of Natural History) have initiated the ETE database to allow broad-scale comparisons of the paleobiology and paleoecology of terrestrial ecosystems, plus their plant and animal communities. The ETE database will document and compare plant and animal assemblages from the Silurian to Recent times and will establish patterns of similarity and novelty in terrestrial ecosystems. Researchers can then determine the degree to which ecological roles of organisms and structural characteristics of ecosystems have changed. These patterns will then be the basis for assessing the impact of environmental conditions on ecosystem structure, and the relationship of such phenomena to evolution within specific groups of organisms.

The ETE database incorporates both primary and derived information about fossil localities and the plant and animal species collected from them (Damuth, 1991). For each locality, in addition to its name, age, and location, there are fields for sedimentological, taphonomic, and paleoecological data. Each locality has a species list (vertebrate, plant, or invertebrate). For each species there is a taxonomic classification and a set of morphological and ecological descriptors that vary with the type of species. A locality-species table associates localities and species and records relative abundance of species at a given locality. The bibliographic table contains publications that were sources of information for the database. The museums table records which museums have material and from which localities. The time units table names geochronological units and their associated maximum and minimum ages (in years). Last, the sedimentary structure and taphonomic table records observations relevant to depositional environment.

An example of linking collections-related data to other data sources is the Environmental Protection Agency–National Oceanographic Data Center (EPA-NODC) Taxonomy System modernization effort. The EPA recently turned to systematists at the National Museum of Natural History, U.S. Department of Agriculture, National Marine Fisheries Service, and the U.S. Fish and Wildlife Service to help improve an existing taxonomic system by developing an underlying logical data model for taxonomy. The database includes valid scientific names, synonyms, and common names. Each valid scientific name is associated with a single taxon of a higher rank, and each synonym is associated with a valid name. The database provides all taxa contained within a higher taxon, scientific names corresponding to common names, and common names applied to any scientific name. The system is seen as critical to supporting EPA's Environmental Monitoring and Assessment Program and Office of Water Quality. The database enables field biologists to associate data recorded in the field or laboratory (water chemistry, locations, numbers of organisms, and biomass) with a taxon. Interactive access between the taxonomy system, the Ocean Data Evaluation System, and a biological survey system called BIOS are planned.

The last two strategies are essential to laying the groundwork for broader-scale information synthesis. These projects may well support the next major step in providing access to natural history collections. These efforts involve standardization of "data architectures" (e.g., definition of data parameters) and development of protocols to allow data sharing across systems. The International Working Group on Taxonomic Databases in the Plant Sciences (TDWG) is an organization that has attempted to establish standards, if none exist, for various data elements in plant taxonomic work, expressly for the purpose of facilitating data exchange, and it is one of several organizations that have efforts underway in these areas. The Association of Systematics Collections Computerization and Networking Committee has also initiated an important effort to develop these standards across all systematics collections.

A systems architecture undertaking is being led by a group from the largest free-standing (non-university associated) natural history institutions and botanical gardens in the United States. The member institutions have agreed to participate as a consortium to plan modernizations of their collection and research information management environments. The purpose is to install at each institution new equipment and software to support research needs, enhance collections management, and improve interconnectivity within and among the consortium institutions. An example of a similar undertaking within a major institution is the new project at the University of California, Berkeley, to integrate data from the various museum collections throughout its campus. This would allow, for example, linking archeological, ethnobotanical, and taxonomic information together on an institutional network. Other institutions are planning to connect integrated online library systems to their research databases to allow direct linkages of library information to research-derived data and vice versa.

## Conclusion

These new approaches all support a primary goal of the nation's systematics collections institutions: to improve information availability to our systematics researchers and to a growing community of information users, including environmentalists, conservationists, and science educators. To achieve this goal, new working relationships have been formed within and among organizations, across taxonomic disciplines, and between systematists and information science and engineering professionals. The new technology makes available entirely new categories of information that now can be derived from collections, and it provides new tools with which to analyze and use both traditional and new kinds of information for research and resource management.

# THE NATIONAL SCIENCE FOUNDATION: FINANCIAL, INTELLECTUAL, AND KNOWLEDGE BROKER FOR SYSTEMATIC BIOLOGY[1]

*James R. Estes*[2]

ABSTRACT

The National Science Foundation (NSF) is the primary financial broker for systematic biology, with NSF funding most basic systematic research in the United States. Systematists generate ideas in the form of proposals to the Foundation, which are subject to merit review by peers. This review process has the potential to enhance the science and, therefore, constitutes one facet of intellectual brokering. Program officers, in turn, react to the proposals and their reviews in making recommendations for awards, and in the process interact with the Principal Investigators (PIs) to provide intellectual counsel. NSF also plays a proactive role in the intellectual brokering of systematics through (1) sponsorship of study groups, workshops, symposia, and conferences; (2) development of initiatives; (3) funding of Small Grants for Exploratory Research (SGER) proposals; and (4) funding Special Creativity Extensions (SCE) to existing NSF awards. Whether reactive or proactive, NSF generally functions early in the research enterprise; the Foundation is not a direct player in knowledge synthesis and analysis—the Foundation does not disseminate the data and results from the projects it funds. Rather, it relies on the scientific community and its system of peer-reviewed journals and indices. However, NSF does fund innovative proposals to develop databases; to computerize museum collection-label data; and to exchange specimens, data, ideas, and syntheses. In this way, NSF does contribute to knowledge and/or data transfer. Information and ideas gained from NSF-supported research efforts could be diffused directly into society-at-large by coupling proposals for scientific studies with proposals for formal and/or informal educational programs. Systematic biologists are in an ideal position to take advantage of any such funding opportunities because of the already extensive interactions that occur between natural history museums and members of the systematic community.

President Harry S. Truman signed the National Science Foundation Act of 1950 (Public Law 81-507) to culminate a decade of debate about the structure and function of the agency. This law with its various amendments provides the National Science Foundation (NSF) authority to promote research in the United States, and in that role, NSF has been a benefactor of basic scientific research (England, 1982). This is especially true for systematic biology, because NSF provides more than 90% of the federal funding awarded to U.S. colleges and universities for studies of phylogeny, classification, and biodiversity (BBS Task Force, 1991).

## NSF AS FINANCIAL BROKER FOR SYSTEMATIC BIOLOGY

During the half-century of NSF's existence, new comparative techniques and methods of analysis have emerged to transform systematic biology, in general, and plant systematics, in particular. The most compelling element in this transformation has been the coupling of molecular and computational biology. The field of plant systematics has also been aided and abetted by the conservative nature of the chloroplast genome. The emergent field of plant molecular phylogenetics has developed so rapidly that a rigorously determined and testable phylogenetic framework for the green plants is already well within our reach (Palmer et al., 1988). Phylogenetic relationships within large and complex families, such as Asteraceae, Fabaceae, and Poaceae, are also yielding to molecular analysis with high levels of resolution (Jansen et al., 1991; Lavin & Doyle, 1991; Lavin et al., 1990; Soreng et al., 1990). It is even possible to probe evolutionary divergence deep within the hierarchy of life using data from molecular sequence analyses of extant taxa and microfossils from deep strata, embedded

[1] I sincerely appreciate the assistance of W. F. Harris, J. Edwards, P. Werner, L. Krishtalka, J. Rodman, T. Yates, F. Griffo, D. Schindel, K. Estrada, P. Olmert, G. Stuck, D. Stonner, and M. McIntosh. I also thank T. H. Barkley for inviting me to speak on a subject about which I was and remain a novice, but for which I now have much greater appreciation, and Peter Raven and the staff of the Missouri Botanical Garden for their hospitality.

as always within the modern evolutionary paradigm (a small sampling of papers includes Buchheim et al., 1990; Gajadhar et al., 1991; Knoll, 1992; Lake, 1991; Palmer et al., 1988; Schlegel, 1991; Woese, 1987). The resulting phylogenetic inferences can then be used to interpret patterns and derive syntheses in fields as diverse as biogeography, behavior, and development (Brooks & McLennan, 1991). These advances would have scarcely seemed possible even a decade ago.

Systematists have also sounded a clear signal that the world faces a crisis over the loss of biological diversity (National Science Board, 1989; Prance, 1984; Solbrig, 1991). This realization has resulted in a renewed interest in surveying and cataloging the world's biota and the consequent writing of floras and faunas (Heywood, 1984b). In this effort, systematists are also beginning to employ more sophisticated systems for data storage and retrieval to ensure that the locality data for each specimen and the descriptions and nomenclature for each taxon can be readily retrieved; thus the flora or fauna can be efficiently and effectively revised (Bisby, 1984; Dallwitz, 1984; Gibbs Russell, 1989; Pankhurst, 1974). Watson et al. (1986) have effectively used this approach for the grasses of Canada, and a consortium of African botanists are accomplishing the same for the entire *Flora of Southern Africa* (Gibbs Russell, 1989, 1990). It is possible that floristic work is at an all-time high, with several major surveys of plant diversity in the temperate and tropical zones either recently completed or well under way (Heywood, 1984a). The printed products of the most modern of these endeavors may be reminiscent of floras and faunas of the past two centuries, but they differ in having a foundation based on detailed databases, and the most forward-looking floristic projects also include equipment for the highly precise determination of map coordinates and involve the potential for interacting with Geographic Information Systems (Rodman, 1989).

This is surely one of the most exciting periods in the history of systematic biology, in part because so much seems within our grasp, but also because we realize the magnitude and importance of the tasks before us.

It is arguable that these, and other, major developments would have transpired in the absence of NSF. However, it is undeniable that the Systematic Biology Program (Table 1) provided funding for much of the development of the theory and techniques of systematic biology: the collection of specimens and data and the interpretation of results that has fueled this burgeoning of systematic biology. In addition, officers of the Systematic Biology Program established a special competition for survey and inventory research (NSF, 1990d), by allocating approximately $2.3 million exclusively to fund floras and faunas. This competition now forms the basis of the newly erected Biotic Surveys and Inventories (BS&I), which with Systematic Biology is in the Division of Environmental Biology (DEB) (Table 1), attesting to the Division's commitment to the importance of cataloging the plants, animals, fungi, and microbes of the world. Research Collections in Systematics & Ecology (RCS&E), also in DEB, provides funds for the maintenance and computerization of those research collections (NSF, 1985a).

It is difficult to envision this flowering of the two cardinal dimensions of plant systematics—phylogenetics and floristics—without the monetary support of NSF (Table 2). With the excitement generated by these two approaches and their use in other contexts, the number of proposals received in Systematic Biology appears to be on the rise (Table 3). Additionally, both molecular and diversity studies are costly—the former requires a large budget for supplies and materials and the latter for travel and fieldwork; both are labor intensive. As a consequence, this past year also saw a dramatic increase in the level of requested funding (Table 3). This placed tremendous stress on a budget that has grown by much smaller increments (Table 2). Regardless, the importance of the roles of Systematic & Population Biology (S&PB) and Biotic Surveys & Inventories (BS&I) as financial brokers of systematic biology is clear and secure.

## NSF as Intellectual Broker for Systematic Biology

### Proposal preparation and review as elements of intellectual brokering

In general, funding of awards by NSF is made in response to proposals submitted by Principal Investigators (PIs), who are members of the research community. Typically this funding is based on the recommendations of program officers (POs), who are at the base of NSF's administrative hierarchy. Funding is, therefore, a grass-roots phenomenon both in the community and at NSF, and the decisions concerning funding or declination of proposals at NSF is primarily reactive. That is, POs in S&PB and BS&I respond to proposals that result from the pool of systematic biologists. Thus, as noted above, POs are important players in the financial brokering of the science, but decisions concerning funding are also at the intersection of

TABLE 1. Reorganization of the programs in environmental biology at NSF. The core of the Systematic Biology Program (represented in greater detail than the remaining programs) was recently united with elements of Population Biology to form the Systematic & Population Biology Cluster (also represented in greater detail than the other clusters). Systematic Biology and Population Biology continue to function as independent units for budgetary and proposal review purposes; although, some programs such as Molecular Evolution may have special panels that are managed by program officers from any of several divisions and programs. The Ecology and Ecosystems programs have also merged to form the Ecology Studies Cluster. A third cluster, Long-Term Projects in Environmental Biology, was formed from the Biological Research Resources Program and the long-term projects unit from Ecosystems. PIs should contact programs officers concerning the submission of proposals in particular research specialties. Only applicable programs are shown in the Division of Integrative Biology and Neurosciences.

financial and intellectual brokering. This results because the continuing dialog between the PO and PI has substantial room for discussions of the science itself. These discussions range through time from initial deliberations concerning an idea for a research project through discussions of the reviews of the proposal.

At the critical first step in the process, scientists interested in submitting a proposal may contact the relevant PO, with telephone or electronic mail being the most effective means of communication at this time. POs can often provide counsel regarding the potential viability of a project in the process of merit review. Frequently, suggestions can be offered that might direct the PI to a focus or protocol that has the potential to improve materially the research proposal, and more importantly, the proposed research. The following hypothetical cases provide examples of the advice POs might offer prospective PIs: (1) an indication that a proposed flora has a lessened chance of being recommended for funding by the Biotic Survey and Inventory Advisory Panel unless a meaningful and useful database is included; (2) a comment that reviewers react more favorably to proposals in molecular systematics if the inferred phylogeny is then used to comprehend other radiation patterns in the taxon; and (3) a suggestion that a monograph with a rigorous analysis of the phylogeny of the taxa would be a more meaningful contribution than *only* a set of keys and descriptions. Of course, the advice carries no guarantees, and the PIs are free to accept, decline, or modify the suggestions, but whether or not these proposals

are funded, the modified research will likely be more significant and have a broader impact on systematics if the recommendations are given careful consideration.

The Foundation is deeply rooted in the academic tradition of merit review. Accordingly, most programs in DEB employ the advice of practicing scientists by (1) mail-solicitation of reviews from specialists in some aspect of the proposed research and (2) convening advisory panels composed of scientists with broad expertise prior to making their own recommendations for awards. This practice provides for a much more thorough review. Perhaps just as importantly, a thorough and critical review elicits suggestions that sharpen the focus, clarify the goals, and improve the protocol of the proposed research. In brief, the review system should have a salutary scientific impact on each proposed project and the PI, and ultimately then on the entire field. Peer review, including review by the POs, is the most important element in the intellectual brokerage practiced by NSF because it can most directly influence individual PIs, albeit the reviews are available only to the individual PI, and then only after the proposal has been funded or declined. The "Panel Summary" is the most important document in this phase of intellectual brokering because it fixes the proposal under consideration within the context of modern systematic biology, and because it identifies both the flaws and strengths of the proposed research. The individual reviews, however, generally are more detailed and cover specific issues concerning taxon and character selection, methods of data collection and analysis, and the potential systematic and taxonomic impact of the work. There is, therefore, considerable responsibility thrust upon a scientist selected to review a proposal, and that responsibility is partitioned between the responsibility of being fair to the PI and being rigorous for the science. Regardless, reviewers should always attempt to improve the proposed work and hence the science.

For this aspect of the system of intellectual brokering to function effectively, it is essential that reviewers write substantive, even if succinct, reviews in which they provide a detailed analysis of both the strengths and the weaknesses of the proposed scientific problem and the research protocol. In some instances, reviewers may have knowledge of only one or a few aspects of the proposal; however, it is incumbent on these reviewers to criticize that aspect of the proposal in which they are expert. Only then does the PI receive the intellectual assistance necessary for development and the Panel and the Program obtain sufficient data to make an informed recommendation. The routine assignment of unqualified ratings of "excellent" or "very good" for all proposals to study particular taxa or to investigate certain processes seldom, if ever, helps the PIs during the Panel's discussion of proposals, and it deprives PIs of the reviewer's expertise. If a proposal is truly excellent, it is vital that the reviewers explicitly and precisely explain in what ways it excels, because panels and programs almost exclusively use the narrative, rather than the rating scale, of the Proposal Evaluation form.

Funds allocated to the programs in systematics, that is S&PB and BS&I, probably always will be insufficient to fund all of the proposed systematic research that is worthy of accomplishment. (It is arguable that such levels of funding would actually have a dampening effect on innovation and advances such as those described for plant molecular phylogenetics.) Rather, because of its limited bud-

get, the Systematic Biology Program must, and should, focus on research that will advance the field, that is thorough and in depth, and that will have an impact beyond the boundaries of the taxon under investigation. It is precisely in this funding environment that reviewers, panels, and program officers can be most creative influences in the discipline. For instance, it seems obvious that POs in the Systematic Biology Program over the period from 1980 to 1989 responded to and encouraged the development of molecular systematics while maintaining the legitimacy of the review process. This creative management of the program was instrumental in the rapid development of molecular systematics and molecular evolution (Goodman, 1992; Goodman et al., 1992) and made possible the breakthrough in understanding phylogeny and evolution of the Plant Kingdom. All the while the Program continued to fund meritorious proposals that were based on other comparative techniques, both traditional and new (Committee of Visitors for the Systematic Biology Program, 1991). At the end of the last decade, the Program also made a bold decision to establish the Survey and Inventory competition, thus enhancing our knowledge of the world's biodiversity.[3] As the new decade opens, the Program will undoubtedly identify other promising new vistas, perhaps including new approaches in systematic biology to understand phenotypic evolution, biogeography, and ecology based on and in the context of phylogenetics (Brooks & McLennan, 1991); the development of algorithms that permit phylogenetic analysis of hybrid complexes; and the refinement of methods of estimating phylogeny using developmental pathways. All the while, the Program must continue to fund the most innovative molecularly and morphologically based phylogenetic analyses and taxonomic revisions. Nevertheless, this phase of intellectual brokering can only be reactive, and somewhat conservative. Other avenues do exist, however, that offer a more active role for NSF program officers.

## NEW DIRECTIONS IN SYSTEMATIC RESEARCH

In addition to funding research by reacting to proposals, the Foundation is directed to initiate basic scientific research (Public Law 81-507); therefore, NSF has the authority to function as an intellectual broker beyond what is possible in the standard competitive grant programs. Appropriately, procedures exist that permit a more proactive role for program officers. This permits flexibility and the capacity to respond to new findings and techniques. Fortunately, NSF is governed and administered by working scientists. The National Science Board (Public Law 81-507) governs and sets policy for the Foundation, and many of its members are active scientists. In addition, many of the administrators in the directorates, divisions, and disciplinary programs are Visiting Scientists (often termed "rotators"), who return to research programs after one or two years in Washington. For instance, currently (i.e., June 1992) in the Division of Environmental Biology (DEB) 75% of the program officers are rotators. In addition, all of the permanent officers are research biologists, and all have taken advantage of NSF's sabbatical program by taking a year's leave in a university setting. The result is that the programs concerned with the biology of species, populations, communities, and ecosystems are steered by peers who are keenly interested in the development of their own sciences and capable of discerning trends within the disciplines.

Program officers may stimulate the launching of new fields of systematic inquiry or the re-charting of traditional areas in at least four ways, and examples will be drawn from the field of biodiversity (similar scenarios could have been described for cladistics, morphometrics, molecular systematics, or molecular evolution):

*1. Funding of study groups, workshops, conferences, and symposia.* This avenue typically involves a dialog between a PO and individual scientists, who may be the representative(s) of scientific societies. These venues provide opportunities for planning research agendas, transferring technologies, discussing common research topics, and presenting research results for a common field of study, respectively. Two examples are the following. (1) Systematics Agenda 2000 had its origins in a study group organized by the Smithsonian Institution and the Association for Systematics Collections to seek a way for the systematics community to express its views and to take action concerning the decline in global biodiversity. A broader charter evolved, and officials at NSF indicated that they would be willing to entertain a proposal to fund additional workshops and conferences. The proposal received favorable reviews and was funded. (2) The workshop on the development of a protocol for botanical surveys held in 1989 resulted from an extensive set of discussions between POs in Systematic Bi-

[3] This decision is worthy of recognition. The program officers in Systematic Biology who responded so positively and effectively are James E. Rodman, David Schindel, and William Moore. John Brooks and James L. Edwards were Division Director and Deputy Division Director, respectively, and provided support for the decision.

ology and the editors of *Flora of North America*. One result was publication of a guide for the development, management, and conduct of floristic projects, *Floristics for the 21st Century* (Morin et al., 1989), which provides counsel to PIs who intend to submit biotic survey (plant, as well as animal and microbial) proposals to BS&I. Adherence to the elements of this publication should lead to more mature and better developed proposals to conduct floristic—and faunistic—research and, not coincidentally, more innovative and useful surveys.

*2. Development of initiatives.* Initiatives provide a mechanism for obtaining additional, or new, funds for the Foundation, divisions, and programs, as well as in the federal budget as a whole. The idea for an initiative may originate at any level in the agency, but often occurs at the program officer level. Initiatives may also grow out of interactions with the scientific community, as products of workshops, recognition of proposal trends, awareness of major unresolved scientific questions, congressional action, directives from the Director of NSF, the National Science Board, or all of these.

Once again using the development of the current NSF programs in biotic surveys and inventories as an example: The directorate-wide (Directorate for Biological Sciences—BIO) competition in Basic Research in Conservation and Restoration Biology (NSF, 1990a) resulted from all of the above mechanisms, as did the Biotic Survey and Inventory competition, which arose from the reallocation of internal funds in the Systematic Biology Program (cf. National Science Board, 1989). This last-mentioned competition is now the basis for a new program (NSF, 1990d; Yates & Estes, 1992). These funds have since been augmented by funds from the U.S. Agency for International Development (A.I.D.) to support biodiversity research in developing countries and by A.I.D. and the National Institutes for Health (NIH) for a program in drug development, biodiversity, and economic development in developing countries (NIH et al., 1992; Schweitzer et al., 1991). The second of these augmentations was developed with the assistance of a workshop jointly funded by NSF. These agencies and others—such as Department of State, Department of Defense, Department of Agriculture, Department of Energy, and Department of Interior—have responded to to a widespread recognition of the need for more biodiversity research. This combined effort therefore had a compounding effect.

*3. Small Grants for Exploratory Research (SGER).* This instrument for funding is designed for investigations that are urgent or risky or that have the potential to result in new directions in basic research (NSF, 1989). They may be initiated by an investigator or, rarely, through the PO contacting a worker with appropriate expertise. Because they do not require an external review, there is a relatively rapid turn-around in funding.

Appropriately, relatively few are granted each year (five in Systematic Biology in fiscal year 1991). Of these, one provided funding to develop techniques for the study of biodiversity of free-living soil nematodes. As the Science Board (NSB, 1989) report recommended, diversity in the rhizosphere needs special attention.

*4. Special Creativity Extensions (SCE).* Programs have the capacity to grant up to two-year extensions for awards when creativity and productivity have been extraordinarily high. SCEs are made without any action on the part of the PIs; in fact, PIs cannot institute a request for such an extension. Not surprisingly, these extensions have been made sparingly.

Four SCEs were made by the Systematic Biology Program over the past three years, and one was awarded to continue a highly creative faunistic survey.

Intellectual brokering at NSF, therefore, has tended to function early in the research enterprise—it functions through initiatives and proposals. In this light, it is not surprising that the NSF direct-access database provides entry to the abstracts (equivalent to the Program Summaries that are submitted with proposals) of funded proposals. This new service, *(STIS) The Science and Technology Information Service* (NSF, 1991b), permits anyone with a modem to scan these abstracts using keyword or topical searches. Thus, it is relatively easy to ascertain if the Foundation has funded research in a particular area and to discern research trends. Other information is also accessible through the use of STIS, including the text of most NSF publications. The Systematic Biology Program also publishes an annual *Awards List* (available by writing the Program), which provides an indication of funding trends, and constitutes the Program's primary effort in direct knowledge brokering.

## NSF as Knowledge Broker for Systematic Biology

Perhaps surprisingly, NSF does not a play a significant role in the formal release or indexing of data that results from funded research projects. There are traditional and historic, as well as economic, reasons for this seeming paradox.

NSF came into being after the basic structure of the U.S. scientific enterprise was well established. Although the basic research enterprise in 1950 was, and remains, centered on colleges and universities and other similar non-profit institutions, in a real sense it consisted of a diffuse, but well-organized, suite of scientific societies with members scattered at institutions throughout the country. One service of these societies has been the dissemination of scientific knowledge among their members and the scientific community at large; as a consequence, most of the societies publish peer-reviewed journals. Most scientific societies also hold or sponsor annual meetings that encompass both independent research reports and symposia. Symposia provide fora for defining new research directions as well as summarizing important research findings. In addition, indexing services were also available in 1950; their computerized descendants provide easy, if sometimes expensive, accessibility to the literature.

The Foundation apparently accepted and placed its trust in the ability of these scientific communities to recognize and to publish the results of worthy scientific research, rather than imposing another layer of bureaucracy and reports. (This philosophy continues to be reflected in the criteria for funding of systematic monographs within Research Collections in Systematics and Ecology (RCS&E) (previously Biological Research Resources Program or BRR) (NSF, 1985b).) The decision to require relatively few and brief reports and to trust in the scientific integrity of the publication system of the societies freed PIs to concentrate on accomplishment of the proposed research, rather than on the writing of extensive, detailed reports. Because the editors, editorial boards, and reviewers work for scientific journals without real compensation, the task is accomplished efficiently, with integrity, and less expensively than if the government managed the system. Thus, NSF depends upon non-governmental agencies to monitor publication of the results of its awards. (Albeit, early in its history, NSF provided a strong foundation for continued funding of *Biological Abstracts* (England, 1982).) In my view this system works effectively and efficiently.

It would be quite erroneous to believe from this lack of direct involvement, that NSF is disinterested or that it fails to provide funding for the important task of knowledge brokering. The Foundation fosters and promotes publication of research results. For instance, publication costs are routinely included in proposal and award budgets, with the NSF budget form even including a specific line item "Publication Costs/Documentation/Dissemination" on the NSF *Summary Proposal Budget* (NSF Form 1030). NSF can also support publication of meritorious research beyond this basic level of support through competition for monograph publication costs within RCS&E as mentioned above. Pertinent for plant systematics, this program subvented the publication of *Systematic Botany Monographs* through its foundling stages, promoting the spectacular success the journal has enjoyed.

NSF requires listings of publications and reprints for the PI's final project report—required of all funded projects—and it requires the inclusion of the section "Results from Prior NSF Support" (NSF, 1990c) for all grant applications where the PI or co-PI has received NSF support in the previous four years. Clearly both these exercises are for the convenience of the review system and are not intended as mechanisms for the dissemination of research syntheses.

The development and maintenance of electronic databases should follow pathways similar to those for the review and publication of research journals. That is, the society or community that collects and uses the data should provide the organizing elements and expertise for the database. NSF already provides seed funds for those database projects that are considered meritorious (NSF, 1990b). The Human Genome database is a prime example (Cinkosky et al., 1991; Roberts, 1991; Salton, 1991). Other databasing needs that involve the systematic community include ongoing attempts to make the data in museums and herbaria more accessible and useful (Bisby, 1984; Gibbs Russell, 1989; NSF, 1990b; Stuessy & Thomson, 1981). RCS&E currently provides funding for collection management, specimen databases, and electronic networking in museums and herbaria (NSF, 1985a). There may also be a need for a central facility for plant molecular sequences and their alignment for the development of phylogenies and another for electronically stored phenotypic data for automated description and key software. It is unclear what the impact of the *Global Change Research Act of 1990* (NSF, 1991a; Public Law 101-606) will have with respect to databases, but clearly it calls for data collection and management of information that is highly relevant to systematic biology, and there will be clear opportunities for the discipline and the research collections.

Perhaps NSF's most influential role in the synthesis of research results is through the funding of symposia, either those in association with the annual meetings of societies or symposia that are free-standing. Once again, NSF is dependent upon

TABLE 4. Funding by Country for Biodiversity in Developing Countries Joint NSF/A.I.D. Competition, fiscal years 1990 and 1991. Total awards = $7,166,220 (NSF funding = $4,677,220; A.I.D. funding = $2,489,000).

| Country | Number of awards | Country | Number of awards |

the research community to recognize the need for syntheses and to write creative proposals for funding. The Annual Systematics Symposium at Missouri Botanical Garden provides one example of NSF funding for meetings that focus entire fields of research, such as the methods of phylogenetic analysis within the Plant Kingdom, the subject of the 1992 symposium. The previously cited *Floristics for the 21st Century* (Morin et al., 1989) accomplished the same goal for floristic research. One final example is the recognition by the ecological community of the need for a center for ecological synthesis and analysis. Accordingly, a proposal was submitted to the Foundation by James H. Brown and Stephen R. Carpenter on behalf of that community for a workshop to complete a needs assessment and task analysis for the establishment of such a national center. Although program officers can stimulate such applications, it seems clear that the ideas are most likely to emerge from the scientists themselves.

## Opportunities for Expanding the Impact of Systematics

I believe that Systematic Biology is a viable scientific discipline with profound implications for humankind. That viewpoint is not, however, universally understood, or perhaps even accepted. There are two great arenas where systematists need to act with vigor to change that perception: (1) developing countries and (2) the American public. Members of our community are already actively engaged in the former domain, although there is much yet to be done. The latter arena promises a more truculent foe, ignorance. There may be a general lack of public understanding of such basic issues as cause and effect, adaptation, evolution, food webs, the role of natural systems in sustaining human populations, humans as organisms, et cetera, et cetera.

TABLE 5. Criteria for funding in the joint NSF/A.I.D. program Biodiversity in Developing Countries.

1. Scientific merit.
2. Impact on host country and its biological diversity:
   a. Conservation of biological diversity.
   b. Contribution to sustainable use of biotic resources.
   c. Significance to development of biodiversity infrastructure.
   d. Effect on economy or on the economic role of studied species or habitat on the economy.

## International Development and Systematic Biology

The community of U.S. systematists, working in concert with NSF and the U.S. Agency for International Development, has had a long and important presence in the Neotropics. These government agencies and members of the U.S. botanical community have played an important role in the development and shaping of systematic research and systematic institutions in developing countries. However, the relationships between botanists and developing countries are changing, and now should, and typically do, involve a partnership arrangement.

All the core programs in DEB fund research in foreign locales, but these may or may not involve foreign scientists and scientific infrastructural development of the host nation. Two programs at the Foundation, however, explicitly encourage this particular level of international involvement. Biotic Surveys & Inventories (NSF, 1990d) urges such an interaction between the U.S. and the foreign scientists, if the proposal involves research in a developing country. Most reviewers of BS&I proposals hold the PI accountable for the degree and level of involvement for such projects. Although expected in most such proposals, this activity is required for the research to be considered for funding through Biodiversity in Developing Countries (BDC) that is jointly supported by NSF and A.I.D. In its first two years, BDC funded 37 projects in 19 countries (Table 4). A.I.D. funds can be used only to support host country scientists and infra-

structure, title to any purchased equipment must remain in-country at the close of the award period, and all awards are subject to the principles that guide A.I.D. (Table 5). Counterpart NSF funds support the U.S. scientists' participation in the projects. A similar situation occurs for the program concerned with conservation of biodiversity, development of pharmaceuticals, and economic condition in third-world countries. This program is jointly funded by NSF, A.I.D., and the National Institutes of Health (NIH et al., 1992; Schweitzer et al., 1991).

International Programs at NSF also promotes international interactions. In my judgment, this program is under-utilized by the community of Systematic Biologists as a possible funding source.

## PRESENTATION OF SYSTEMATIC BIOLOGY TO THE GENERAL PUBLIC

NSF funds meritorious proposals for the transfer of scientific knowledge and ideas to society-at-large. One means of accomplishing such a transfer is to couple scientific studies with formal and/or informal educational programs. This combination of basic science and education may be proposed in single, successive, or concurrent proposals (NSF, 1988a, b). Thus, systematists might propose exhibits or lecture-series that explain systematic biology as a scientific discipline and that use the results of a funded project.

Systematic biology is in an ideal position to take advantage of any such funding opportunities because of the extensive interactions between natural history museums and herbaria and systematists. Museums and herbaria have received NSF support for development of instructional materials for classroom use and participation in teacher training efforts. Too often, however, these efforts have been conceived and proposed by non-scientists from public education offices without direct input from evolutionary biologists or systematists.

## SUMMARY

NSF funds most basic U.S. research in systematic biology and acts as an intellectual broker at various junctures in the chain of events that lead from the germinal idea for a research effort to the formulation of formal and rigorous inferences. However, the Foundation is not a direct player in the formal release of the data and conclusions that result from funded projects. Nevertheless, the Foundation can act as a knowledge broker in the funding of international and educational grants.

# REVISED CIRCUMSCRIPTIONS AND SUBGENERIC TAXONOMIES OF *CALANDRINIA* AND *MONTIOPSIS* (PORTULACACEAE) WITH NOTES ON PHYLOGENY OF THE PORTULACACEOUS ALLIANCE[1]

*Mark A. Hershkovitz*[2]

## Abstract

Cladistic analysis of Portulacaceae supports a revised taxonomy of *Calandrinia* sensu lato. *Calandrinia*, as here circumscribed, comprises ca. 14 western American species in three sections: *Calandrinia*, *Acaules*, and *Monocosmia*. Previous taxonomies classified over 100 species in *Calandrinia* but recognized *Monocosmia* as a distinct genus. *Calandrinia* sects. *Calandrinia* and *Monocosmia* are probably cladistically nested in section *Acaules* and are not sister groups of either *Rumicastrum* or *Montia*, as proposed in a previous cladistic analysis. *Montiopsis* Kuntze, traditionally included in *Calandrinia*, comprises ca. 15 western South American species in two subgenera, *Montiopsis* and *Dianthoideae*. At present, cladistic analysis provides only weak evidence linking *Calandrinia* and *Montiopsis* to one another and poorly resolves their precise relationships to other Portulacaceae. This analysis supports a taxonomic distinction between the eastern American/African and western American members of Portulacaceae, but poorly resolves the relationship between the two groups. Cactaceae, Basellaceae, Didiereaceae, and perhaps Hectorellaceae, which were not included in the analysis, belong to the eastern American/African group. The present analysis provides a framework for additional studies of phylogeny of the portulacaceous alliance and of Centrospermae in general.

*Calandrinia* Kunth, in its broadest circumscription, comprises more than 100 perennial and annual herbaceous species in western North America, western South America, and Australia, and represents the most diverse genus in the family (cf. Carolin, 1987, in press; Hershkovitz, 1990a, 1991a, b; Kelley, 1973; McNeill, 1974; Nyanyano, 1986a, 1990; Pax & Hoffmann, 1934; von Poellnitz, 1934a). Considerable evidence has emerged that *Calandrinia* sensu lato is an unnatural genus (Carolin, 1987; Hershkovitz, 1990a, 1991a), although differences in opinion remain regarding its taxonomy (Table 1) and the phylogenetic relationships of its constituent taxa to one another and to other Portulacaceae. As part of a continuing effort to clarify phylogeny in Portulacaceae, the primary aim of the present paper is to help establish natural circumscriptions of *Calandrinia* and its segregates. Because *Calandrinia* comprises such a phylogenetically divergent assemblage, however, the scope of this study encompasses all of Portulacaceae as well as the closely allied families Basellaceae, Cactaceae, Didiereaceae, and Hectorellaceae.

## Taxonomic History of *Calandrinia*

The traditional subgeneric and sectional taxonomy of *Calandrinia* was developed by Reiche (1897, 1898) and von Poellnitz (1934a) for the

[1] This manuscript is revised from a chapter submitted as part of a doctoral dissertation at the University of California, Davis. I gratefully acknowledge assistance from Jim Doyle, the late Richard Eyde, Donna Ford, Philip Hershkovitz, Walt Kelley, June McCaskill, Joan Nowicke, George Russell, Rudy Schmid, John Strother, Grady Webster, Stanley Yankowksi, two anonymous reviewers, and the curators of the following herbaria: B, CAS, DAV, F, L, M, NA, P, RSA, UC, US. This research received financial support from a Smithsonian Graduate Student Fellowship, a Smithsonian Pre-doctoral Fellowship, a Smithsonian Short-Term Visitor Award, two Jastro-Shields Scholarships from the University of California, Davis, two travel awards from the Department of Botany, University of California, Davis, and P. Hershkovitz.

TABLE 1. Classification history of members of *Calandrinia* sensu lato and related taxa. Listed below are the generic and sectional assignments of members of *Calandrinia* sensu lato and other taxa regarded here as cladistically related (see also Carolin, 1987; Ford, 1992; Hershkovitz, 1990a, 1991a, 1992). The table compares traditional classifications with those adopted by Nyanyano (1986a, 1990), Carolin (1987, in press), and the present paper. The traditional classification synthesizes the taxonomy proposed by Añón (1953), Kelley (1973), Kelley & Swanson (1986), Mathew (1989), McNeill (1974), Pax & Hoffmann (1934), Peralta (1988), von Poellnitz (1934a), and Reiche (1897, 1898). This table lists only explicitly proposed synonymy. For example, Nyanyano included *Calandrinia axilliflora* as a species of *Calandrinia* sect. *Cistanthe*, but did not include *Calandrinia* sect. *Axillares* as a synonym of the latter (cf. Carolin, 1987, in press; Kelley, 1973; Reiche, 1897, 1898). The synonymy is not perfect, i.e., the assignment of particular species varies among the classifications, particularly in Nyanyano's (1986a) treatment. Except for *Rumicastrum* sect. *Basales*, the sectional assignments for the Australian calandrinias in Carolin's (1987) work depart markedly from those of von Poellnitz (1934; see also Syeda & Ashton, 1989). The more recent circumscriptions of the sections of *Rumicastrum* are accepted here uncritically. Reiche's (1897) subgeneric assignments of the sections of *Calandrinia* are indicated in parentheses. The nomenclatural authority is listed the first time each taxon is listed in the table.

American and Australian species, respectively. Reiche (1897) recognized two subgenera (*Glabrae* and *Hirsutae*) and 12 sections of *Calandrinia* in Chile (Table 1). Reiche (1902; cf. 1897, 1898) assigned the type species, *C. caulescens* Kunth (= *C. ciliata* (Ruiz & Pavón) DC), to *C.* (*Glabrae*) sect. *Compressae* (thus, sect. *Calandrinia*). Reiche's system was later extended, implicitly or explicitly, to cover extra-Chilean American species by Añón (1953), Kelley (1973), MacBride (1937), and Peralta (1988). Two additional American sections of *Calandrinia*, sections *Macrocarpae* (Añón, 1953) and *Pachypodeae* (Kelley & Swanson, 1986), were later proposed to accommodate species that did not correspond to any of Reiche's sections. These new sections were not assigned to subgenera. Also, *Montiopsis* Kuntze and *Calandriniopsis* Franz were established on the basis of species referable to subgenus *Hirsutae* (Carolin, in press; Ford, 1992). *Montiopsis* was accepted by Pax & Hoffman (1934) and Nyanyano (1986a, 1990) but was not mentioned by Carolin. *Calandriniopsis* was accepted by Pax & Hoffmann (1934), but not by Añón (1953), Nyanyano (1986a, 1990), or Carolin (in press).

The Australian calandrinias were classified in six sections by von Poellnitz (1934a; see Table 1). One of the sections (sect. *Partitae*) is actually synonymous with *Anacampseros* sect. *Tuberosae* (Carolin, 1987: 410; not mentioned by Gerbaulet, 1992). The other sections remained in taxonomic limbo for many years: they were subsequently referred to merely as the Australian calandrinias (Kelley, 1973; Pax & Hoffmann, 1934) and were never fully integrated into Reiche's (1897) subgeneric classification. Thus, a later "cladistic analysis of *Calandrinia*" (Syeda & Ashton, 1989; see also Syeda & Carolin, 1990) included only the Australian species, while a revision of the sectional taxonomy of *Calandrinia* (Nyanyano, 1986a; see also below) referred only to the American sections.

Within the last six years, three workers have proposed revised supraspecific classifications of all or part of *Calandrinia* sensu lato (Table 1), including Nyanyano (1986a, 1990), Carolin (1987, in press), and Hershkovitz (1990a, b, 1991a–c).

Syeda & Ashton (1989) and Syeda & Carolin (1990) did not formally propose a revised sectional taxonomy of the Australian species based on their cladistic analysis. Their analysis will not be considered in detail here except in reference to their data, much of which was incorporated in Carolin's (1987) work.

Nyanyano's (1986a, 1990) treatment most closely follows the traditional classification but is unsatisfactory especially because each of the three sections of *Calandrinia* sensu lato he circumscribed includes species with traits contrary to the sectional diagnoses. For example, Nyanyano (1986a) characterized section *Calandriniopsis* as pubescent, yet included therein the glabrous *Calandrinia* sect. *Amarantoideae* (cf. Hershkovitz, 1991b; Kelley, 1973); and characterized section *Cistanthe* as glabrous, yet included therein the pubescent *Calandrinia* sect. *Parviflorae* (cf. Ford, 1992; Hershkovitz, 1993; Kelley, 1973). Also, contrary to the states found in many of the included species, Nyanyano's (1986a) generic key diagnosed *Calandrinia* sensu lato as having 5–10 stamens and no tricolpate pollen (cf. Kelley, 1973), and his tribal key to Portulacaceae (Nyanyano, 1990) diagnosed Calandrineae as pubescent, perennial herbs or shrubs, and thus misrepresents the glabrous and/or annual members (cf. Kelley, 1973; Pax & Hoffmann, 1934; Reiche, 1898). Finally, Nyanyano (1986a) failed to mention the Australian sections of *Calandrinia* sensu lato, as well as several American taxa, in his treatment.

In his cladistic analysis of Portulacaceae, Carolin (1987) assigned the 18 traditionally recognized sections of *Calandrinia* sensu lato (excluding sects. *Partitae* and *Pachypodae*, which belong to other genera—see Table 1; Hershkovitz, 1991c) among 11 OTUs that, in his analysis, showed cladistic relationships with several different genera of Portulacaceae. Carolin concluded that *Calandrinia* sensu lato was not monophyletic and proposed restricting its generic circumscription to include only section *Calandrinia* (including sect. *Axillares*; Table 1). In his shortest cladogram (1987, fig. 7), *Calandrinia* sensu stricto is a sister group to the monotypic genus *Monocosmia*; these are, in turn, a sister group to the Australian calandrinias. Carolin preferred a slightly longer cladogram in which *Calandrinia* sensu stricto + *Monocosmia* is a sister group to his OTU *Naiocrene* (*Montia* sensu McNeill, 1975); he attributed the additional length of his preferred cladogram to character state changes that might be morphologically correlated. He concluded that the relationships of the *Calandrinia* sensu stricto + *Monocosmia* clade were unresolvable without additional study. Carolin (1987, in press) recommended assigning other members of *Calandrinia* sensu lato variously to *Cistanthe*, *Baitaria*, *Rumicastrum*, and *Schreiteria* (Table 1).

In previous papers, I discussed Carolin's (1987) work in the light of additional evidence from leaf morphology (Hershkovitz, 1990a, 1991a, b, 1992, 1993). I corroborated Carolin's opinion that *Calandrinia* sensu lato is unnatural and should be segregated into several genera. I adopted Carolin's proposal to classify four of Reiche's (1897) *Calandrinia* sections and the genus *Philippiamra* (syn. *Silvaea*) in *Cistanthe* (Table 1). My classification of *Cistanthe* departed from Carolin's in segregating *Cistanthe* sect. *Philippiamra* from section *Amarantoideae* and in recognizing *Calyptridium* (including *Spraguea*) and the monotypic *Lewisia* sect. *Strophiolum* as sections of *Cistanthe* (Table 1). I tentatively accepted Carolin's proposed circumscriptions of *Rumicastrum* and *Schreiteria*, but I presented evidence that the *Calandrinia* sensu stricto + *Monocosmia* clade is most closely related to and possibly nested within *Calandrinia* sect. *Acaules*, which Carolin referred to *Baitaria* (Table 1). Hence, I advocated including *Monocosmia* (see also Hershkovitz, 1991c) and *Baitaria* in *Calandrinia*, although I found no unequivocal evidence linking section *Acaules* with the other members of *Baitaria* sensu Carolin (i.e., *Calandrinia* sect. *Dianthoideae* and subg. *Hirsutae*; Table 1). In the present paper, I treat the last two as *Montiopsis* subgenera *Dianthoideae* and *Montiopsis*, respectively (Table 1).

## Phylogenetic Reanalysis of the Relationships among Members of *Calandrinia* sensu lato

My earlier taxonomic conclusions on *Calandrinia* sensu lato employed cladistic concepts but no formal numerical analysis other than preliminary McClade (Maddison & Maddison, 1987) manipulations of data modified from Carolin's (1987). I provide here a more extensive numerical analysis of Portulacaceae that aims primarily to clarify the circumscription and relationships of members of *Calandrinia* sensu lato. This work synthesizes my earlier reinterpretation (Hershkovitz, 1990a) of several characters included in Carolin's (1987) analysis, new evidence from leaf morphological studies (Hershkovitz, 1990a, 1991b, 1993), and additional character analyses as noted in Appendix

1. This analysis falls far short of a comprehensive revised phylogeny of Portulacaceae, especially because this family is probably paraphyletic with respect to Basellaceae, Didiereaceae, Hectorellaceae, and Cactaceae (see discussion). Along with Portulacaceae, these families constitute what I call the portulacaceous alliance (Hershkovitz, 1991d; "portulaca alliance" of Gibson & Nobel, 1986; Portulacineae of Thorne, 1976, 1983). Also, data for the poorly known genera *Talinella* (see Nyanyano, 1986b) and *Amphipetalum* (see Spichiger, 1988) remain to be incorporated, and a new genus, *Xenia*, was segregated from *Anacampseros* (Gerbaulet, 1992; see also below) while this manuscript was in review. Except for Hectorellaceae (see Skipworth, 1961), however, there is no evidence that the excluded taxa are especially close relatives of *Calandrinia*. The excluded taxa appear to be related to eastern American/African members of Portulacaceae, whereas members of *Calandrinia* sensu lato except for section *Macrocarpae* (Carolin, 1987) and the Australian endemics, seem to be related to western American Portulacaceae (Hershkovitz, 1990a, 1991a, d; cf. Carolin, 1987; see also discussion). My assumption, at this point, is that neither the eastern American/African nor western American group is polyphyletic, and that one group effectively provides an outgroup or set of outgroups for the other. Excluding phenetically distinctive members of the eastern American/African group will not prevent at least partial recovery of phylogenetic information pertinent to *Calandrinia* sensu lato, although ultimately a more thorough analysis will be necessary. Another problem with the present analysis is that while Portulacaceae and allies are clearly members of the order Centrospermae, their position in the order, hence the polarity of many of their variable characters, remains uncertain (Hershkovitz, 1989, 1991d; cf. Rodman et al., 1984; Carolin, 1987).

## Materials and Methods

*1. Taxa.* The 33 OTUs (excluding a hypothetical ancestor) recognized in the present analysis (Table 2) are substantially the same as Carolin's (1987) but with changes and precautions described below.

I treated *Rumicastrum*, *Claytonia*, and *Lewisia* as single OTUs based on Carolin's (1987) finding that each is monophyletic. Even if monophyletic, *Lewisia* is problematic because of its polymorphism and poorly correlated character states among the species (Hershkovitz, 1992). I will reconsider this problem in my discussion of the results.

Although Carolin (1987) determined that *Montia* is monophyletic, I treated section *Naiocrene* (1–2 spp.; McNeill, 1975) as a distinct OTU. Because it includes the only rosettiform perennial species of *Montia*, section *Naiocrene* possibly represents the basalmost clade in the genus. This section possesses traits that are otherwise discordant

Table 2. Taxa for cladistic analysis. Listed below are the full names of the OTUs recognized in the present analysis. The circumscriptions of the taxa are as proposed by Carolin (1987, in press) except where modified by Hershkovitz (see Table 1). Four taxa (*Montiopsis* subg. *Montiopsis*, *Claytonia*, *Rumicastrum*, and *Lewisia*) split for analytical purposes by Carolin (1987) are here lumped because Carolin determined that each is monophyletic. Traditional synonyms of autonyms are listed.

*Anacampseros* L. sect. *Anacampseros* (≡ *A.* § *Telephiastrum* (Medik.) Fenzl)
*Anacampseros* sect. *Avonia* E. Mey. ex Fenzl
*Anacampseros* sect. *Tuberosae* von Poelln.
*Calandrinia* Kunth sect. *Calandrinia* (≡ *C.* sect. *Compressae* Reiche)

*Talinum* sect. *Phemeranthus* (Raf.) DC.

in *Montia*, however, including brachytetracytic stomata and a chromosome base number of 11 (see Appendix 1). Thus, treating *Montia* as a single OTU scored for the character states of section *Naiocrene* is problematic.

As noted above, I assigned *Calandrinia* sect. *Dianthoideae* and subgenus *Hirsutae* to *Montiopsis* subgenera *Dianthoideae* and *Montiopsis*, respectively. My choice of subgeneric rank for these entities permits recognition of Reiche's (1897, 1898) sectional divisions of subgenus *Montiopsis*. Reiche divided this subgenus into *Calandrinia* sects. *Hirsutae* (perennials), *Condensatae* (robust annuals), and *Parviflorae* (diminutive annuals); these circumscriptions are at least partially artificial (Ford, 1992).

The OTUs for *Cistanthe* are the sections I have recognized elsewhere (Table 1). Except for the addition of *C.* sect. *Strophiolum*, these correspond to Carolin's OTUs for the equivalent taxa.

My previous analysis (Hershkovitz, 1990a) indicated that the apparent cladistic affinities of *Calandrinia* sects. *Calandrinia* and *Monocosmia* might vary depending on how *Calandrinia* sect. *Acaules* was scored for its variable traits. No species of section *Acaules* has the entire suite of traits that I had earlier cited as evidence linking this section with section *Calandrinia*. Hence, I treated as independent OTUs five putative species of section *Acaules* (Hershkovitz, 1993) possessing different combinations of character states.

I have retained Carolin's two OTUs for *Talinum*, but they may be unsatisfactory for phylogenetic analysis. Elsewhere, three (Pax & Hoffmann, 1934) or four (Nyanyano, 1986a) subdivisions of *Talinum* have been recognized, and it is not clear how Carolin would have assigned these to his two sections. Specifically, Carolin (in press) divided *Talinum* into section *Phemeranthus* (enveloping seed aril present; ca. 25 spp.) and section *Talinum* (enveloping seed aril absent; ca. 6 spp.). *Talinum* group "B" of Pax & Hoffmann (1934: 249), more or less equivalent to "sect. *Concentricum*" of Nyanyano (1986a), includes up to 16 species that apparently lack the enveloping aril (Nyanyano, 1986a) but, in other respects, span the morphological extremes between the broad-leaved, diffusely branched species typifying section *Talinum* and the terete-leaved, rosettiform species typifying section *Phemeranthus*. I cannot account for these species in the context of Carolin's classification, but I leave this problem unresolved.

In addition to the above, I have previously discussed possible paraphyly among the sections of *Cistanthe* (Hershkovitz, 1991a). Other candidates for paraphyletic OTUs include *Calandrinia* sect. *Calandrinia* and *Montiopsis* subg. *Dianthoideae* (Hershkovitz, 1990a), in which other OTUs may be nested. For the present analysis, I retained these phenetically distinct but possibly paraphyletic OTUs but will reconsider the specific consequences in the discussion. The potential pitfalls of paraphyly would best be avoided by species-level analysis of the family, which is beyond the scope of the present study.

*2. Outgroup.* The outgroups of Portulacaceae or, more appropriately, the portulacaceous alliance, are unknown (Hershkovitz, 1989, 1990a, 1991a, in prep.; cf. Carolin, 1987; Rodman, 1990; Rodman et al., 1984); hence most character state polarities cannot be established by the two-outgroup method proposed by Maddison et al. (1984). In the present analysis, I designated a hypothetical ancestor scored as "0" for 28 of the 46 total characters with the balance scored as unknown. The character state polarities were subjectively determined on the basis of state distributions among other Centrospermae, which presumes that the portulacaceous alliance is derived therein (but see Hershkovitz, 1989).

*3. Characters.* Appendix 1 lists 46 mostly binary characters and data sources, and Table 3 lists the OTU scores. A few of the characters are multi-state/unordered. A "0" is entered for all states designated as ancestral a priori and, for convenience, states determined to be primitive a posteriori. Otherwise, the state designations are arbitrary.

I did not follow infrageneric analyses published elsewhere to derive scores for *Rumicastrum* or the OTUs of *Anacampseros*. Contrary to OTU scores I adopt here, Syeda & Ashton (1989) and Syeda & Carolin (1990) presumed that such traits as inaperturate pollen and numerous carpels are primitive in *Rumicastrum* (see Appendix 1). Some scores indicated in Gerbaulet's (1992) *Anacampseros* analysis, published while this manuscript was in review, are contrary to those adopted here. I have attempted to note all discrepancies in Appendix 1. Because Gerbaulet's results are generally consistent with those here and also because *Anacampseros* is phylogenetically relatively distant from *Calandrinia* and *Montiopsis*, I did not reanalyze using Gerbaulet's scores.

Infrataxon variation was problematic in scoring many OTUs (Table 3). I attempted to score variable OTUs for the presumed primitive state. In some

cases, I scored variable OTUs for the derived state of a polarized character, especially where I suspect that the "primitive" state is secondary. For example, I scored *Rumicastrum* for having tuberous roots—the putatively derived state in Portulacaceae—even though most species are not tuberous. Tubers in *Rumicastrum* occur in perennial species (Pate & Dixon, 1982; West, 1986), however, which I presume to be primitive with respect to the annuals, although this has not been demonstrated, specifically, in *Rumicastrum* (see, e.g., Syeda & Carolin, 1990). I used an approach suggested by Nixon & Davis (1991), viz, dividing polymorphic entities into monomorphic OTUs, to alleviate variation problems in *Calandrinia* sect. *Acaules* and, to a lesser extent, in *Montia* (see above). Nevertheless, infra-OTU variation remains for one or more characters (nine in *Portulaca*) in 18 of 33 OTUs, and character variation in other Centrospermae is also problematic in my consideration of ancestral states (see Appendix 1). I hope to be able to solve these problems in follow-up analyses. At this point, I just emphasize that such variation exists and note where it might affect the results.

Many workers (e.g., Doyle & Donoghue, 1986; Nixon & Davis, 1991; Sanderson & Donoghue, 1989) have recognized that cladistic analyses incorporating missing data scores can be misleading because the data, if available, might yield alternative results. Nevertheless, Table 3 includes three sorts of missing data scores, all scored as unknown ("?") in the parsimony program (see below). These include instances where the character state presumably exists in the OTU but has not been adequately or at all investigated ("?" in Table 3); where infrataxon variation prohibits a defensible scoring decision for the entire OTU ("V" in Table 3); and where "X" characters (Doyle & Donoghue, 1986) are employed.

Doyle & Donoghue (1986) devised "X" characters in order to reduce biases in inter-OTU distances where some OTUs lack a particular character that has two or more unpolarizable states. For example, they used "X" scoring for seed shape because radially and bilaterally symmetrical seeds are plausibly derivable from one another, as well as from the seedless condition, by a single evolutionary step. A three-state ordered transformation series was not justifiable, and simply using three unordered states (i.e., seeds absent/radiospermic/platyspermic) would bias against the homology of seed presence per se. Treating the different seed types as independent binary characters (i.e., seeds radiospermic vs. not and seeds platyspermic vs. not) would necessitate two steps in the derivation of one type from the other. Doyle & Donoghue treated seed presence/absence as one character and seed shape as another, with seedless taxa scored as unknown ("X") for the latter. In the present analysis, I adopted "X" scoring for leaf fimbrial vein anatomy (char. 14), stomatal subtype (char. 16), trichome ribbing (char. 21), the derivation of solitary flowers (chars. 22, 23), bract morphology (char. 26), capsule valve morphology after dehiscence (char. 41), and chromosome base numbers when other than nine (char. 46).

In addition to uncertain polarities and missing scores, continuous, rather than discrete, character state variation poses a problem for the present analysis (see Stevens, 1991). Indeed, some of the character states here recognized as different, e.g., petal numbers five, rarely six, versus usually more than five, blatantly overlap. Other states merely intergrade, but the scores reflect consistent distinctions between taxa. For example, in Portulacaceae as a whole, festooned brochidodromous leaf venation (char. 12) intergrades with brochidodromous, which intergrades with other venation patterns (see Hershkovitz, 1990a, 1991a, 1992, 1993). The distribution of this trait in the cladograms must be evaluated with the variation in mind. I emphasize that the scores employed here represent approximations or, in effect, hypotheses of actual character state differences that must eventually be validated by the sort of analyses proposed by Stevens (1991).

*4. Analysis.* I analyzed the Table 3 data matrix using PAUP 3.0r (Swofford, 1991) on a Macintosh Classic II computer with 6 megabytes of memory (RAM) plus "Virtual RAM" (VRAM). I allotted 4.5 and 8.5 kilobytes of memory to PAUP for use without and with VRAM, respectively, and set MAXTREES at 9,000–10,000 and 17,000–22,000 for the lower and higher memory allotments, respectively. I found that, with my hardware, increasing the number of trees in memory beyond 18,000 slows PAUP beyond practical functionality.

For all searches, I used MULPARS, Lundberg rooting, and the designated ancestral states (ANCSTATES) options. By including the ancestor in the search parameter, I generated rooted trees. As recommended by Swofford (1991), I used a variety of PAUP's customizable search modes to facilitate parsimony analysis. The options include taxon addition sequences that vary the configuration and length of the initial tree and "heuristic" branch-

TABLE 3. Data matrix for Portulacaceae. Characters and states are described in Appendix 1. Question marks denote missing, incomplete, or uninterpretable data. A "V" denotes that the character is too variable in the taxon to score with confidence. An "X" denotes a missing character, rather than missing data (see text). Underlined scores indicate infrataxon variability encompassing two or more states.

swapping algorithms that vary the extent to which existing trees are modified in the search for new trees. The fastest algorithm, "nearest neighbor interchange" (NNI), rearranges branches locally, and hence it may not find shorter trees with radically different topologies. The slowest and most thorough heuristic algorithm, "tree bisection-reconnection" (TBR), rearranges trees radically in its search for shorter trees. Intermediate between these is "subtree pruning-regrafting" (SPR). I experimented with all three modes according to the objective of the particular search, but I found that SPR was dispensable for my purposes.

Other PAUP options used here include strict, semistrict, and majority-rule consensus tree computation, the last of which also produces a table of all clades and their frequency among all of the trees in memory; character change and apomorphy lists that output the character state changes occurring for all characters and at all internodes, respectively; the tree filter, which finds among the trees in memory those of particular lengths or topologies; search constraints, which search for trees of particular predefined topologies in any of the search modes; and "starting trees," which permits PAUP to swap on one or more specified trees. The specific utility of each of these options in the present study is described below in the results.

## RESULTS

From 100 replicates of rapid searches initiated using a random taxon addition sequence, variously TBR or NNI, and 30-tree limits, I found minimal length trees of 107 steps. The consistency index (CI) of 107-step trees is 0.449; the rescaled consistency index (RC; Farris, 1989) is 0.346. Because of the "missing data" scores and infra-OTU character variation, the actual CI and RC may be lower (Nixon & Davis, 1991; Sanderson & Donoghue, 1989). Using the present data, I filtered from ca. 29,000 previously saved trees over 11,000 107-step trees and none shorter. The ca. 29,000 trees had been generated using a slightly different data matrix. Entering the ca. 11,000 trees as starting trees, I used TBR to increase their number to over 15,000 107-step trees with over 13,000 remaining to swap. I then switched to NNI, which is faster but finds fewer of the possible equally parsimonious trees, and increased the number of trees to over 19,000, with over 14,000 remaining to swap. At this point, I aborted the search because, from previous experience using similar data sets, I found that such a ratio of trees saved/remaining is an indication that the total number of equally parsimonious trees is at least an order of magnitude

higher, in this case exceeding the memory capacity of both the hardware and the program. Moreover, with this large tree buffer, PAUP was swapping on less than two trees per minute.

In order to generate a reliable consensus tree given the memory limitation (i.e., to avoid an over-representation of particular topologies among the total number of trees), I initiated additional searches using TBR to completion constraining for two particular topologies that were rare among the ca. 19,000 as determined by the clade frequency table: a constraint for trees with *Claytonia* + *Montia* (2 OTUs) + *Lewisia* as outgroups to the remaining OTUs (in 43 of 19,000 trees), and one for trees with *Calandrinia acaulis* + *C. caespitosa* + *C. carolinii* forming a clade (38/19,000). These searches yielded a total of over 5,000 additional 107-step trees.

The strict consensus tree of the total ca. 24,000 107-step trees (saved in three files) is shown in Figure 1. The black, shaded, and diagonally hatched branches delineate the western American, eastern American/African, and Australian taxa, respectively (Hershkovitz, 1991a, fig. 3). Putative positions of Cactaceae, Basellaceae, Didiereaceae, and *Talinella* (see below) are indicated by dashed branches. The semistrict consensus tree topology (Bremer, 1990) generated from the 17,000-tree treefile was identical to the strict consensus. The consensus tree is not a phylogeny (Anderberg & Tehler, 1990; Maddison, 1989): its "length" is 114—seven steps longer than that of its completely bifurcate resolutions. It does show, however, which groups are monophyletic in all 24,000 rearrangements and all unambiguous consensus character state changes (i.e., excluding those dependent on the particular resolution). The transitions indicated in Figure 1 for characters 15 and 24 appear equivocal but are not: by using constrained searches such as those described below, I determined that resolutions consistent with alternative positions for these transitions do not occur among 107-step trees.

For reference, all character state changes determined using the accelerated transition (ACCTRAN) optimization are listed in Appendix 2. Collectively, Appendix 2 presents a distorted picture of character state evolution in Portulacaceae in that seven superfluous changes are indicated and many changes would appear differently using alternative optimizations. In one or more optimizations, characters not indicated on the consensus tree undoubtedly provide synapomorphies for one or more clades in any of the possible resolutions, e.g., fimbrial vein presence (char. 13) must support at least one subclade in any resolution within the *Calandrinia* clade. Because of the large number of trees, however, it is not practical to evaluate the character evidence for each permutation of the consensus. The various alternatives for ambiguous or equivocal character state changes not shown in Figure 1 are not all mutually compatible, i.e., the topology required to assign a particular character state change to a given node of the consensus tree effectively prohibits other changes from simultaneously occupying that node. I did not attempt to identify a permutation of the consensus tree that would resolve the largest number of ambiguities.

From the clade frequency matrices (not shown), I found a wide variety of resolutions of the polytomous nodes, but not all possible sister group relationships were evident. To determine which of the possible sister group relationships among the unresolved basal 5-tomy were compatible with 107-step trees, I initiated additional searches using appropriate constraints, TBR and/or NNI, a random addition sequence with 50 or more replicates, and 30-tree limits. Table 4 shows all compatible relationships and the length of the shortest trees found for incompatible groupings. Table 4 also shows minimal tree lengths generated when constraining for alternative sister group relationships of the *Calandrinia* clade, the *Montiopsis* clade, the *Calandrinia* + *Montiopsis* clade, the eastern American/African clade (see above; cf. Fig. 1), and the *Calandrinia* + *Montiopsis* + eastern group clade.

I used constrained topology searches in order to evaluate additional phylogenetic hypotheses, e.g., Carolin's (1987) results that showed *Calandrinia* sections *Calandrinia* and *Monocosmia* linked with *Rumicastrum* or *Montia* (see above). From more than 50 replicates using a random addition sequence and NNI, I found minimal length trees of 116 and 111 steps, respectively, for the alternative relationships. Likewise, searches initiated using appropriate constraints to evaluate Carolin's (1987) result showing *Baitaria* as monophyletic generated minimal length trees of 110 steps. I have previously suggested that *Calandrinia* sect. *Acaules* is paraphyletic with respect to sections *Calandrinia* and *Monocosmia*. Constraining for the monophyly of section *Acaules* generated 108-step trees. Constraining for a clade comprising all OTUs formerly assigned to *Calandrinia* sensu lato excluding those sections that were based on taxa belonging to other genera (e.g., sect. *Pachypodeae*) generated 122-step trees. Constraining for the monophyly of *Talinum* sects. *Talinum* and *Phemeranthus* (cf. Carolin, 1987) generated 109-step trees. Finally, be-

1

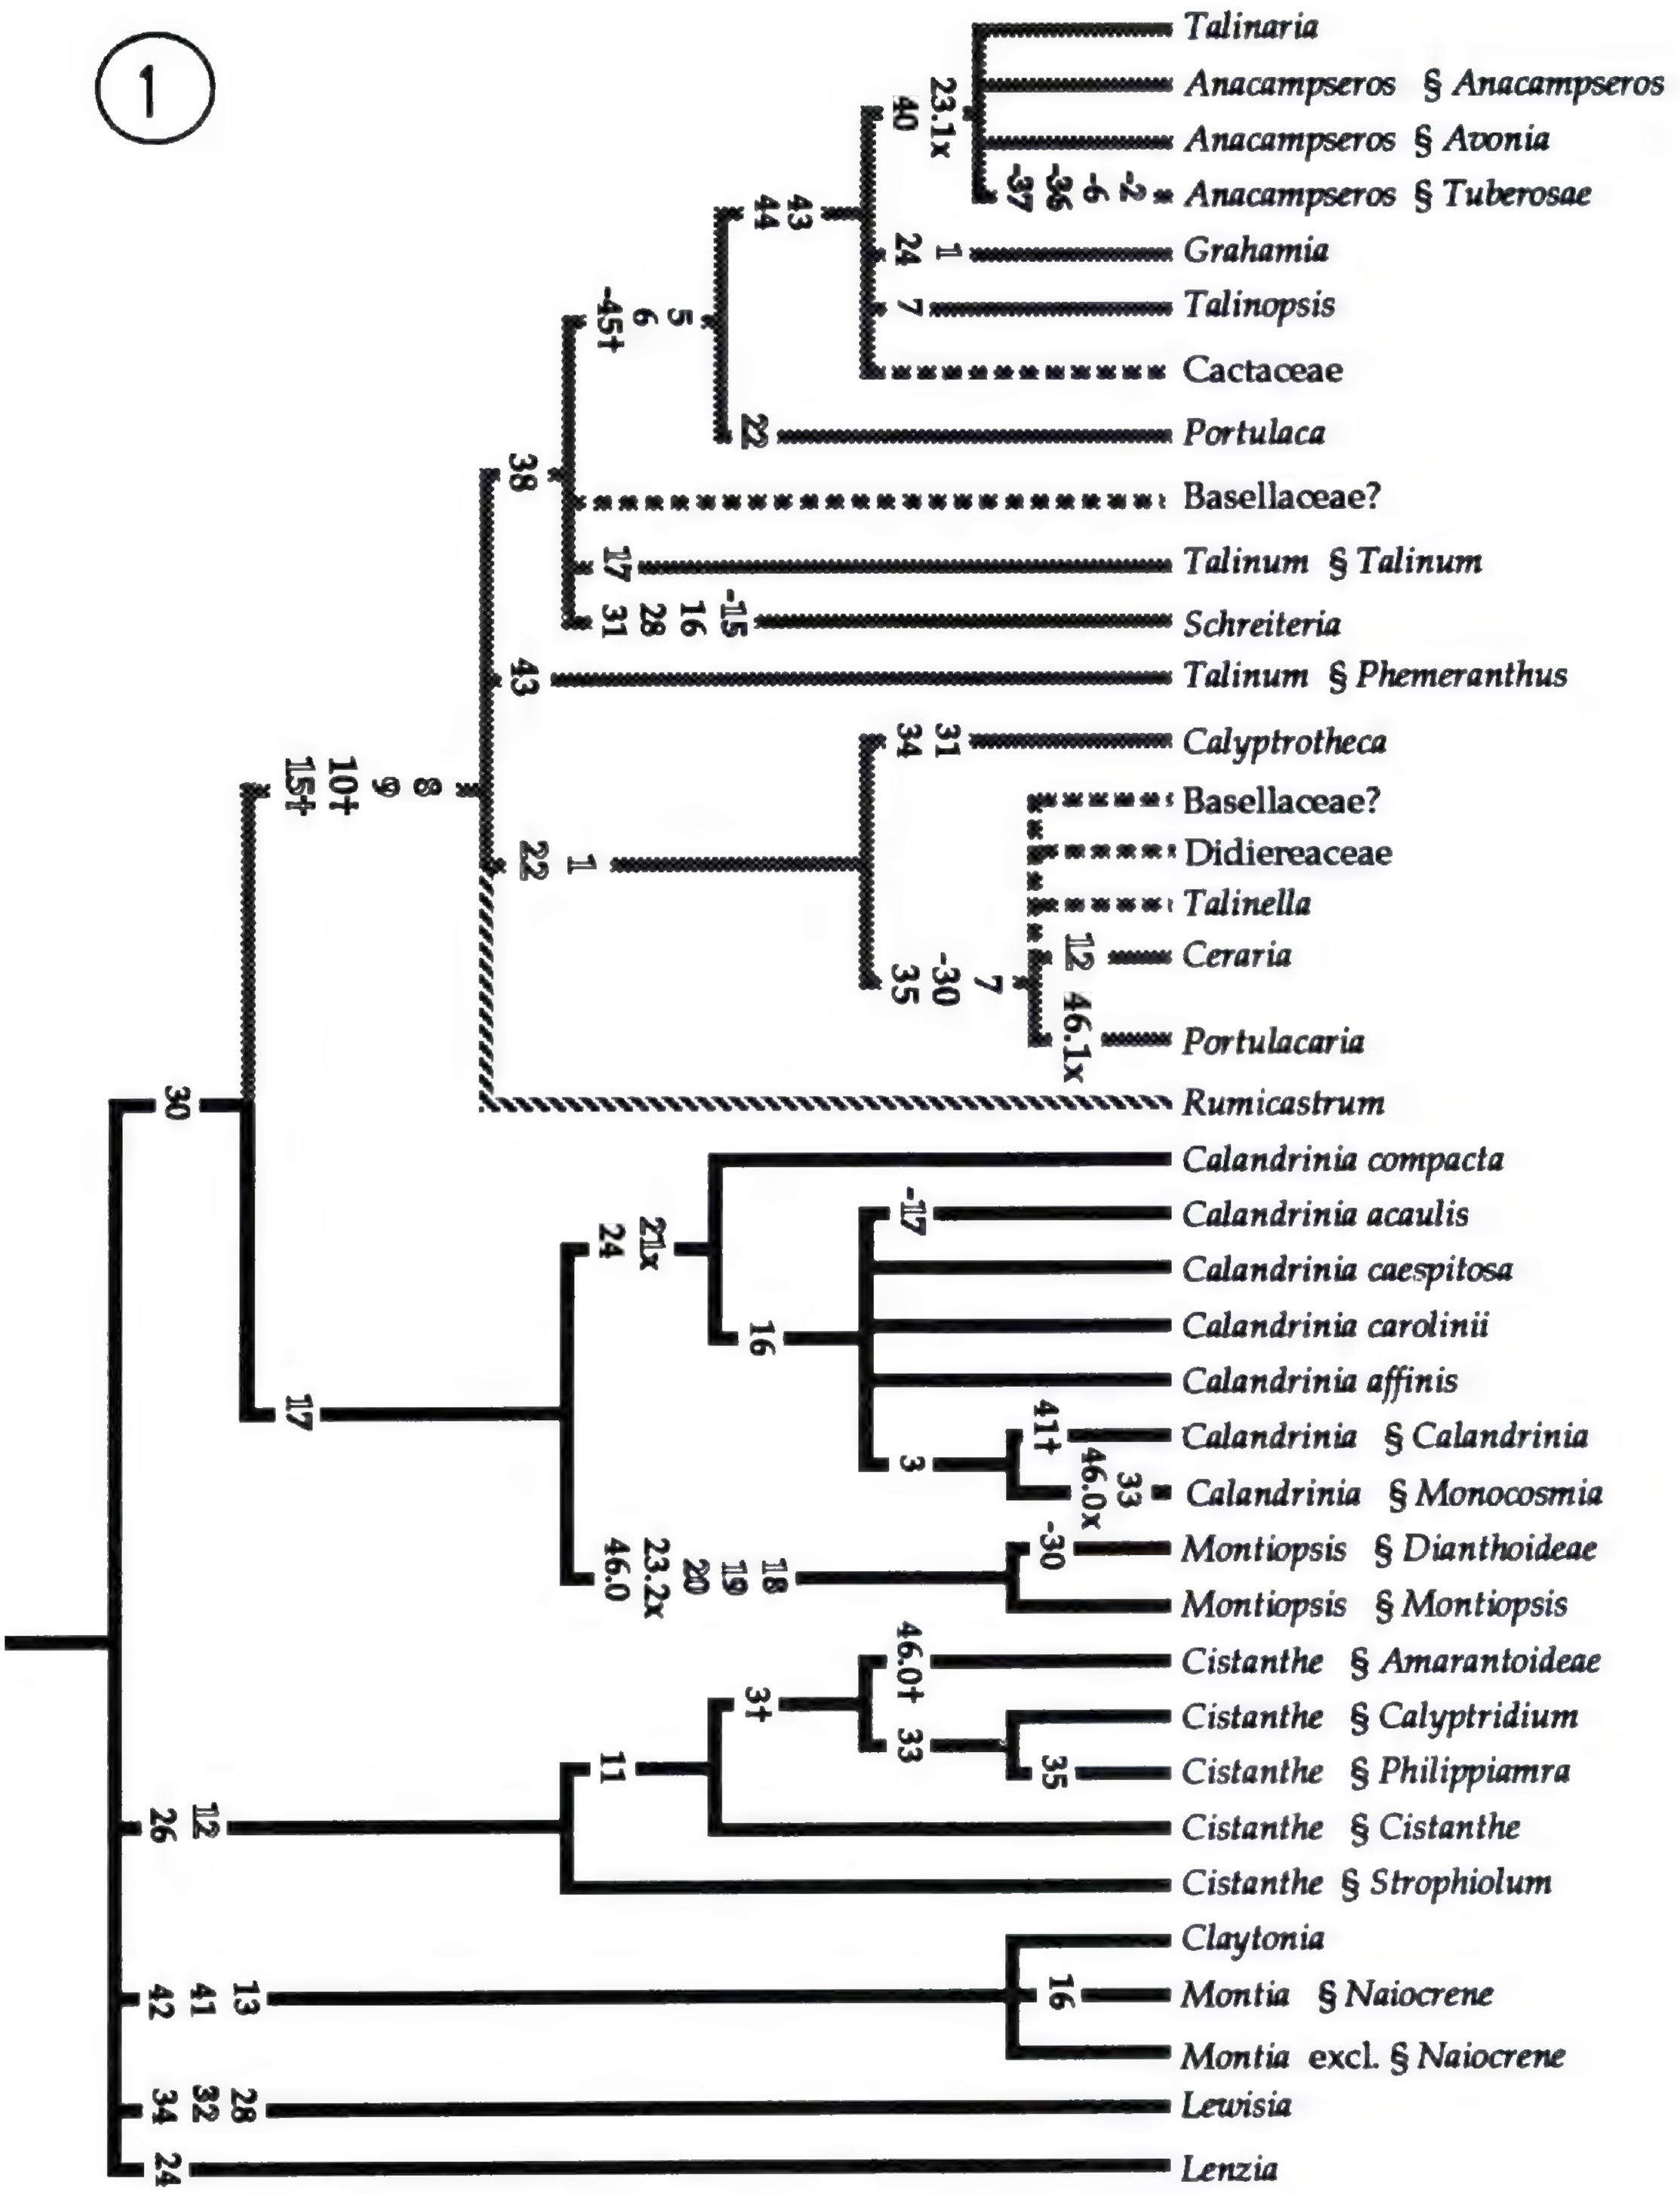

FIGURE 1. Consensus tree for Portulacaceae. Shown here is the consensus for 24,000 107-step cladograms found in the present phylogenetic analysis. The eastern American/African, Australian, and western American taxa are delineated by, respectively, gray shaded, diagonally hatched, and black branches. Taxa delineated by hyphenated branches were not included in the computer analysis, but were added in manually (see discussion). Unambiguous character state changes are shown on the branches (cf. Appendix 1). Polarized characters are shown in black, unpolarized characters are shown in white, and "x" and "†" denote characters scored as unknown ("X" character or missing value) for an OTU on an adjacent branch (cf. Table 3). The positions of the character 15 and 24 transitions appear equivocal but are consistent with all known 107-step resolutions of the tree.

TABLE 4. Sister group relationships compatible with 107-step trees. Denoted below by "+" are sister group relationships that occur among the 107-step trees found in the present analysis (cf. Fig. 1). The minimum length of trees with incompatible sister group relationships is also indicated. The generic taxonomy follows Table 2. The taxon designated "E. group" refers to the eastern American/African group of Portulacaceae (see text; cf. Fig. 1). "Ingroup minus taxon" refers to a sister group relationship between the indicated taxon and the remainder of Portulacaceae. In the case of the E. group, the ingroup is, effectively, a clade comprising the western American group (see text; cf. Fig. 1).

cause Figure 1 shows two unambiguous reversals to tricolpate from panaperturate pollen (cf. Hershkovitz, 1989, 1991a), I constrained for trees showing the reversal to be at least equivocal. This search generated 108-step trees that are included among those showing the eastern American/African and western American groups as monophyletic (Table 4).

To summarize, for purposes of the present study, the most important results shown in Figure 1 include, first, evidence consistent with my earlier conclusions (Hershkovitz, 1990a, 1991a) that *Calandrinia* sects. *Calandrinia*, *Acaules*, and *Monocosmia* form a monophyletic group. Second, a single trait (trichome presence, char. 17) supports the sister group relationship between *Calandrinia* and *Montiopsis*, although the trichomes in the two genera are structurally distinct (Hershkovitz, 1993). In trees only one step longer, *Montiopsis* has at least six possible alternative sister groups (Table 4). Third, the consensus is consistent with Carolin's (1987) results indicating that *Calandrinia* sensu lato is unnatural and that *Cistanthe* is monophyletic. Fourth, the tree supports my proposal (Hershkovitz, 1991a, d) that the western American and eastern American/African Portulacaceae are phylogenetically set apart from one another. In this analysis, the latter appear to be monophyletic and the former paraphyletic but equivocally monophyletic in trees one step longer (Table 4).

## Discussion

Although the highly polytomous Figure 1 consensus tree might be dissatisfying for its lack of resolution, it serves the primary purpose of this study, which is to determine the relationships of Carolin's (1987) *Calandrinia* sensu stricto + *Monocosmia* clade and, in general, to advance taxonomic understanding of *Calandrinia* sensu lato. The results of this analysis also provide a framework for additional study of more precise relationships within the segregates of this genus, as well as among other Portulacaceae and Centrospermae.

### A. Taxonomy and Relationships of *Calandrinia* and *Montiopsis*

The consensus tree supports my earlier contention (Hershkovitz, 1990a) that *Calandrinia* sects. *Calandrinia* and *Monocosmia* are closely related to section *Acaules* and my hypothesis that the last is paraphyletic with respect to the first two. The paraphyly of section *Acaules* is evidenced by a single unambiguous character state change (presence of tetracytic/staurocytic stomata, char. 16) and, ambiguously, by another (fimbrial vein presence or subtype (chars. 13, 14). I also emphasize that section *Calandrinia* is possibly paraphyletic with respect to section *Monocosmia*. The only eligible autapomorphy for section *Calandrinia* (capsule-valve inrolling, char. 41) is nonuniversal (Appendix 1) and not readily evaluated in section *Monocosmia*.

While I believe that the results of the present analysis adequately evidence the monophyly of *Calandrinia*, I do not believe that a cladistic sectional taxonomy can be justified in the absence of a species-level analysis, especially because the functional OTUs employed here for section *Acaules* form a clade in trees only one step longer than the shortest. Because I am unable to offer anything cladistically more defensible, Carolin's (in press) circumscriptions of sections *Acaules* and *Calandrinia* (including sect. *Axillares*) are here retained.

Also consistent with my earlier conclusions (Hershkovitz, 1990a), the present analysis shows *Montiopsis* as monophyletic and linked only weakly with *Calandrinia*. The monophyly of *Montiopsis* is evidenced by its unique inflorescence (char. 23), assorted multicellular trichomes (chars. 18–20), and chromosome base number (char. 46). According to Figure 1, the reversal from panaperturate to tricolpate pollen provides an autapomorphy for subgenus *Dianthoideae*. I have previously noted (Hershkovitz, 1991a) that reversals from panaperturate to tricolpate pollen indicated in Carolin's (1987, fig. 7) cladogram (for subg. *Dianthoideae* and the *Portulacaria* + *Ceraria* clade) are actually equivocal. In the present analysis, both are unambiguous but become equivocal by allowing an additional step or, as I determined fortuitously, by scoring *Calandrinia caespitosa* for lacking trichomes. For this reason, and because there appears to be no precedent for such a reversal elsewhere among angiosperms, I hesitate to accept this trait as an autapomorphy or, without additional analysis, a phylogeny that requires such a reversal. Otherwise, I cannot document an autapomorphy for subgenus *Dianthoideae*, so the possibility that it is paraphyletic with respect to subgenus *Montiopsis* must be considered (see also below). Subgenus *Montiopsis* can be diagnosed on the basis of a unique trichome type that consists of elongated, intertwined cells (Ford, 1992; Hershkovitz, 1993; Kelly, 1973) and also, perhaps, on the basis of its pantoporate pollen.

As noted above, the sister group relationship between *Montiopsis* and *Calandrinia* is supported only by the shared presence of trichomes (char. 17), although the trichomes are structurally dis-

tinct. I have also noted leaf venation and epidermal similarities between *Montiopsis* and *Calandrinia* (Hershkovitz, 1993). Specifically, venation patterns in *Montiopsis* superficially resemble those in some species of *C.* sect. *Acaules* (although the similarity is in the shared lack of distinctive features) and tetracytic/staurocytic stomata occur in *M.* subg. *Dianthoideae*. Against the weak evidence favoring a *Montiopsis/Calandrinia* sister group relationship, however, there is also weak evidence to the contrary. In previous PAUP runs, I inadvertently scored *Calandrinia caespitosa* for lacking trichomes (although it is variable for this trait, and I scored it correctly for trichome morphology, char. 21). These searches generated the ca. 29,000 (108-step) trees from which the ca. 11,000 107-step trees were filtered using the corrected data (see above). In fact, the 29,000 trees in the earlier search probably represent only a small fraction of the total number of 108-step trees given that particular data file. In any case, with the single different score, all of the possible sister group relationships for *Montiopsis* indicated in Table 4 occurred among minimal length trees. This result renders the trichome evidence for a *Calandrinia* + *Montiopsis* sister group relationship even more tenuous because of its dependence on precise relationships and character state distributions in *Calandrinia* that cannot, at present, be adequately evaluated. I had previously been inclined to retain *Montiopsis* in *Calandrinia*, but given the relative homogeneity of each genus and the possibility that they are not closely related, their segregation seems warranted. Perhaps the only justification for retaining *Montiopsis* in *Calandrinia* would be if *M.* subg. *Dianthoideae* proved to be paraphyletic with respect to both *Calandrinia* and *M.* subg. *Montiopsis*. I have considered this possibility (Hershkovitz, 1990a). but it remains unscrutinized.

Figure 1 shows *Calandrinia* and *Montiopsis* together forming the sister group to the eastern American/African Portulacaceae evidenced by the shared derivation of panaperturate pollen. As I noted above, this sister group relationship is also contingent upon the homology of trichomes in *Calandrinia* and *Montiopsis*, and the relationship becomes equivocal in trees one step longer than minimal (Table 4). Among the 108-step trees are those showing a sister group relationship between *Calandrinia* and *Claytonia* + *Montia* (Montieae), reminiscent of Carolin's (1987) suggestion of a close relationship between *Calandrinia* (minus sect. *Acaules*) and *Montia*. The latter seems unlikely not only on parsimony grounds, but because either *Calandrinia* (sensu Hershkovitz) or Montieae must then be artificial. Nevertheless, a *Calandrinia*/Montieae relationship deserves additional scrutiny, especially because my data matrix presumes that putative similarities in inflorescence and fruit morphology in *C.* section *Calandrinia* and Montieae are not homologous (see Appendix 1).

See Table 5 for a synopsis of a revised sectional taxonomy of *Calandrinia* and *Montiopsis*.

### B. TAXONOMY AND RELATIONSHIPS OF OTHER MEMBERS OF *CALANDRINIA* SENSU LATO

Figure 1 confirms Carolin's (1987) general result that the remaining members of *Calandrinia* sensu lato are phylogenetically interspersed among several other traditional genera of Portulacaceae. My earlier proposed circumscription of *Cistanthe*, which includes members of *Calandrinia* sensu lato and three to four other traditional genera (Table 1), is upheld. The consensus of the infrasectional relationships differs from, but is not inconsistent with, what I suggested earlier (Hershkovitz, 1991a, fig. 3). Specifically, my earlier figure shows either section *Strophiolum* or *Cistanthe* as possible sister groups of the remainder of the genus. As I noted before, however, section *Cistanthe* is highly polymorphic and section *Amarantoideae* lacks an unequivocal autapomorphy; hence resolution of phylogeny within *Cistanthe* will necessitate a species-level analysis.

According to Figure 1, the remaining two members of *Calandrinia* sensu lato, *Rumicastrum* and *Schreiteria*, are members of the eastern American/African Portulacaceae and are not closely related to other members of *Calandrinia* sensu lato. *Rumicastrum* is rosettiform, however, and individual species possess leaf morphological features characteristic of *Cistanthe* (Hershkovitz, 1991b). Hence, I hesitate to conclude that its position in the consensus tree is correct. My results for *Rumicastrum* are difficult to compare with Carolin's (1987, fig. 7) because of overall topological differences in our respective trees. Nevertheless, ignoring the position of *Calandrinia* sects. *Calandrinia* and *Monocosmia* in Carolin's tree, the closest relatives of *Rumicastrum* and *Schreiteria* are members of the eastern American/African group. This result is not inconsistent with Figure 1.

The possibility that *Rumicastrum* (or *Rumicastrum* + *Talinum* sect. *Phemeranthus*, which occurs in some trees) is basal in the eastern American/African group may prove to be significant in resolving the problem of pollen evolution in Portulacaceae. To avoid the reversal to tricolpate pol-

TABLE 5. Key to and synopsis of the *Calandrinia* sections and *Montiopsis* subgenera. The diagnoses are based on data presented in Appendix 1 and Table 3.

A. *Calandrinia*
- 1a. Plants perennial, rosettiform, without leafy aerial stems; leaves glabrous or with unicellular-ribbed, sometimes papillate trichomes; flowers solitary, arising from basal leaf axils; stigmas 3 5; seeds several in a 3(–4)-valvate capsule . . . . . A2. *C.* sect. *Acaules*
- 1b. Plants annual, rosettiform, with leafy aerial stems arising from rosette axils; leaves usually with unicellular-ribbed, sometimes papillate trichomes, rarely truly glabrous; flowers arising variously from leafy, bracteate, or naked nodes of aerial stem, hence sometimes apparently racemose or paniculate; stigmas 2–3; seeds several in a 3-valvate capsule or 1–2 in a 2-valvate, incompletely dehiscent fruit.
  - 2a. Leaves probably always with (sometimes papillate) unicellular trichomes; flowers arising from axils of alternating leaves or bracts alternating with leaves on 0–1-branched aerial stems, hence sometimes apparently racemose; stigmas 3; seeds several in a 3-valvate capsule . . . . . A1. *C.* sect. *Calandrinia*
  - 2b. Leaves with papillate trichomes or glabrous; flowers arising variously and irregularly from leaf or bract axils or naked nodes on branched aerial stems, hence apparently paniculate; stigmas 2; seeds 1–2 in a 2-valvate, incompletely dehiscent achene-like fruit . . . . . A3. *C.* sect. *Monocosmia*

B. *Montiopsis*
- 1a. Plants perennial; multicellular trichomes variously uniseriate or multiseriate and glandular or eglandular (or rarely absent), but never formed by elongate, intertwined hair cells; pollen tricolpate . . . B1. *M.* subg. *Dianthoideae*
- 1b. Plants annual or perennial; multicellular trichomes variously uniseriate or multiseriate and glandular or eglandular, but trichomes formed by elongate, intertwined (sometimes barbed) hair cells always present; pollen pantoporate . . . . . B2. *M.* subg. *Montiopsis*

**A. Calandrinia** Kunth in HBK, Nov. Gen. Sp. 6: 77. 1823. nom. conserv. TYPE: *C. caulescens* Kunth (type conserv.; = *C. ciliata* (Ruiz & Pavón) DC.).

**A1. C.** sect. **Calandrinia.** About 5 spp. of temperate western America and montane southern Mexico, Guatemala, and temperate South America.

**A2. C.** sect. **Acaules** Reiche, Ber. Deutsch. Bot. Ges. 15: 500. 1897. TYPE: *C. acaulis* Kunth (lectotype, here designated). About 8 spp. of the Andes region, with one disjunct to southern Mexico.

**A3. C.** sect. **Monocosmia** (Fenzl) Hershkovitz, Phytologia 70: 223. 1991. TYPE: *C. monandra* (Ruiz & Pavón) DC. One species in Chile and Argentina.

**B. Montiopsis** Kuntze, Revis. Gen. Pl. 3(2): 14. 1898. TYPE: *M. boliviana* Kuntze (= *M. cumingii* (Hook. & Arn.) D. I. Ford).

**B1. M.** subg. **Montiopsis.** About 15 spp. of temperate western South America.

**B2. M.** subg. **Dianthoideae** (Reiche) D. I. Ford, Phytologia 74: 277 1993. TYPE: *M. cistiflora* (Gillies ex Arn.) D. I. Ford (lectotype, selected by Ford) About 3 spp. of temperate western South America.

len in trees as long as 108 steps, *Portulacaria* + *Ceraria* (± *Calyptrotheca*) must be the basal branch in the eastern American/African clade or *Portulacaria* + *Ceraria* must occupy the second most basal branch. Thus, with *Rumicastrum* occupying the basal branch, tricolpy is, at best, equivocally primitive in this group, and the number of topologies that permit tricolpy to be primitive is restricted.

## C. PHYLOGENETIC RELATIONSHIPS AMONG OTHER GENERA OF PORTULACACEAE

A thorough consideration of the relationships among Portulacaceae or, more appropriately, the portulacaceous alliance, is ultimately critical for resolving the precise relationships among members of *Calandrinia* sensu lato but is beyond the scope of the present paper. Nevertheless, the results of the present analysis are at least sufficient to compare with Carolin's (1987) results and to offer general conclusions.

Figure 1 supports my earlier notion (Hershkovitz, 1991a, b, d) of a phylogenetic partition between the fundamentally eastern American/African members of Portulacaceae and the western American and places the Australian endemic *Rumicastrum* in the former group. In trees one step longer, the eastern American/African and western American groups are each equivocally monophyletic (Table 4). Figure 1 can be compared with Carolin's (1987, fig. 8) area cladogram in which all of the minor clades he recognized except *Rumicastrum* can be assigned to eastern America/Africa or western America. Figure 1 also reproduces, albeit with less resolution, Carolin's clade "H," comprising *Portulaca*, *Talinopsis*, *Grahamia*, *Anacampseros*, and *Talinaria*. Gerbaulet (1992) discussed in detail monophyly and interrelationships among the last four genera ("*Ana-*

*campseros* group"; but see discussion of Cactaceae below). My results with respect to relationships within and proximal to the *Anacampseros* group would have differed using Gerbaulet's (1992) character data, but I suspect that the fundamental conclusions presented here (viz, the circumscription of *Calandrinia* sensu stricto, the eastern American/African vs. western American distinction, and even the relative position of the *Anacampseros* group) would remain. Figure 1 shows *Portulacaria* and *Ceraria* as sister groups, but this relationship has not been controversial (cf. Carolin, 1987, in press; McNeill, 1974; Nyanyano, 1989; Pax & Hoffmann, 1934; Rauh & Schölch, 1965).

Because of the potential problems in OTU delimitation, infra-OTU character variation, and character analysis, Figure 1 must be interpreted cautiously. For example, *Lewisia* comprises species with character combinations suggestive of other Portulacaceae (Hershkovitz, 1992), including species of *Calandrinia* sect. *Acaules* (Kelley & Swanson, 1985). Phylogenetic resolution within *Lewisia* will establish its primitive character states, and hence clarify its relationships to other genera, including *Calandrinia* and *Montiopsis*. Also, in the present analysis I found *Talinum* to be polyphyletic and *T.* sect. *Phemeranthus* as a possible sister group of *Rumicastrum*. The first result is consistent with Carolin's (1987). Nevertheless, both results should be regarded as highly suspect until the putative distinctions between the *Talinum* OTUs are better articulated. Also questionable is an especially close relationship between *Calyptrotheca* and *Portulacaria* + *Ceraria*. *Calyptrotheca* includes two arborescent species that otherwise resemble *Talinum* sect. *Talinum* species and differ from *Portulacaria* and *Ceraria* in having broad, not especially succulent leaves and showy flowers with numerous stamens and ovules. Figure 1 shows opposite leaves as a synapomorphy of *Calyptrotheca* with *Portulacaria* + *Ceraria*, but subopposite leaves characterize *Talinum paniculatum* (Jacq.) Gaertn. (pers. obs.).

Consistent with Carolin's (1987) findings, the present analysis does not support any existing suprageneric taxonomy of Portulacaceae (e.g., McNeill, 1974; Nyanyano, 1990; Pax & Hoffmann, 1934), including Carolin's (in press). Each of the earlier systems contains a polyphyletic taxon, variously Talineae or Calandrinieae, that comprises one-third to one-half of all Portulacaceae genera, including *Talinum* and *Calandrinia*, but usually excludes such taxa as *Calyptrotheca* and *Calandrinia* sect. *Monocosmia*. Whatever its name or precise composition, this large taxon is misinformative and should be abandoned. Other established suprageneric categories, such as the tribe Montieae (excluding *Wangerinia*; Carolin, 1987), remain defensible cladistically.

Unfortunately, the present results do not suggest an alternative comprehensive classification. Conceivably, the eastern American/African and western American groups could constitute subfamilies, but I hesitate to formalize this because of the lack of additional evidence on their precise interrelationship and because the eastern American/African group is probably paraphyletic with respect to Basellaceae, Cactaceae, and Didiereaceae (see below). Likewise, the unresolved position of Cactaceae may confound Carolin's (1987, in press; see also Gerbaulet, 1992) otherwise defensible circumscription of tribe Portulaceae. Each of the branches from the polytomous nodes in Figure 1 might be recognized as a suprageneric taxon. As I have noted, however, some of the bifurcately resolved nodes are poorly supported or disputable. By collapsing such nodes, the suprageneric taxonomy would be nearly redundant with the generic taxonomy. Even in 107-step trees, a suprageneric classification of *Talinum* is problematic. Thus, for now, I recommend listing the genera as a single linear series with established monophyletic suprageneric categories (e.g., Montieae and Portulaceae sensu Carolin) referred to only informally. Ultimately, I believe that phylogenetic evidence will warrant segregating most or all of the western American taxa into a distinct family, expanding the existing circumscriptions of Cactaceae, Basellaceae, and Didiereaceae to include their portulacaceous sister taxa, and retaining Portulacaceae only for the monophyletic residue.

### D. PHYLOGENETIC RELATIONSHIPS OF UNANALYZED MEMBERS OF THE PORTULACACEOUS ALLIANCE

I did not include Basellaceae, Didiereaceae, Cactaceae, Hectorellaceae, *Talinella*, or *Amphipetalum* in this analysis because I have not yet studied these adequately and because I do not believe that their inclusion would affect the present conclusions regarding the circumscriptions of *Calandrinia* and *Montiopsis*. I also did not consider *Xenia*, which was segregated from *Anacampseros* (Gerbaulet, 1992) while this manuscript was in review. All but Hectorellaceae probably belong to the eastern American/African clade as evidenced by their nonrosettiform habit, nonclasping, constricted leaf bases, parallelocytic/nonbrachyparacytic stomata, and (although unknown for *Amphipetalum*) copious mucilage (Cronquist, 1981; Eggli, 1984; Gibson

& Nobel, 1986; Hershkovitz, unpublished; Paliwal, 1965; Rauh, 1956; Bacigalupo in Spichiger, 1988). These taxa will be considered in future work, but a summary of existing information can be included here.

*1. Basellaceae.* Basellaceae have nearly always been linked with Portulacaceae (reviewed in Sperling, 1987), especially with *Ceraria* and *Portulacaria* because of their single-seeded indehiscent fruits (Pax & Hoffmann, 1934; Sperling, 1987). Basellaceae agree better with *Talinum* sect. *Talinum* in leaf venation pattern (Hershkovitz, unpublished), more herbaceous habit (at least the leaves and leafy stems), and panaperturate pollen (vs. tricolpate in *Ceraria* and *Portulacaria*; cf. Sperling, 1987). Unlike *Ceraria* and *Portulacaria*, Basellaceae and *Talinum* lack epidermal wax crystals (Engel & Barthlott, 1988), but this may be a symplesiomorphy. Evidence for a close Basellaceae–Didiereaceae sister group relationship (Rodman et al., 1984) is problematic (Hershkovitz, 1989). Actually, Basellaceae and Didiereaceae do share traits, e.g., single-seeded, indehiscent fruits, but in the context of Portulacaceae, these would be, at best, symplesiomorphies (i.e., with *Ceraria* and *Portulacaria*).

*2. Didiereaceae and Talinella.* Didiereaceae resemble *Ceraria* and *Portulacaria* in gross form, leaf venation pattern (Hershkovitz, unpublished), floral and inflorescence morphology (Rauh & Schölch, 1965), and epidermal micromorphology (Engel & Barthlott, 1988). Didiereaceae have also been linked with Cactaceae on the basis of serological evidence (Jensen, 1965), vegetative anatomy (Rauh, 1983; Rauh & Dittmar, 1970; Rauh & Reznik, 1961), and graft compatibility (see Cronquist, 1981; Gibson & Nobel, 1986; Rauh, 1983). Existing arguments are moot if both Cactaceae and Didiereaceae are interrelated via Portulacaceae and their similarities attributed to symplesiomorphy. Important differences between Didiereaceae and Cactaceae include perianth morphology, the absence of axillary hairs/scales in the former, and their biogeographic remoteness. Didiereaceae also resemble *Talinella* in their woody habit, much-branched inflorescences, and small flowers (Hershkovitz, 1991d; cf. Baillon, 1886; Carolin, in press; Pax & Hoffmann, 1934). The affiliation of *Talinella*, a poorly known Madagascar-endemic genus of 2–4 spp., with Portulacaceae has been questioned (Carolin, in press; Nyanyano, 1986b; Pax & Hoffman, 1934). *Talinella* is distinctive in having axile rather than free-central placentation, but its combination of betalain pigments, globular sieve-tube plastid inclusions, dichlamydous perianth, bipartite calyx, and nonbrachyparacytic or parallelocytic stomata (Behnke et al., 1975; Nyanyano, 1986b) along with normal secondary growth and copious mucilage (pers. obs.) does not occur outside of the eastern American/African group of the portulacaceous alliance. Within this group, the balance of its features suggests that *Talinella* is closest to Didiereaceae, *Ceraria*, and *Portulacaria*.

*3. Cactaceae.* A close relationship of Cactaceae to Portulacaceae has been advocated previously (Chorinsky, 1931; Gibson & Nobel, 1986; Schumann, 1899; Thorne, 1976, 1983) and perhaps indirectly via Didiereaceae (Jensen, 1965; Rauh, 1983; Rauh & Dittmar, 1970), but the position of Cactaceae among Centrospermae (indeed, among angiosperms) has been at least as controversial as Centrospermae origins and phylogeny as a whole (see, e.g., Benson, 1982; Bittrich & Hartmann, 1988; Boke, 1964; Buxbaum, 1949; Croizat, 1960; Cronquist, 1981, 1988; Engler, 1925; Erbar, 1986, 1988; Leins & Schwitalla, 1986, 1988; Leuenberger, 1986; Moeliono, 1970; Takhtajan, 1980, 1986; Zimmerman, 1985). Traits of Cactaceae that, compared to other Centrospermae, support a relationship with Portulacaceae include the combination of betalains, normal secondary growth, and petals (see Cronquist, 1981). There is general agreement that the leafy genus *Pereskia* is the most primitive among cacti, but opinions differ as to which species is the most primitive *Pereskia* (compare, e.g., Gibson & Nobel, 1986; Leuenberger, 1986). Both Leuenberger (1986) and Gibson & Nobel (1986) presumed that one or another arborescent, tropical, northern South American *Pereskia* species was primitive in the genus, although arborescence in the portulacaceous alliance is otherwise restricted to African taxa and only a few otherwise widely distributed species of Portulacaceae occur in northern South America. Leuenberger (1986) presumed that a shrubby (vs. arborescent) habit, tuberous roots, and stem stomata are derived traits within *Pereskia*, yet all occur among eastern American/African Portulacaceae (Carolin, in press; pers. obs. for stem stomata, e.g., in *Talinum* spp.).

The presence of axillary hairs and scales in Cactaceae (Chorinsky, 1931; Schumann, 1899) suggests a relationship to the clade comprising *Portulaca*, *Anacampseros*, *Talinaria*, *Talinopsis*, and *Grahamia* (Fig. 1). Among these, the poorly studied monotypic, Patagonian genus *Grahamia* resembles *Pereskia* most closely. *Grahamia* is a

woody scrambler with proleptic shoots that terminate in a single showy flower subtended by a whorl of somewhat spinescent sepaloid bracts (Carolin, in press; Pax & Hoffmann, 1934; cf. Leuenberger, 1986). A close *Grahamia–Pereskia* relationship might be counterevidenced by traits diagnosing the monophyly of Gerbaulet's (1992) "*Anacampseros* group," as well as by the chromosome base number 11 in Cactaceae versus nine in Carolin's Portulaceae. A more detailed evaluation of the evidence on cactus origins, however, is beyond the scope of the present paper.

*4. Hectorellaceae.* At present, I am unable to discern any known features of the geophytic, New Zealand endemic Hectorellaceae that would allow its unequivocal assignment to either the eastern American/African or western American groups of Portulacaceae (cf. Nyanyano, 1986a; Skipworth, 1961). Hectorellaceae are copiously mucilaginous (Yoong et al., 1975) with apparently anomocytic (Skipworth, 1961), brachyparacytic, or even cylclocytic stomata (Hershkovitz, unpublished). The leaves are highly reduced and specialized, however, so it is difficult to compare their morphology with leaves of other Portulacaceae.

*5. Amphipetalum.* Bacigalupo (in Spichiger, 1988) proposed a close relationship between *Amphipetalum* and *Calyptrotheca* because they share 6-valvate acropetally dehiscent capsules. This trait has been reported to occur in *Talinum* (*Talinum*) *rivae* Chiov. (von Poellnitz, 1934b; cf. Carolin, in press), but perhaps this Somalian endemic actually belongs to *Calyptrotheca*. Acropetally dehiscent 3-valvate capsules occur in *Talinum paniculatum* (Jacq.) Gaertn., however (Galati, 1986). The herbaceous habit, small size (< 0.5 m high), sparsely or unbranched inflorescence, numerous ovules (> 10), and ≥ 40-porate pollen of *Amphipetalum* are contrary to the traits of *Calyptrotheca* and suggest a closer relationship to *Talinum* section *Talinum* spp. (Carolin, 1987, in press; Nyanyano, 1986a; Pax & Hoffmann, 1934), although the pollen pore number of *Amphipetalum* exceeds that reported in any species of *Talinum*. *Amphipetalum* shares with *Montiopsis* an indumentum of uniseriate, multicellular trichomes.

### E. WHAT IS PRIMITIVE IN THE PORTULACACEOUS ALLIANCE?

The consensus tree (Fig. 1) is disappointing in its failure to identify which taxon or taxa form the sister group of the remainder. Table 4 shows that several resolutions are possible among the 107-step trees, and many more emerge when an additional step is allowed. But this result is possibly as informative as it is uninformative, i.e., it shows that the distributions of putatively primitive traits in the family are poorly correlated. For example, tricolpate pollen does not co-occur with the chromosome base number nine (Appendix 1; cf. Table 3). The paradoxical discordance of character state distributions can be appreciated in view of the following speculative model of portulacaceous evolution based on biogeography.

Biogeographic evidence might suggest that the eastern American/African group is more ancient than the western American. The former group, with or without *Rumicastrum*, is distributed in three Gondwanan continents and Madagascar. Basellaceae (aside from cultivated and/or weedy species; see Sperling, 1987), Cactaceae, *Talinum*, *Anacampseros/Talinaria*, *Portulaca*, and possibly *Amphipetalum/Calyptrotheca* are disjunct between America and Africa. *Portulaca* and *Anacampseros* are also disjunct to Australia (Carolin, 1987; Geesink, 1969; Pax & Hoffmann, 1934). Except for the African species of *Rhipsalis*, the disjunct taxa do not appear to be specialized for long-distance dispersal, which suggests that the eastern American/African group may have differentiated during a period when the flora was more easily interchanged, i.e., ca. 50 million years ago or earlier (cf. Gibson & Nobel, 1986; Leroy, 1978; Raven, 1983; Raven & Axelrod, 1974). Endemism in the western American group is almost entirely limited to generally montane and/or desert regions of temperate western America. The exceptions include a distinctive species of *Montia* in Australia/New Zealand (Nilsson, 1966a) and other eastern American or Eurasian species of Montieae that are otherwise closely related to western American species (cf. McNeill, 1975). That *Calandrinia* (*Calandrinia*) *ciliata* is native to Australia (cf. von Poellnitz, 1934a) has not been confirmed (Kelley, 1973; cf. West, 1986). Considering that the geophysical events responsible for creating the present-day ecological attributes of temperate western America are believed to have occurred within the last 15 million years, one might conclude that the western American group differentiated much more recently than the eastern American/African group (cf. Raven & Axelrod, 1978; Solbrig, 1976). Moreover, the North American taxa of this group are believed to have been derived from the South American (Raven & Axelrod, 1978; but see also Hershkovitz, 1991a).

Contrary to the biogeographic scenario, the cladistic results suggest that the western American

group is as old as if not older than the eastern American/African group (Fig. 1). The positions of individual taxa in the consensus tree are sometimes no less counterintuitive. For example, *Portulaca* might seem to be relatively primitive among Portulacaceae: It occurs on three southern continents, most species have the typical centrospermous chromosome base number nine, and some species have the putatively primitive inflorescence type for the family (Carolin, 1987; Geesink, 1969, 1987). *Portulaca* is epigynous and has $C_4$ photosynthesis, but these are likely autapomorphies. Yet, in Figure 1, *Portulaca* emerges as derived among Portulacaceae because of its panaperturate pollen and axillary hairs and scales. The only tricolpate members of the eastern American/African group are *Ceraria* and *Portulacaria*, which otherwise appear derived in their growth form and fruit morphology. Many western American taxa have tricolpate pollen and, among these, species of *Lewisia* have dichasial inflorescences. Indeed, the present analysis showed *Lewisia* as a possible outgroup of the remainder of the analyzed taxa. Yet, *Lewisia* is characterized by a derived fruit type, and the species with dichasia have such derived traits as glandular-dentate sepals, laterocytic stomata, and chromosome base numbers of 12, 14, 15 (i.e., the dichasial species may be derived within *Lewisia*; Hershkovitz, 1992; cf. Mathew, 1989). Moreover, the genus is restricted to western North America.

From the above comparison, it is clear that Portulacaceae exhibit a high degree of what Takhtajan (1991 and citations therein) calls heterobathmy, i.e., a disharmonious distribution of primitive and derived traits. Takhtajan's observation that high degrees of heterobathmy characterize grade groups is perhaps applicable here in view of the probable paraphyly of Portulacaceae. Alternatively, the perception of high heterobathmy may reflect conceptual constraints as to which traits are necessarily primitive. For example, if enough phylogenetic evidence accumulates that the chromosome base number nine and perhaps even tricolpy are advanced conditions in various Portulacaceae, the degree of perceived heterobathmy in the group would be reduced.

### F. THE PORTULACACEOUS ALLIANCE AND CENTROSPERMAE PHYLOGENETIC RESOLUTION

The results of the present analysis accord with my earlier admonition that progress in resolving Centrospermae phylogeny is constrained by poor understanding of phylogeny within the included traditional families (Hershkovitz, 1989, 1991f). Higher-level phylogenetic analysis requires comparison of demonstrably or at least plausibly primitive character states of polymorphic taxa. For Portulacaceae, a set of putatively primitive character states cannot at present be established because different polarities for several characters remain equally defensible. Moreover, the results presented here indicate that some traits present among Portulacaceae and typical of possible centrospermous outgroups, such as the chromosome base number nine, cannot be presumed primitive in the former. Finally, the likelihood that other traditional centrospermous families, i.e., Cactaceae, Basellaceae, Didiereaceae, and Hectorellaceae, are phylogenetically nested within Portulacaceae suggests that phylogenetic analysis among the last must precede advances in the understanding of the first three.

The hindsight provided by formal cladistic analysis is not required to appreciate these precautions. Irrespective of the taxonomic system followed, even the most rudimentary analysis of character variation among Portulacaceae should reveal the extent of polymorphism at lower taxonomic levels and indicate that the primitive character states for the family are not readily discernable. Likewise, close relationships of Cactaceae, Basellaceae, Didiereaceae, and Hectorellaceae to specific members of Portulacaceae rather than to the family as a whole were explicitly proposed in classical literature. The portulacaceous alliance is not unique in its degree of phylogenetic irresolution and possible paraphyly of familial and lower level taxa: similar taxonomic problems characterize other Centrospermae as well (Hershkovitz, 1991e, f).

This emphasis on problems of polymorphism and paraphyly should not imply that portulacaceous and/or Centrospermae phylogeny are hopelessly complex and unresolvable. Rather, inroads are possible by preliminary resolution of such problems at the lower taxonomic levels, such as that presented here for *Calandrinia* sensu lato. Additional progress in resolving portulacaceous phylogeny will be facilitated by similar analysis of other polymorphic taxa, e.g., *Talinum* and *Lewisia*. Collectively, such studies will help consolidate the portulacaceous OTUs, thereby facilitating analysis of Centrospermae as a whole. Naturally, scrutiny of lower level taxa in other Centrospermae will also be required.

## CONCLUSIONS

Although phylogeny of Portulacaceae remains poorly resolved, the present cladistic analysis supports the segregation of *Montiopsis*, *Cistanthe*,

*Rumicastrum*, and *Schreiteria* from *Calandrinia*. *Calandrinia* should be restricted to sections *Calandrinia*, *Monocosmia*, and *Acaules*. The first two may be cladistically nested in the last, and section *Monocosmia* may be nested in section *Calandrinia*. *Montiopsis* is a monophyletic genus with two subgenera, *Montiopsis* and *Dianthoideae*, and the latter may be paraphyletic. *Calandrinia* and *Montiopsis* are possibly sister groups but uncertainty to this effect and the distinctions between the two genera warrant their separation. The present analysis also supports my earlier circumscription of *Cistanthe* (Hershkovitz, 1991a) and hypothesized distinction between the eastern American/African and western American members of Portulacaceae. Otherwise, relationships among Portulacaceae and members of this family to Basellaceae, Cactaceae, Didiereaceae, and Hectorellaceae remain poorly resolved. The number and magnitude of unresolved problems preempt, for now, the reliability of familial-level phylogenetic analyses of Centrospermae (cf. Rodman, 1990). Some of the problems are, at present, more approachable than others, and subsequent research should emphasize analyses of the more polymorphic genera.

APPENDIX 1. Characters and character states for Portulacaceae. Listed below are the characters, analyses, and states used in the present cladistic analysis. The scores for the taxa are provided in Table 3. Where presumed, effective polarities, i.e., characters scored as "0" in the hypothetical ancestor, are indicated. The "0" designation also denotes a posteriori determined primitive states. Otherwise, the state designations are arbitrary.

HABIT (CHARS. 1–3)

Portulacaceae are sorted here according to their woodiness, presence of a basal leaf rosette, and phenology. Other Centrospermae are variously woody or herbaceous; therefore, the polarity of this character is equivocal, although, unlike members of the portulacaceous alliance, most other woody Centrospermae have anomalous secondary thickening (Cronquist, 1981). Portulacaceae can be largely sorted according to those that produce a prominent basal or suprabasal rosette in which axillary, ephemeral aerial flowering stems arise versus those in which the aerial stems proliferate vegetatively. Even these two categories intergrade, e.g., in *Montiopsis*. Studies of seedling development may permit better assignment of character states and/or evaluation of the validity of this character. Both growth forms occur commonly in other Centrospermae, hence I designate no polarity. I presume perennials persisting via the caudex or main stem to be primitive with respect to annuals. I scored *Naiocrene* as perennial and *Montia* as annual. Perennials occur among the latter, but they apparently persist via stolons rather than a caudex or main crown (Nilsson, 1966a).

Carolin (1987) and Gerbaulet (1992) employed alternative character state definitions in their analyses. Carolin (1987) categorized Portulacaceae variously as phanerophytes, passive chamaephytes, active chamaephytes (including protohemicryptophytes and rosette hemicryptophytes), and therophytes. For Portulacaceae, the first three categories intergrade, i.e., some taxa scored by Carolin as passive chamaephytes (e.g., *Talinum* sect. *Talinum*) perennate via distal buds on erect branches rather than from rosette axils (e.g., in *Cistanthe* spp.). The former condition seems more akin to the phanerophytic habit, and the latter to rosette hemicryptophytes. *Calandrinia* sect. *Acaules* and most *Lewisia* spp. must be regarded as rosette hemicryptophytes, rather than passive chamaephytes as Carolin scored them. The active chamaephyte category is ignored here because so characterized Portulacaceae seem to be derived members of otherwise rosette-forming perennial taxa, e.g., *Claytonia* species. Gerbaulet (1992) recognized three size classes of chamaephytes and four types of habit (including rosettiform). Her data indicate that my scoring of *Anacamsperos* sect. *Tuberosae* as rosettiform is incorrect.

1. Stems herbaceous or woody only at the base, 0; stems becoming woody throughout, 1.
2. Plants not rosettiform, 0; plants rosettiform, 1.
3. Plants perennial, 0; plants annual, 1.

ROOTS (CHAR. 4)

Carolin's (1987) characters and scoring are adopted here. Tuberous roots are uncommon outside of the portulacaceous alliance, and I presume them to be derived. Syeda & Ashton (1989) presumed tuberous roots to be a derived trait for *Rumicastrum*, but tuberous roots occur in the perennial species (Pate & Dixon, 1982), so I scored *Rumicastrum* as tuberous.

4. Roots not tuber-forming, 0; roots tuber-forming, 1.

STEMS (CHARS. 5, 7)

Carolin's (1987) interpretation and scoring are adopted here. Unless axillary hairs and scales/bristles are considered homologous to stipules in Caryophyllaceae and/or Molluginaceae, these structures are presumably derived. Gerbaulet (1992) recognized several scale types within *Anacampseros*, and she scored scale morphology in *Grahamia*, *Talinaria*, and *Talinopsis* as unknown. Her results also indicate that, contrary to my score, axillary hairs are primitively absent in *Anacampseros* sect. *Avonia*.

5. Stems without axillary hairs, 0; stems with axillary hairs, 1.
6. Stems without axillary scales/bristles, 0; stems with axillary scales/bristles, 1.

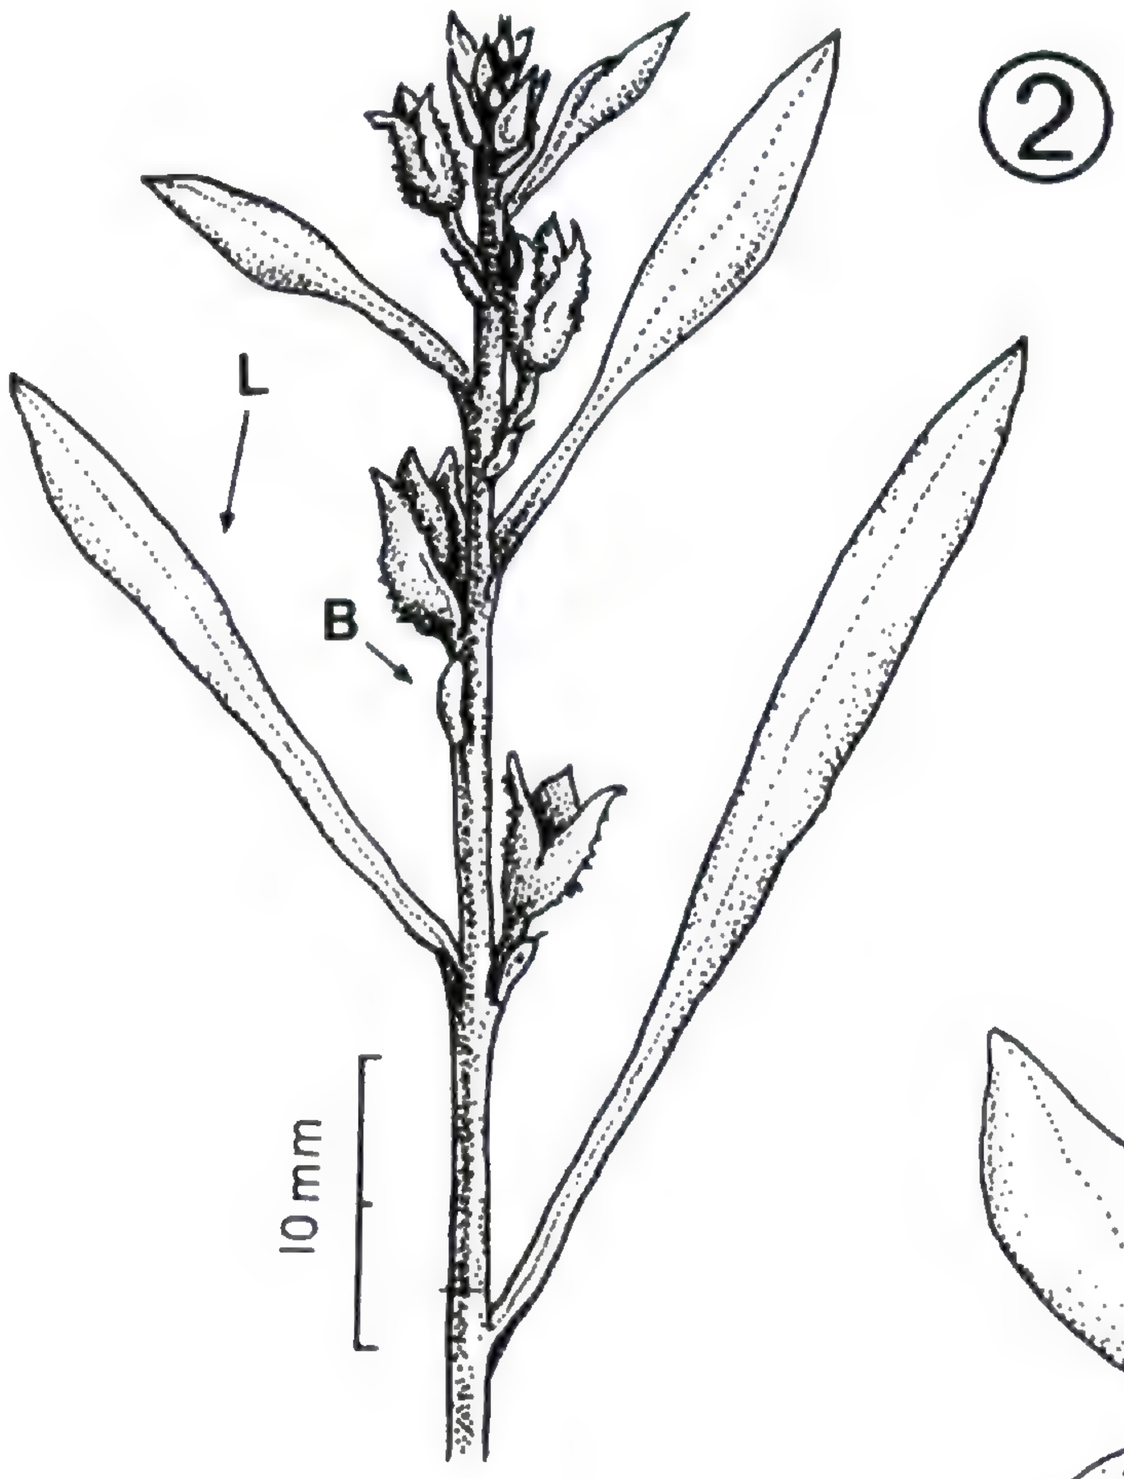
LEAVES (CHARS. 7–21)

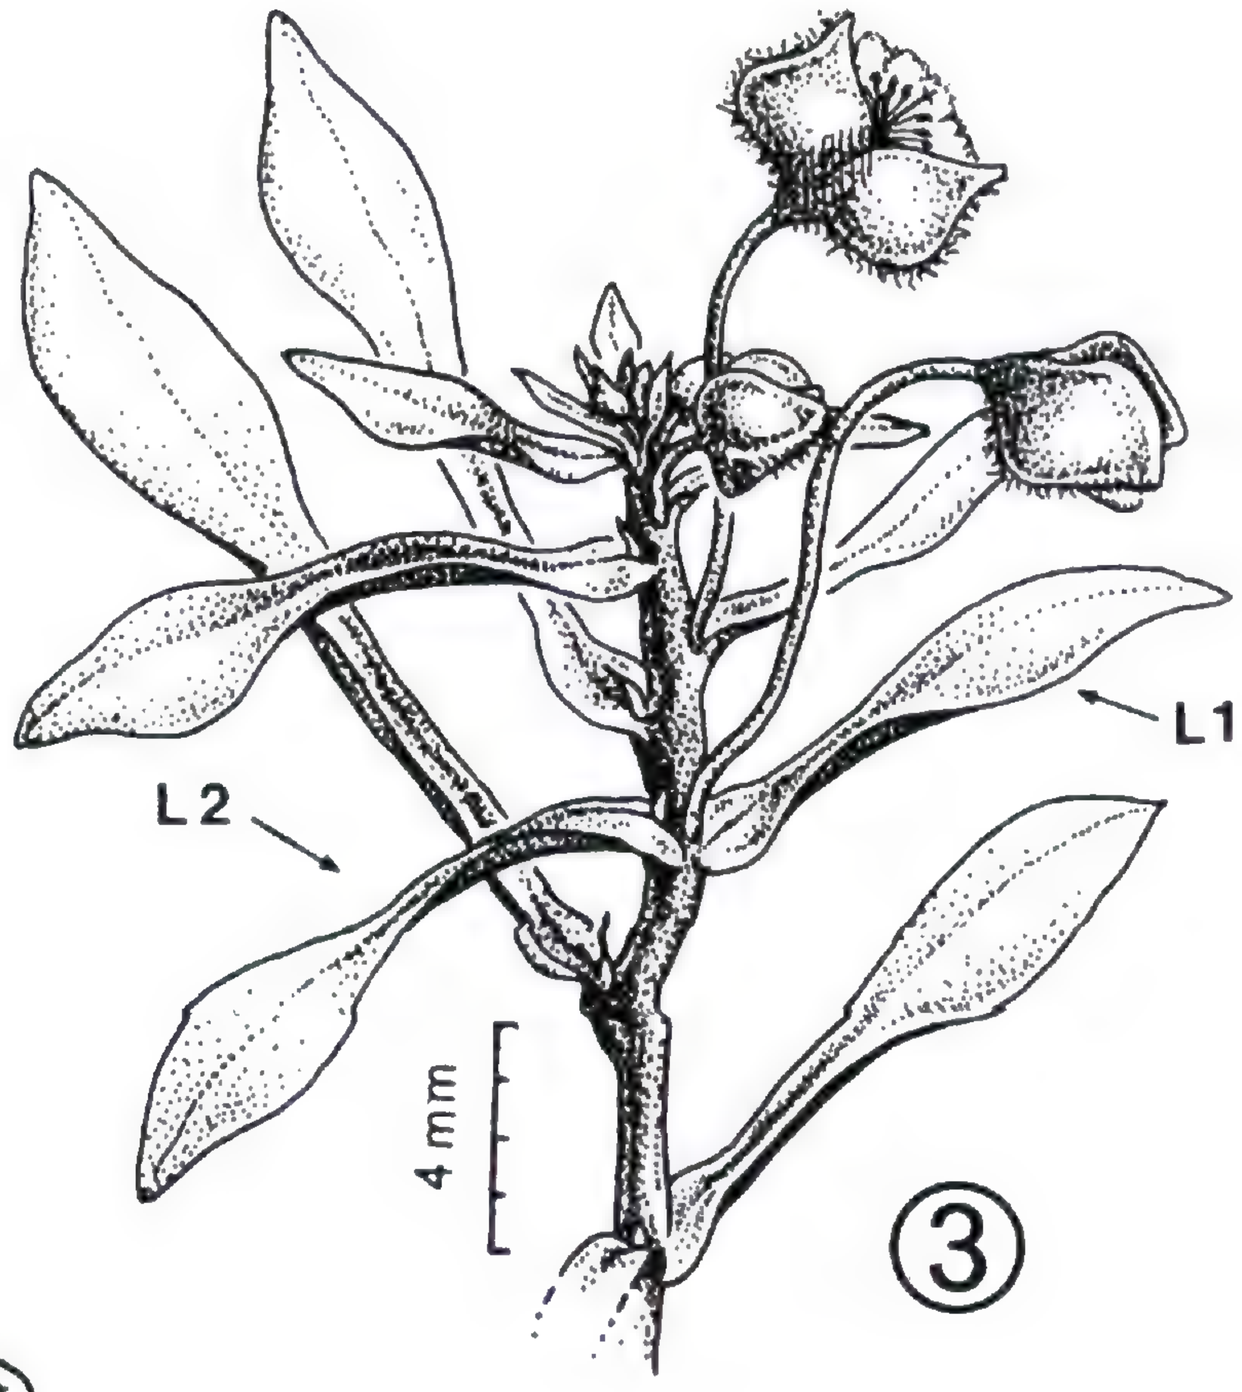
The leaf characters and data are from Hershkovitz (1990a, 1991b, 1992, 1993, unpublished), including reevaluated data from Becker (1895), Carolin (1987), Kelley (1973), Metcalfe & Chalk (1950), Nilsson (1966a, 1970, 1971a, b), and references cited in these. I exclude several characters that I have reported on elsewhere because of excessive infra-OTU variation, lack of variation at the level of the present OTUs, and/or inadequate data. These include petiole morphology, primary vein anatomy, vein density, presence of three-dimensional venation, the number of epidermal cells in contact with the guard-cell pair, the presence of an outer cycle of subsidiary-like cells (Hershkovitz, 1993), stomatal density, and stomatal index.

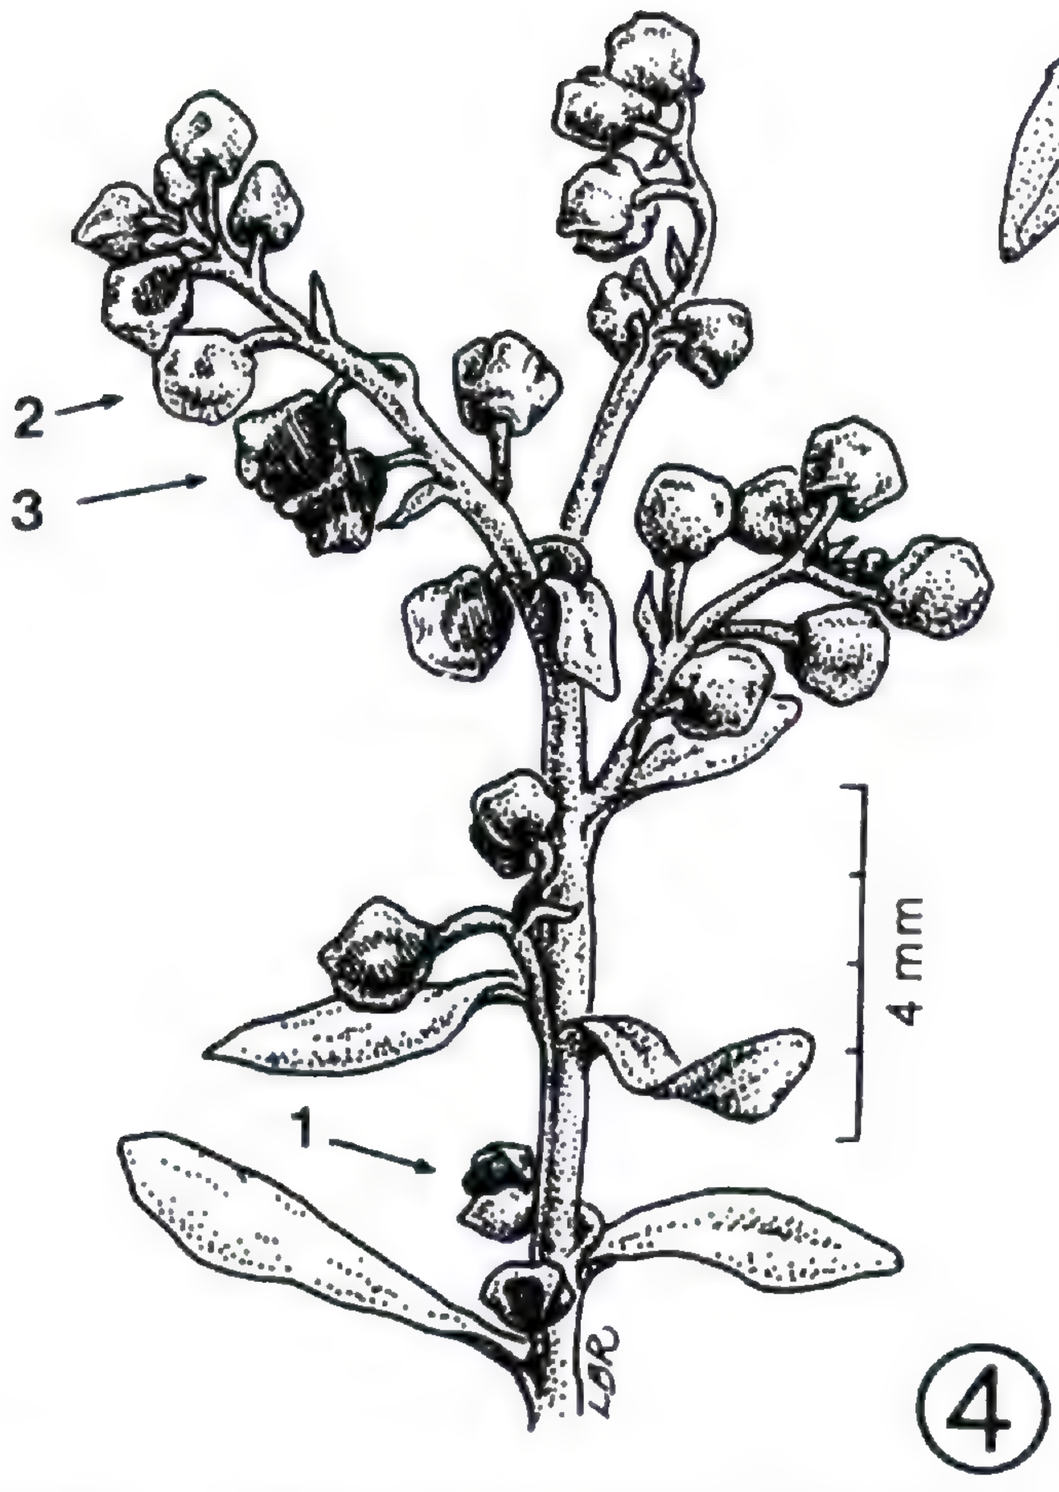
*A. Leaf position.* I tentatively presume alternate leaves to be primitive, but opposite leaves occur in many Caryophyllaceae, Molluginaceae, and Aizoaceae. Carolin misscored this character for *Calyptrotheca*. Opposite leaves are rare in *Portulaca* but characterize the putatively most primitive species (Geesink, 1969, 1987). I scored the genus as "?".

7. Leaves alternate, 0; leaves opposite, 1.

*B. Leaf base morphology.* Clasping, nonclasping, jointed, and nonjointed leaf bases occur in other Centrospermae, hence I designate no polarity for the leaf base characters. I previously interpreted the leaf bases of *Rumicastrum* as clasping (Hershkovitz, 1990a), but according to West (1986), they are not. My interpretation was based on herbarium, rather than live specimens, so I here







FIGURES 2–4. Inflorescence morphology in *Calandrinia*. — 2. Inflorescence of *Calandrinia* (*Calandrinia*) *ciliata* [U.S.A., California: *Hershkovitz s.n.* (spirit collection)]. Note the lack of dense coiling and the leaf (L) and bract (B) associated with each flower. — 3. Inflorescence of *Calandrinia* (*Calandrinia*) *axilliflora* [Chile, Region O'Higgins:

adopt West's opinion. It is possible that *Rumicastrum* is intermediate for this character.

8. Leaf bases jointed, 0; leaf bases not jointed, 1.
9. Leaf bases clasping, 0; leaf bases not clasping, 1.

*C. Leaf mucilage cells.* Copious mucilage production by relatively large numbers of foliar mucilage cells does not appear to be common among other Centrospermae; hence I presume it to be derived. Copious mucilage production characterizes at least some species of *Cistanthe* and *Rumicastrum,* but I have not adequately surveyed either genus; hence I scored these as unknown. Mucilage cells occur in *Calandrinia* sect. *Calandrinia* and species of *Lewisia* (Becker, 1895), but the mucilage content of the leaves appears to be relatively slight (pers. obs.).

10. Leaf mucilage cells none or few and not conspicuous, 0; leaf mucilage cells conspicuous and relatively numerous, 1.

*D. Leaf vein anatomy.* I have not found ribbonlike veins (Hershkovitz, 1991b) to occur among other Centrospermae; hence I presume them to be derived. This character proved difficult to score: minor veins in leaves of some taxa are almost always ribbonlike, but in other taxa they are only weakly manifested. There may be no distinct boundary between the character states, and ribbonlike veins may prove to be at least infrequently present in taxa scored as absent. The scoring adopted here for variable taxa biases against homoplasy.

11. Ribbonlike veins absent, 0; ribbonlike veins present, 1.

*E. Leaf venation pattern.* Festooned brochidromous venation occurs among other Centrospermae, although simple brochidodromous is more common. Without more confidence as to which Centrospermae are closest to the portulacaceous alliance, I leave the polarity uncertain. Festooned brochidodromy intergrades with simple brochidodromy among Portulacaceae and, among the OTUs scored as present, is absent in the smallest and/or narrowest leaves. The scoring adopted here for variable taxa biases against homoplasy.

12. Leaf venation not festooned brochidodromous, 0; leaf venation festooned brochidodromous, 1.

*F. Leaf fimbrial vein.* Fimbrial veins occur in other Centrospermae but only in otherwise apparently derived taxa (e.g., among Caryophyllaceae subfamilies Alsinoideae and Caryophylloideae). Thus, I presume fimbrial veins to be derived in Portulacaceae. There are two types of fimbrial veins in Portulacaceae: those that become perpendicular to the primary vein at the leaf apex, and those that become more parallel (Hershkovitz, 1990a, 1993). The transformation series adopted here permits fimbrial vein presence to serve as a synapomorphy while requiring only one step between each of the three states. I scored *Calandrinia affinis* as present for fimbrial veins, although the species is variable for the trait, and I am not certain that my specimens are correctly determined (cf. Hershkovitz, 1993).

13. Fimbrial vein absent, 0; fimbrial vein present, 1.
14. Fimbrial vein becoming perpendicular to the primary vein at the apex, 0; fimbrial vein parallel to the primary vein at the apex, 1; fimbrial vein absent, X.

*G. Stomata.* Parallelo- and/or nonbrachyparacytic stomata (see Hershkovitz, 1990a, 1991b) do not appear to be common outside of the portulacaceous alliance; hence I am inclined to presume that this state is derived. The most common stomatal type outside of the alliance, anomocytic (Hershkovitz, unpublished; Metcalfe & Chalk, 1950), is rare and probably derived within the alliance. Hence I leave the stomatal type polarity undetermined. Brachytetra- and staurocytic stomata are presumably derived with respect to brachyparacytic. I presume that laterocytic stomata, which are apparently restricted to *Lewisia* spp., are derived from brachyparacytic (Hershkovitz, 1992). Likewise, I presume that anomocytic stomata of *Montia* spp., *Lewisia* spp., and *Montiopsis* spp. (Hershkovitz, 1990a, 1992, 1993; Metcalfe & Chalk, 1950; Nilsson, 1966a, 1970, 1971a, b; Nyanyano, 1986a, c) are derived from brachyparacytic, which characterize other species of these genera. Brachytetra-/staurocytic stomata occur in *Montiopsis* sect. *Dianthoideae*, but I scored this taxon for their absence.

15. Stomata predominantly brachyparacytic and/or similar types (see Hershkovitz, 1990a, 1991b), 0; stomata predominantly parallelocytic and/or nonbrachyparacytic, 1.
16. Stomata predominantly brachyparacytic, nonbrachyparacytic, or parallelocytic, 0; stomata commonly brachytetracytic and/or staurocytic, 1.

*H. Foliar trichomes.* Several trichome types have a limited distribution among Portulacaceae. Trichomes occur commonly among Centrospermae; hence no polarities are presumed within Portulacaceae. I have adopted a transformation series that treats unicellular trichomes as an intermediate in deriving ribbed, glandular, multicellular and/or multiseriate trichomes (see Kelley, 1973). Unicellular foliar trichomes occur in several eastern American/African OTUs, although Carolin (1987) scored all of these as lacking such. I scored OTUs possessing trichomes as present unless I believed them to be unquestionably derived therein. Gerbaulet's (1992) results indicate that I should have scored *Talinaria* and possibly *Ceraria* as possessing trichomes, and *Anacampseros* sect.

←

*Gay s.n.* (P)]. Note the lack of dense coiling and the two leaves (L1 and L2) associated with each flower.—4. Terminal branch of highly ramified inflorescence of *Calandrinia* (*Monocosmia*) *monandra* [Argentina, Río Negro: *Buchtien 37* (US)]. Some flowers are solitary and axillary (1), some are associated with bracts (2), and some are apparently bractless (3). Drawings by Leslie Randall.

FIGURE 5. Cleared developing inflorescence of *Claytonia sibrica* L. [U.S.A., California: near Hupa, *Manning s.n.* (UC)] showing dense coiling. Scale bar = ca. 3 mm.

*Tuberosae* should have been scored as lacking them. Trichomes do not occur in *Montia* (contra Carolin, 1987, appendix 2), and if unicellular trichomes in *Calandrinia* sect. *Acaules* spp. are indeed glandular, they are probably not homologous to multicellular glandular trichomes of *Montiopsis* (cf. Carolin, 1987). I have not been able to confirm the presence of trichomes in *Lenzia* (cf. Carolin, 1987). Unribbed unicellular trichomes have been reported in *Rumicastrum quadrivalvis* F. Muell., ined. (Kelley, 1973), but I have been unable to verify the identity of the examined specimen (Hershkovitz, 1993). In any case, I scored *Rumicastrum* as absent. Epidermal papillae occur in several other Portulacaceae, including *Montia* and *Cistanthe* (Hershkovitz, 1990a, 1991b). Here, I distinguish between papillae, which are merely swollen epidermal cells, and trichomes, in which the center of the emergent cell wall has a distinct U- or V-shaped protuberance. Gerbaulet (1992) used the term "papillae" for what I here consider trichomes. Finally, I have adopted "X" scoring for the ribbed trichome character so that the interderivation of ribbed, unribbed, and no trichomes requires a single step.

17. Foliar trichomes absent, 0; foliar trichomes present, 1.
18. Foliar trichomes unicellular, 0; foliar trichomes multicellular, 1.
19. Foliar trichomes uniseriate, 0; foliar trichomes multiseriate, 1.
20. Foliar trichomes nonglandular, 0; foliar trichomes glandular, 1.
21. Foliar trichomes nonribbed, 0; foliar trichomes ribbed, 1; foliar trichomes absent, X.

INFLORESCENCE (CHARS. 22–26)

*A. Inflorescence type.* I tentatively concur with Carolin (1987) in presuming that monochasia and solitary flowers are derived in Portulacaceae. That metaxytriads are primitive cannot be established a priori, however (cf. Carolin, 1987): this type was unequivocally derived in Carolin's cladogram.

Carolin (1987) interpreted the inflorescence in *C.* sect. *Calandrinia* as monochasial, but I regard the "inflorescence" to be a vegetative sympodium with solitary, axillary flowers. In the context of Weberling's (1989) definition of an inflorescence, my interpretation is problematic but, nevertheless, emphasizes the evident distinction in inflorescence morphology between section *Calandrinia* and Portulacaceae with unquestionably monochasial inflorescences. In *Cistanthe* and Montieae, for example, including *Claytonia sibirica* L. (Fig. 5), the developing inflorescence is strongly coiled, and the inflorescence bracts are much smaller than foliage leaves or, in some species, absent. In *Calandrinia* (*Calandrinia*) *ciliata* (Ruiz & Pavón) DC. (Fig. 2), the developing inflorescence is cincinnoid but leafy throughout. Each flower is associated with one leaf and one small bract, and the cauline leaves are gradually reduced distally but otherwise identical to the basal leaves. Axillary buds occur in both the leaf and bract axils (pers. obs.). In *Calandrinia axilliflora* Barnéoud (Fig. 3), flowers arise from the axils of otherwise normal foliage leaves that alternate with leaves having vegetative axillary buds. In some specimens, the inflorescence has very short internodes and thus resembles a whole rosettiform plant of *Calandrinia* sect. *Acaules*. The character scoring I adopt for section *Calandrinia* is obviously interpretation-laden; hence the results must be judged accordingly. *Calandrinia* (*Monocosmia*) *monandra* (Ruiz & Pavón) DC. (Fig. 4) has a unique inflorescence structure that I cannot classify. It is highly branched, the main stem is leafy toward the base, and both single flowers and multiflowered branches may arise from leafy, bracteate, or naked nodes. I have also observed cauliflory in this species. Since my earlier work (Hershkovitz, 1990a), I have also reexamined the inflorescence of *Montiopsis* and have concluded that it conforms to either a botryoid or a bostryx (cf. Weberling, 1989)—either way, the inflorescence is similar in all members of the genus and distinct from other Portulacaceae (cf. Carolin, 1987). My new interpretation is based only on studies of herbarium material and requires developmental analysis to verify.

I tentatively scored *Lewisia* for having dichasia, but monochasia and solitary flowers also occur in this genus (Hershkovitz, 1992; Mathew, 1989). It is possible that dichasia are secondary in *Lewisia* because they occur in species with a presumably derived chromosome base num-

ber (Hershkovitz, 1992). Solitary flowers also occur in *Anacampseros* sect. *Avonia*, *Talinum* sects. *Talinum* and *Phemeranthus*, and *Rumicastrum* (von Poellnitz, 1933, 1934a, b), but I presume that this is not the primitive condition. In any case, the transformation series I adopt here requires only one step between dichasia, cincinni, botryoids/bostryces, and solitary flowers, while metaxytriads are scored as one step from dichasia and two steps from the other types, assuming that dichasia would constitute an intermediate state.

22. Flowers in metaxytriads, 0; flowers not in metaxytriads, 1.
23. Flowers in metaxytriads or dichasia, 0; flowers in nonleafy cincinni, 1; flowers in botryoids/bostryces, 2; flowers solitary or apparently in cincinni with at least one normal foliage leaf per flower, X.
24. Flowers not solitary, 0; flowers solitary or apparently in cincinni with at least one normal foliage leaf per flower, 1.

*B. Inflorescence bracts.* For inflorescence bract polarities, I concur with Carolin (1987) that two equal bracts are primitive, and that equal or subequal bracts are primitive with respect to markedly unequal. The bract size differential is also problematic. I have scored only the *Cistanthe* sections for unequal bracts, but the degree of intergradation with subequal bracts in other taxa (e.g., *Montiopsis*) should be scrutinized quantitatively. While this manuscript was in review, I reevaluated bract morphology in *Calandrinia* (see also Hershkovitz, 1993). *Calandrinia acaulis* and *C. carolinii* have jointed peduncles, with a pair of foliaceous bracts subtending the pedicel. *Calandrinia affinis* has unjointed peduncles, usually with a pair of small, scalelike bracts near the base. Rarely, one of these is foliaceous and more proximal to the flower. (Peralta (1988, fig. 2B) illustrated three bracts in *C. affinis*, two basal and scalelike and one foliaceous, but I have not observed this condition.) Based on preliminary observations, I had scored *C. affinis* as having one bract or none. Moreover, I now question my interpretation of the bracts in section *Calandrinia*. I had scored these taxa for one bract or none, but it is possible that the leaf pair in *C. axilliflora* or the leaf/bract pair in other species are homologous with the foliaceous bract pair in *C. acaulis* and *C. carolinii*. I leave this problem unresolved pending additional analysis.

25. Inflorescence bracts two per flowering node, 0; inflorescence bracts one or none, 1.
26. Bracts of a pair ± equal, 0; bracts of a pair markedly unequal, 1; bracts one or none, X.

### Perianth (chars. 27–29)

The apparently biseriate perianth of Portulacaceae has been variously interpreted as homologous to a bimerous involucre plus tepals (Cronquist, 1981, 1988; Eckardt, 1976; Gerbaulet, 1992; Stebbins, 1974) or as a true biseriate perianth (Carolin, 1987; Geesink, 1969, 1971; Milby, 1980; Sharma, 1954; Soetiarto & Ball, 1969). For practical purposes, I adopt the latter interpretation.

*A. Sepal morphology.* The degree of sepal persistence through fruit maturity varies within the taxa circumscribed here (e.g., in *Rumicastrum* spp., Syeda & Ashton, 1989; in *Talinum* spp., Macbride, 1937), but early deciduous sepals are probably primitive in some taxa. Like Carolin (1987), I scored *Talinum* for deciduous sepals, but those of *T. paraguayensis* Speg. seem perfectly persistent (pers. obs.). That persistent sepals are primitive overall is assumed, but deciduous sepals occur among other Centrospermae.

Glandular-toothed bracts and sepals occur in *Lewisia* and *Schreiteria*, and I presume them to be derived. Glandular and dentate sepals that occur in *Montiopsis* are problematic. The glands are associated with trichomes, hence I do not consider them homologous to glandular teeth. The denticulations in this genus appear to be associated with the base and flanks of the sepals and bracts, whereas those of *Lewisia* and *Schreiteria* are concentrated toward the apex. Thus, I scored *Montiopsis* as absent for glandular-dentate bracts and sepals. Some species of *Montiopsis* sect. *Montiopsis* do have lobed (dentate?) sepals, however (Ford, 1992; Peralta, 1988, figs. 6I, 7G). I interpret the sepals of some *Cistanthe* taxa, especially those of section *Calyptridium*, as erose rather than dentate. I suspect that dentate bracts in most *Lewisia* spp. are derived, but I scored the genus as present to test the remote possibility that *Lewisia* and *Schreiteria* are somehow related.

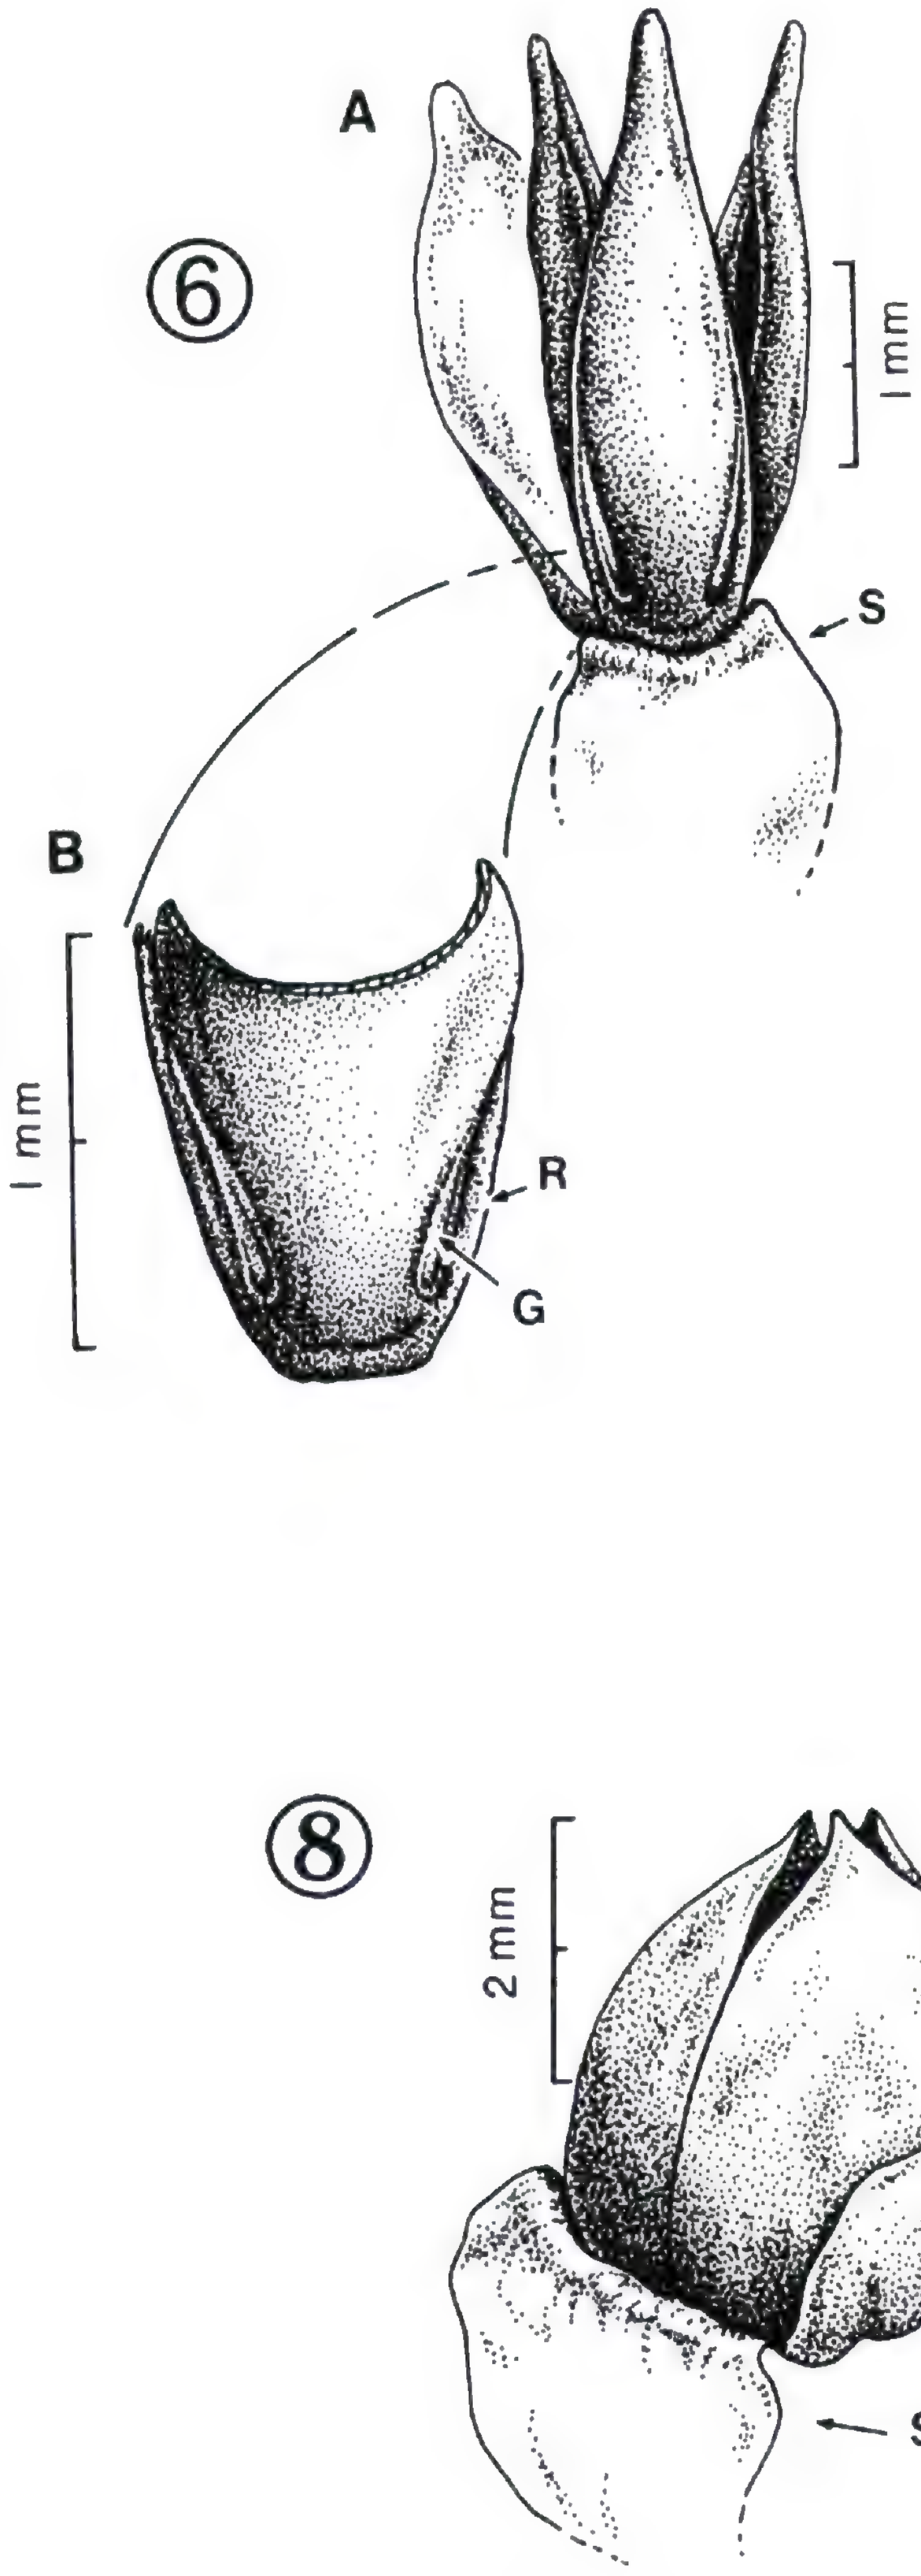
27. Sepals persistent, 0; sepals deciduous, 1.
28. Sepals and bracts not glandular-dentate, 0; sepals and bracts glandular-dentate, 1.

*B. Petal numbers.* Petal numbers are problematic because they vary within and intergrade among taxa. Some taxa, however, seem to have consistently higher petal numbers than others. Carolin (1987) presumed that higher petal numbers were primitive in Portulacaceae (as did Syeda & Aston, 1989, and Syeda & Carolin, 1990, for *Rumicastrum*), but I scored fewer petals as primitive because higher petal (or tepal) numbers are, among Centrospermae, not common outside of the portulacaceous alliance, and then they are probably independently derived (e.g., among Aizoaceae; Bittrich & Struck, 1989). Irrespective of Carolin's (1987) polarity determination for this trait, his scores for this character are sometimes incorrect; e.g., for *Anacampseros* and *Talinaria* (Pax & Hoffmann, 1934; McNeill, 1977; von Poellnitz, 1933). As with the preceding character, the score for the variable taxon *Lewisia* is experimental.

29. Petals typically five to six or fewer, 0; petals typically more than five, 1.

### Stamens

Carolin (1987) scored *Grahamia* and *Portulaca* for having connate stamens adnate to the petals. The condition in these species is possibly extreme, but similarly fused stamens are probably the general condition among Portulacaceae (see, e.g., Peralta, 1988, for *Calandrinia* sensu lato and Mathew, 1989, for *Lewisia*). I prefer not



FIGURES 6–8. Capsule morphology in *Montia* and *Calandrinia*.—6. Dehisced capsule of *Montia parvifolia* [U.S.A., California: *Thomas 3543* (US)]. A. Whole fruit showing capsule-valve inrolling, the narrow teardrop-shaped grooves near the margins of the capsule valve base, and the marginal ribs. A sepal has been folded down to show

to recognize stamen fusion as a character in this analysis. I agree with Carolin (1987) that stamen number is too highly variable within OTUs (sometimes within individuals) to be useful at the present level of analysis, especially because the outgroup condition is equivocal.

POLLEN (CHARS. 30, 31)

The pollen character transformation series proposed by Carolin (1987) is problematic because, irrespective of whether narrow- and broad-pantocolpate pollen can always be distinguished, Carolin's transformation series requires two steps between these states. Possibly intermediate states occur: several taxa reported by Carolin (1987) to be pantocolpate were reported by Nyanyano (1985, 1986a) to be pantoporate. Gerbaulet (1992) reported, however, that contrary to mine and Carolin's scores, *Anacampseros* sect. *Anacampseros* has pantoporate pollen. The transformation series adopted here presumes only that three apertures are primitive with respect to several, and that colpi are primitive with respect to pores.

30. Pollen tricolpate, 0; pollen panaperturate, 1.
31. Pollen colpate, 0; pollen porate, 1.

STIGMAS (CHARS. 32, 33)

The comments for petal number are applicable here: stigma numbers intergrade, the polarity is uncertain, and some of Carolin's (1987) scores are not in agreement with the literature, e.g., for *Anacampseros* (cf. Pax & Hoffmann, 1934; von Poellnitz, 1933). Two stigmas are unusual among Portulacaceae, however, and are presumed to be derived. The score for *Lewisia* tests the possibility that the genus is related to *Portulaca* or *Grahamia*.

32 Stigmas two or three, atypically four, 0; stigmas typically four or more, 1.
33. Stigmas three or more, 0; stigmas two, 1.

FRUIT (CHARS. 34–42)

The fruit characters, polarities, and scores proposed by Carolin (1987) are largely adopted here, with some exceptions. The polarities of the fruit epidermal cell characters are left uncertain. These characters should be better scrutinized because I believe they may intergrade more than Carolin's scoring would indicate, especially in *Talinum* sects. *Talinum* and *Phemeranthus*. The fruit of *Talinum* (*Talinum*) *rivae* Chiov. is acropetally dehiscent (Carolin, in press; von Poellnitz, 1934b), but I suspect that this Somalian species actually belongs to *Calyptrotheca*. Acropetal dehiscence has been described for *Talinum paniculatum* (Jacq.) Gaertn. (Galati, 1986). According to Carolin (in press), the exocarp and endocarp in *Talinum* sect. *Talinum* sometimes separate (cf. Carolin, 1987). Carolin (1987) scored *Calandrinia* sect. *Monocosmia* as indehiscent, but elsewhere (Carolin, in press) reported occasional valvate dehiscence. Thus, I scored this section as dehiscent. Contrary to mine and Carolin's scores, Gerbaulet (1992) scored *Grahamia* for having a pericarp not differentiated into two layers.

I have disagreed (Hershkovitz, 1990a) with Carolin's (1987) interpretation of the pericarp of *Calandrinia* sect. *Calandrinia*: the distinctive "grooves and ribs" that characterize the capsule base of Montieae (Fig. 6) do not occur in the capsule base of any members of *C.* section *Calandrinia*. The capsule in the latter may, as Carolin (1987) noted, inroll after dehiscence (e.g., in *C. ciliata*; Fig. 7), but the capsule in *C. axilliflora* Barnéoud does not markedly inroll (Fig. 8). I scored *Calandrinia* as present for capsule valve inrolling and absent for capsule valve grooves and ribs. I scored indehiscent taxa and *Monocosmia* as unknown ("X") for character 41.

34. Fruit without acropetal, valvate dehiscence, 0; fruit with acropetal, valvate dehiscence, 1.
35. Fruit dehiscent, 0; fruit indehiscent, 1.
36. Fruit epidermal cells with sinuous radial walls, 0; fruit epidermal cells with straight walls, 1.
37. Fruit epidermal cells elongate, 0; fruit epidermal cells isodiametric, 1.
38. Pericarp not strongly differentiated into two layers, 0; pericarp strongly differentiated into two layers, 1.
39. Exocarp and endocarp not separating, 0; exocarp and endocarp separating, 1.
40. Exocarp not deciduous, 0; exocarp deciduous, 1.
41. Capsule valves not inrolling after dehiscence, 0; capsule valves inrolling after dehiscence, 1; fruit indehiscent, X.
42. Capsule valves not grooved and ribbed at the base, 0; Capsule valves grooved and ribbed at the base, 1.

SEEDS (CHARS. 43–44)

I have retained Carolin's (1987) characters, polarities, and scores for seed traits. As Carolin pointed out, however, the homology between the "aril" of *Talinum* sect. *Phemeranthus* and that of *Anacampseros* has not been established (see also Gerbaulet, 1992). I also note that many Portulacaceae have (usually less conspicuous) micropylar appendages (Corner, 1976; Hershkovitz, 1992), but I have not yet analyzed the variation in this feature.

←

the capsule base. B. Magnified view of capsule base showing grooves and ribs.—7. Dehisced capsule of *Calandrinia* (*Calandrinia*) *ciliata* [U.S.A., California: *Wolf 3542* (US)] showing capsule-valve inrolling. A grooved, ribbed base is not present. A sepal has been folded down to show the capsule base.—8. Partially dehisced capsule of *Calandrinia* (*Calandrinia*) *axilliflora* [Chile, Region Aconcagua: *Steudel s.n.* (P)]. Neither capsule-valve inrolling nor a grooved, ribbed capsule base is evident. Following dehiscence, the capsule valves may retain their shape or twist and fold irregularly. A sepal has been folded down to show the capsule base. G = groove, R = rib, S = sepal. Drawings by Leslie Randall.

43. Seeds without enveloping aril, 0; seeds with aril, 1.
44. Embryo encircling the perisperm, 0; embryo not encircling the perisperm, 1.

CHROMOSOME NUMBER (CHARS. 45, 46)

This character is added here based on data compiled and/or reported by Bernardello (1989), Hershkovitz (1992), Nilsson (1966b), Nyanyano (1986a), and Ford (1992; unpublished). The data are incomplete for most of the larger taxa. The base number 9 is tentatively presumed to be primitive because it is the most widespread among other Centrospermae (Ehrendorfer, 1976), but base numbers of 8 also occur among otherwise primitive Aizoaceae (Bittrich & Struck, 1989). The base number 8 occurs in derived species of *Portulaca* but is possibly primitive in *Claytonia* (see Gerbaulet, 1992, for discussion and references). Because of variability, I scored *Claytonia* as unknown. No ordering for base numbers of 10, 11, or 12 is supposed—these can all be derived from 9 via one step. My character definitions are faulty in treating nonequivalent states (i.e., 10, 11, and 12) as homologous. I resort to this treatment because the primitive base number in some well-surveyed taxa, e.g., *Lewisia* and *Montia*, is uncertain but clearly not 9. I scored *Cistanthe* sect. *Strophiolum* as unknown but not 9, but my conclusion that its base number is 11 or 12 is speculative (Hershkovitz, 1992). Gerbaulet (1992) reported $x = 9$ in *Talinaria*, which I scored as unknown. My consensus tree (Fig. 1), however, predicted $x = 9$ in this genus.

45. Chromosome base number 9, 0; chromosome base number not 9, 1.
46. Chromosome base number 10, 0; chromosome base number 11, 1; chromosome base number 12, 2; chromosome base number 9, X.

APPENDIX 2. Character state changes in the consensus tree. Listed below, by character number (cf. Appendix 1) and tree node (Fig. 9; cf. Fig. 1) are the character state changes of the consensus cladogram for Portulacaceae as output using PAUP's "list changes" option and "accelerated transition" optimization in the "describe trees" command. The number of changes listed is 114; hence the list includes excess homoplasious changes with respect to any 107-step resolution of the consensus tree. Unambiguous changes are shown in Figure 1. "CI" = consistency index.

# LEAF MORPHOLOGY OF *CALANDRINIA* AND *MONTIOPSIS* (PORTULACACEAE)[1]

*Mark A. Hershkovitz*[2]

ABSTRACT

*Calandrinia* sect. *Calandrinia*, *C.* sect. *Monocosmia*, and some species of *C.* sect. *Acaules* share identical leaf blade and petiolar morphology, fimbrial veins, predominantly brachytetracytic and staurocytic stomata surrounded by a cycle of subsidiary-like cells, and unicellular ribbed trichomes or papillar trichomes. Other species of *C.* sect. *Acaules* have irregularly brochidodromous venation without a fimbrial vein, predominantly brachyparacytic stomata, and/or no trichomes; venation and stomatal morphology in these species is similar to that found in *Montiopsis*. Leaves of *Montiopsis* lack petioles, have glandular or eglandular, uniseriate- and/or multiseriate-multicellular trichomes (although some examined specimens of *M.* subg. *Dianthoideae* appear to be glabrous), and generally have brachyparacytic stomata (although some examined specimens of subgenus *Dianthoideae* have a small proportion of brachytetracytic/staurocytic stomata with an outer cycle of cells). Leaves of *M.* subg. *Montiopsis* also have barbellate trichomes apparently composed of elongate hair cells, and have predominantly brachyparacytic or anomocytic stomata. Phylogenetic analysis of foliar characters of Portulacaceae: (1) supports a close relationship between *C.* sects. *Calandrinia* and *Monocosmia* and species of *C.* sect. *Acaules;* (2) indicates that *C.* sect. *Acaules* may be paraphyletic with respect to the preceding taxa; (3) provides weak evidence contradicted by nonfoliar evidence that *Claytonia* and *Montia* may be nested within *Calandrinia;* (4) provides weak evidence linking *Montiopsis* with *Calandrinia*; and (5) indicates that foliar characters may not be more homoplasious than nonfoliar. Phylogenetically analyzed systematic accounts of foliar morphology, such as that presented here, may provide a basis for advancing theories on the relationship between leaf form, function, and ontogeny.

In previous papers (Hershkovitz, 1991a, 1992), I demonstrated the utility of foliar morphology in clarifying phylogenetic relationships among members of Portulacaceae. The present paper presents and evaluates foliar morphological data for *Calandrinia* Kunth and *Montiopsis* Kuntze.

The circumscriptions of *Calandrinia* and *Montiopsis* accepted here are based on a cladistic reanalysis of Carolin's (1987) data for Portulacaceae that incorporates the leaf morphological evidence presented below (Hershkovitz, 1993). *Calandrinia* and *Montiopsis* include ca. 29 of the 100–150 species formerly classified in *Calandrinia* sensu lato. I had previously advocated retaining *Montiopsis* in *Calandrinia* (Hershkovitz, 1990; see also 1991b, fig. 3), but cladistic analysis does not strongly support this relationship (Hershkovitz, 1993). *Calandrinia*, as here circumscribed, includes ca. 14 species in three sections: (1) *C.* sect. *Calandrinia* (≡ *C.* sect. *Compressae* Reiche; including *C.* sect. *Axillares* Reiche; ca. 5 spp. of western America); (2) *C.* sect. *Acaules* Reiche (ca. 8 spp. of western South America and Mexico); and (3) *C.* sect. *Monocosmia* (Fenzl) Hershkovitz (1 sp. in Chile and Argentina). *Montiopsis* is restricted to temperate South America and includes two subgenera, *M.* subg. *Montiopsis* (≡ *Calandrinia* subg. *Hirsutae*; ca. 15 spp.) and *M.* subg. *Dianthoideae* (Reiche) D. I. Ford (ca. 3 spp.).

## MATERIALS AND METHODS

Gross leaf morphology, leaf venation pattern, and epidermal morphology were examined and photographed according to the protocols I described previously (Hershkovitz, 1991a). The morphology

[1] This manuscript is revised from a chapter submitted as part of a doctoral dissertation at the University of California, Davis. I gratefully acknowledge assistance from Jim Doyle, the late Richard Eyde, Donna Ford, Philip Hershkovitz, Walt Kelley, June McCaskill, Joan Nowicke, George Russell, Rudy Schmid, John Strother, Grady Webster, Stanley Yankowski, two anonymous reviewers, and the curators of the following herbaria: B, CAS, DAV, F, L, M, NA, P, RSA, UC, US. This research received financial support from a Smithsonian Graduate Student Fellowship, a Smithsonian Pre-doctoral Fellowship, a Smithsonian Short-Term Visitor Award, two Jastro-Shields Scholarships from the University of California, Davis, two travel awards from the Department of Botany, University of California, Davis, and P. Hershkovitz.

TABLE 1. Species, citations, and specimens examined for venation and epidermal features. Listed by genus, section, species, locality, collector, number, and herbarium are specimens of *Calandrinia* and *Montiopsis* prepared for venation ("v") and epidermal ("e") study. Specimens of *Calandrinia* sect. *Acaules* are identified according to the key in Table 2. Determinations of species for *Montiopsis* are fide Ford (1992). Specimens of *Montia* and *Rumicastrum* illustrated for foliar features are also cited. Locality information is limited to the largest political division within a country.

*Rumicastrum* sp. WITHOUT DATA: Walter Kelley cleared leaf collection, no. K-242.

is described according to the terminology suggested by Dilcher (1974) for leaf size and shape, Hickey (1979) for venation pattern, Wilkinson (1979) for stomatal configuration, and Kelley (1973) for trichomes. The data presented here are supplemented with data from Becker (1895), Carolin (1987), Ford (1992), Kelley (1973), Nyanyano (1986a, b), and Peralta (1988). Table 1 lists the species, their full citations, and representative specimens. All specimens examined for epidermal and venation features are listed. Also listed are species, citations, and specimens of other Portulacaceae here illustrated.

Since submitting the morphological data presented here as part of a dissertation (Hershkovitz, 1990), I have substantially revised my taxonomic opinions on the species of *Calandrinia* sects. *Calandrinia* and *Acaules*. I previously treated *Calandrinia compressa* Schrad. ex DC. as a synonym of *C. ciliata* (Ruiz & Pavón) DC., but the former, restricted to Chile, is distinguished by its strongly compressed calyx of deltoid sepals. *Calandrinia ciliata*, apparently largely extra-Chilean, has a more campanulate calyx and more ovate sepals. Both species, however, are highly polymorphic, and several segregates have been described for each (cf. Reiche, 1898; Rydberg, 1932: 291, spp. 2–10).

The taxonomy of *Calandrinia* sect. *Acaules* is more complex and less satisfactory. Table 2 presents a revised, but still tentative, key to the species. Part of the confusion in my earlier work (Hershkovitz, 1990) stems from the "disappearance" of *Baitaria acaulis* Ruiz & Pavón from the floristic literature and/or the assumption that this name was synonymous with *Calandrinia acaulis* Kunth. Syntypes of *Baitaria acaulis* reportedly

TABLE 2. Provisional key to the species of *Calandrinia* sect. *Acaules* Reiche.

1a. Peduncles jointed; inflorescence bracts 2, foliaceous, attached above the middle of the peduncle.
  2a. Stamens 5–10; capsule usually membranous at maturity; leaves without trichomes or papillar trichomes (Ecuador, Colombia, Mexico, Venezuela) or occasionally with papillar trichomes along the leaf margin (Argentina, Bolivia, Peru).
    3a. Flowers ≤1 cm long ..... *C. acaulis* var. *acaulis*
    3b. Flowers ca. 2 cm long ..... *C. acaulis* var. *magna*
  2b. Stamens 12–20; capsule usually indurate at maturity; leaves often with trichomes or papillar trichomes ..... *C. carolinii*
1b. Peduncles not jointed; inflorescence bracts none or 2, scalelike and attached near the base of the peduncle, or 2, one scalelike, basal and one foliaceous, attached more apically
  4a. Inflorescence bracts 2.
    5a. Inflorescence ≤half as long as leaves, stamens ca. 8. ..... *C. colchaguensis*
    5b. Inflorescence >half as long as leaves, stamens >20.
      6a. Leaves linear-oblanceolate, flat, more than twice as broad as thick, glabrous or with trichomes or papillar trichomes along the leaf margin. ..... *C. affinis*
      6b. Leaves linear-filiform, ca. as broad as thick, with extra-marginal trichomes or papillar trichomes ..... *C. graminifolia*
  4b. Inflorescence bracts none.
    7a. Peduncles longer than leaves.
      8a. Stamens 6–7, petals pink to white ..... *C. fuegiana*
      8b. Stamens more than 7, petals rose, orange, or yellow ..... *C. caespitosa*
    7b. Peduncles shorter than leaves ..... *C. compacta*

include some plants of *Calandrinia acaulis*. The former species is now *Calandrinia carolinii* Hershkovitz & Ford (Hershkovitz & Ford, 1993). Plants of *C. carolinii* have usually been misidentified as *C. acaulis*. Realizing this error, I had mistakenly referred them to *C. colchaguensis* Barnéoud (Hershkovitz, 1990: 242). Likewise, I referred bona fide material of *C. colchaguensis* to *C. affinis* Gillies ex Arn. The last two species are very similar, however, and intergrade in their overlapping range (D. I. Ford, pers. comm.). I also referred to *Calandrinia compacta* Barnéoud diminutive Bolivian plants of *C. acaulis*. I previously recognized, primarily on geographical bases, *C. megarhiza* Hemsley (Central America) and *C. saltensis* Hauman (Argentina), as distinct from *C. acaulis* (South America). I now believe such distinctions are not warranted. *Calandrinia megarhiza* and *C. saltensis*, which represent the range extremes of *C. acaulis*, are distinguishable from one another by the presence of trichomes and slightly higher stamen number of *C. saltensis*. These traits are variable, however, in *C. acaulis* from Peru and Bolivia. Finally, I previously included *Calandrinia fuegiana* Gand. in *C. caespitosa* Gillies ex Arn. (cf. Peralta, 1988). I now recognize the former as distinct, although I have no leaf anatomical data for the species.

Identification of specimens of *Montiopsis* subg. *Dianthoideae* follows Peralta (1988), except that I refer *M. hirtella* Philippi to *M. gayana* (D. I. Ford, pers. comm.). Identification of specimens of *Montiopsis* subg. *Montiopsis* follows Ford (1992).

In order to evaluate the systematic significance of the foliar morphological data presented here, I reanalyzed my earlier PAUP analysis of Portulacaceae (Hershkovitz, 1993), comparing results generated by variously weighting and excluding foliar and nonfoliar characters. The data and character analyses are from Hershkovitz (1993, table 3, appendix 1).

## Results

### A. Leaf Morphology

*1. Gross leaf morphology.* The gross leaf morphology in *Calandrinia* and *Montiopsis* can be discerned from the illustrations of cleared leaves (Figs. 1–30, see below).

Leaves of *C.* sect. *Calandrinia* are mostly 10–70 mm long and 2–15 mm wide (nanophyllous to microphyllous; Dilcher, 1974); the basal leaves are usually larger than the cauline leaves. Within these size parameters, leaf shape varies from linear to oblanceolate or, when the lower portion of the leaf is more abruptly constricted into a winged petiole, often rhombic, ovate, or deltoid above the point of constriction and attenuated below (e.g., *C. axilliflora*, Fig. 1).

Leaves in *C.* (*Monocosmia*) *monandra* (Fig. 5) are ca. 25 mm long and 8 mm wide, generally wide-petiolate, rhombic above the point of constriction, and grossly indistinguishable from similarly sized and shaped leaves in *C.* sect. *Calandrinia*.

Leaves in *C.* sect. *Acaules* (Figs. 6, 9, 12, 15, 18) are all basal and exhibit a similar morphological range to those in *C.* sect. *Calandrinia*, but they are indistinctly to not at all petiolate, perhaps more succulent (although not readily evaluated from herbarium specimens), and/or much longer (up to 150 mm in *C. acaulis* var. *magna*).

Leaves in *Montiopsis* subgenera *Dianthoideae* (Figs. 19, 20, 23, 24) and *Montiopsis* (Figs. 27, 28) are usually 3–20(–40) mm long and usually less than 3 mm wide (leptophyllous to nanophyllous; Dilcher, 1974), usually oblanceolate to linear, and sessile or with a weakly defined petiolar region between the clasping leaf base and lamina. The leaf base margins in some specimens of *M. andicola* (Fig. 19) and *M. gayana* (subg. *Dianthoideae*) are irregularly dentate. The dentations intergrade with marginal trichomes toward the leaf apex (see below). Slight degrees of dentation also occur in conjunction with trichomes in *M.* subg. *Montiopsis*.

The leaf bases in all members of *Calandrinia* and *Montiopsis* are flattened, somewhat clasping to nearly sheathing, and not obviously jointed at the abscission zone.

*2. Leaf venation pattern.* Figures 1–30 illustrate gross leaf venation patterns of *Calandrinia* and *Montiopsis*; for comparative purposes, Figure 31 illustrates venation in *Montia parvifolia*. Figures 32–37 illustrate fine venation of *C.* sects. *Calandrinia*, *Monocosmia*, and *Acaules*. Figures 38–41 illustrate leaf apical venation in *C.* (*Calandrinia*) *axilliflora*, *C.* (*Monocosmia*) *monandra*, *C.* (*Acaules*) *carolinii*, and *Montia parvifolia*. The descriptions presented here are based on studies of over 150 cleared leaves from 65 individuals of ca. 23 species that represent the gross morphological extremes in *Calandrinia* and *Montiopsis* as evident from herbarium specimens. My comparisons of the data are based on examination of ca. 1,500 cleared leaves representing nearly all

species or species groups of Portulacaceae and ca. 500 additional cleared leaves from ca. 250 selected species throughout Centrospermae.

Venation in *C.* sect. *Calandrinia* (Figs. 1–5, 32, 33, 38) is characterized by a primary vein that is prominent basally but much diminished toward the leaf apex (Fig. 3) or distinct but ramified at the extreme apex (Fig. 38); secondary veins and prominent distal ramifications thereof that form indistinct loops ("arches"; cf. Hickey, 1979) near the leaf margin (Figs. 2, 4) or merge with the fimbrial vein (Fig. 1; see also below); and tertiary veins (sometimes constituting the highest distinct vein order, e.g., in Figs. 1, 32) that reticulate irregularly and/or give rise to freely ending veinlets (Fig. 32) or, in larger leaves, to a fourth order of reticulating veins (Fig. 32).

Areolation is imperfect; the areoles are variably sized and irregularly shaped (Figs. 32, 33) but, in contrast to Hickey's (1979) characterization of imperfect areolation, there are relatively few freely ending veinlets: the ultimate vein-enclosures usually contain no veinlets or one, usually unbranched, veinlet. A statistical study of the number and distribution of freely ending veinlets per ultimate vein enclosure, a potentially useful taxonomic character in *Calandrinia*, was not undertaken.

The marginal venation in leaves of *C.* sect. *Calandrinia* is characterized by a fimbrial vein (= a contiguous vein following the leaf margin; Figs. 1–4, 38), which is only weakly consolidated in the basal portion of the leaf but exceedingly prominent toward the leaf apex, where it becomes perpendicular to and overtops the primary vein (Fig. 37).

Leaf venation in *C.* sect. *Monocosmia* (Figs. 5, 34, 39) is, in all respects, indistinguishable from that in *C.* sect. *Calandrinia*.

Some species of *C.* sect. *Acaules* possess a fimbrial vein similar to that in *C.* sect. *Calandrinia*, e.g., *C. affinis* (Figs. 6–8, 35), *C. acaulis*, *C. acaulis* var. *magna* (Figs. 9–11, 36), and *C. carolinii* (Figs. 12–14, 37, 40). Other taxa lack a fimbrial vein, e.g., *C. compacta* (Figs. 15, 16), *C. caespitosa* (Figs. 17, 18), and some specimens of *C. affinis*. A fimbrial vein is weakly evident in small-leaved specimens of *C. acaulis* from Bolivia and Peru and the single examined specimen from Argentina ("*C. saltensis*"). In general, the fimbrial vein is less well consolidated in *C.* sect. *Acaules* (especially in *C. carolinii*; Figs. 12–14, 37, 40) than in *C.* sects. *Calandrinia* and *Monocosmia* but, as in the last sections, it becomes perpendicular to and overtops the primary vein at the leaf apex (Fig. 40). The primary vein in *C.* sect. *Acaules* is more or less distinct at the leaf apex (Fig. 10) or ramified at the extreme apex as in *C.* sects. *Calandrinia* and *Monocosmia* (Figs. 7, 13, 16, 17; especially evident in Fig. 40).

Otherwise, venation in *C.* sect. *Acaules* appears less well organized than in *C.* sect. *Calandrinia*. The secondary veins, especially toward the leaf apex, may merge with the fimbrial vein (Figs. 7, 10); toward the leaf base, the secondary veins form distinct secondary loops within the confines of the fimbrial vein (Figs. 8, 11, 14, 35–37). In leaves lacking a fimbrial vein, the secondary veins form

irregular loops or recurve and ramify freely (Figs. 15–18). The higher-order venation in *C.* sect. *Acaules* (Figs. 7, 8, 10, 11, 13, 14, 16, 17, 35–37) is more open than in *C.* sects. *Calandrinia* and *Monocosmia*: the tertiary veins are more freely ramified; the areolation is less developed; more, and more highly branched, freely ending veinlets occur per ultimate vein-enclosure; and the marginal venation (in those taxa lacking a fimbrial vein) consists of irregular loops and freely ending veinlets. A fourth order of veins is sometimes distinct in larger leaves of *C.* sect. *Acaules* (Fig. 11).

The fimbrial vein in *C.* sects. *Calandrinia* and *Monocosmia* and species of *C.* sect. *Acaules* superficially resembles that found in Montieae, e.g., in *Montia parvifolia* (Figs. 31, 41). In Montieae, however, the fimbrial vein merges with the prominently dilated primary vein at the leaf apex and remains (or becomes) parallel to it; this morphology characterizes fimbrial veins in certain Caryophyllaceae (Hershkovitz, unpublished). The perpendicular orientation of the fimbrial vein at the leaf apex in *Calandrinia* is unique.

Venation in *Montiopsis* subgenera *Dianthoideae* (Figs. 19–25) and *Montiopsis* (Figs. 26–31) resembles that in species of *C.* sect. *Acaules* that lack fimbrial veins. The primary vein remains prominent and distinct at the leaf apex or becomes ramified at the extreme apex. The secondary veins may be irregularly ramified/reticulate (e.g., *M. andicola*, Fig. 22), ramified/recurved (e.g., *M. gayana*, Fig. 24), or form irregular loops (e.g., *M. gayana*, Fig. 23; *M. umbellata*, Figs. 26, 27; and *M. trifida*, Fig. 30). The tertiary veins form the highest distinct order and are irregularly ramified to reticulate.

Areolation is imperfect; the ultimate vein enclosures often have three or more, often branched, freely ending veinlets; and the marginal venation is finely looped to open. In some specimens of *M.* (*Dianthoideae*) *andicola*, a single veinlet protrudes into some of the larger basal leaf dentations (Fig. 19). The smallest leaves in these sections show little organization in venation pattern: one or two pairs of weakly distinct, ramified (rarely looped), secondary veins give rise to a few reticulating veins or freely ending veinlets.

*3. Stomatal morphology.* Nyanyano (1986a, b) reported that, among the 22 species of *Calandrinia* sensu lato investigated, 15 had paracytic stomata and 7 had (presumably brachy-)tetracytic stomata. Nyanyano (1986a) did not identify the species of *Calandrinia* sensu lato examined other than the few he illustrated, so the correlation between his data and the taxonomic circumscriptions employed in the present paper cannot generally be ascertained. Nyanyano (1986a) did, however, illustrate brachytetracytic stomata in *C.* (*Acaules*) *acaulis* and also reported tetracytic stomata in *C.* (*Monocosmia*) *monandra*. He did not report variation in stomatal morphology within species, although variation in stomatal type is the rule in

individual leaves of *Calandrinia* and many other members of Portulacaceae (Hershkovitz, 1991a, 1992, unpublished).

Figures 42–54 illustrate stomatal morphology in species of *Calandrinia* and *Montiopsis*; for comparison, Figure 55 illustrates stomata of *Montia parvifolia*. I examined stomatal morphology in 33 specimens of ca. 25 species of *Calandrinia* and *Montiopsis*. For comparison, I examined stomata in selected taxa throughout Portulacaceae.

Stomata of *C.* sect. *Calandrinia*, including *C. alba* (Fig. 42), *C. breweri* (Fig. 43), and *C. axilliflora* (Fig. 44) are predominantly staurocytic (Figs. 42-1, -3, -4; 43-2; 44-1, -2) to brachytetracytic (Figs. 42-3, 43-1). The contact cells (i.e., the cells bordering the guard cells) are often surrounded by an additional cycle of "subsidiary-like" epidermal cells morphologically intermediate between subsidiary cells and ordinary epidermal cells (Fig. 42-2, -3). The inner tangential walls of these cells, which abut the subsidiary cells, form smooth arcs, but the outer tangential walls are generally more sinuous, like ordinary epidermal cells. Other stomatal types occur infrequently in *C.* sect. *Calandrinia*, including brachyparacytic, intermediates between brachyparacytic and brachytetracytic (e.g., brachyparacytic with one polar subsidiary cell, Fig. 44-3), hemi-amphibrachyparacytic (Fig. 43-3; cf. Hershkovitz, 1991a), amphibrachyhexacytic, anomocytic, and other minor morphological variants not readily classified. The number of contact cells in *C.* sect. *Calandrinia* is usually four or five.

*Calandrinia* (*Monocosmia*) *monandra* (Fig. 45) has stomatal morphology very similar to that of *C.* sect. *Calandrinia*.

Staurocytic and brachytetracytic stomata also occur commonly to predominantly in most of the examined taxa of *C.* sect. *Acaules*, including *C. carolinii* (Fig. 46), *C. colchaguensis* (Fig. 47), and *C. caespitosa* (Fig. 48). An outer cycle of subsidiary-like cells is also evident (Figs. 46-1; 47-2; 48-1, -2) but may be incomplete or poorly defined. Brachyparacytic and related stomatal types (e.g., amphibrachyparacytic, hemi-amphibrachyparacytic) appear to be more common in specimens of *C.* sect. *Acaules* (especially in *C. caespitosa*; Fig. 48) than in *C.* sects. *Calandrinia* and *Monocosmia*; such stomata predominate only in *C. compacta* (Fig. 49). Irrespective of stomatal type, the number of contact cells in *C.* sect. *Acaules* is usually four or five, rarely three or six.

The predominance of brachytetracytic and staurocytic stomata found in *C.* sects. *Calandrinia*, *Monocosmia*, and *Acaules* resembles the condition found in *Montia parvifolia* (Fig. 55). In this species, however, an outer cycle of cells is less discernable.

Brachy- to amphibrachyparacytic stomata predominate in *M.* subg. *Dianthoideae*, e.g., in *M. gayana* (Fig. 50) and *M. andicola* (Fig. 51). Staurocytic stomata sometimes occur commonly but never predominantly (e.g., *M. gayana*, Fig. 50). These staurocytic stomata are often surrounded by an irregular outer cycle of subsidiary-like cells similar to that found in *Calandrinia*. The number of contact cells in *M.* subg. *Dianthoideae* is most commonly four or five.

Brachy- to amphibrachyparacytic stomata also predominate in *M.* subg. *Montiopsis*, e.g., in *M. copiapina* (Fig. 52), *M. gilliesii* (Fig. 53), *M. capitata*, and *M. umbellata*. Staurocytic stomata occur infrequently in *M. copiapina*, and an outer cycle of subsidiary-like cells is sometimes distinguishable. Hemibrachyparacytic and anomocytic stomata predominate in *M. parviflora* (Fig. 54). The number of contact cells in *M.* subg. *Montiopsis* is usually four but may be as many as six (Fig. 54).

*4. Trichome morphology.* Kelley (1973) reported unicellular ribbed trichomes in all species of *C.* sect. *Calandrinia*; no trichomes in *C.* sect. *Acaules*; glandular or eglandular, unbranched or branched multiseriate-multicellular trichomes in all species of *Montiopsis*; and, additionally, barbellate multiseriate-multicellular trichomes in all species of *Montiopsis* subg. *Montiopsis*. Carolin (1987) scored *C.* sects. *Calandrinia* and *Monocosmia* for having simple trichomes, the OTUs of *Montiopsis* for having both multicellular and glandular trichomes, and *C.* sect. *Acaules* for having glandular trichomes (but neither unicellular nor multicellular trichomes). Peralta's (1988) descriptions of trichomes in Mendozan species of *Montiopsis* accord

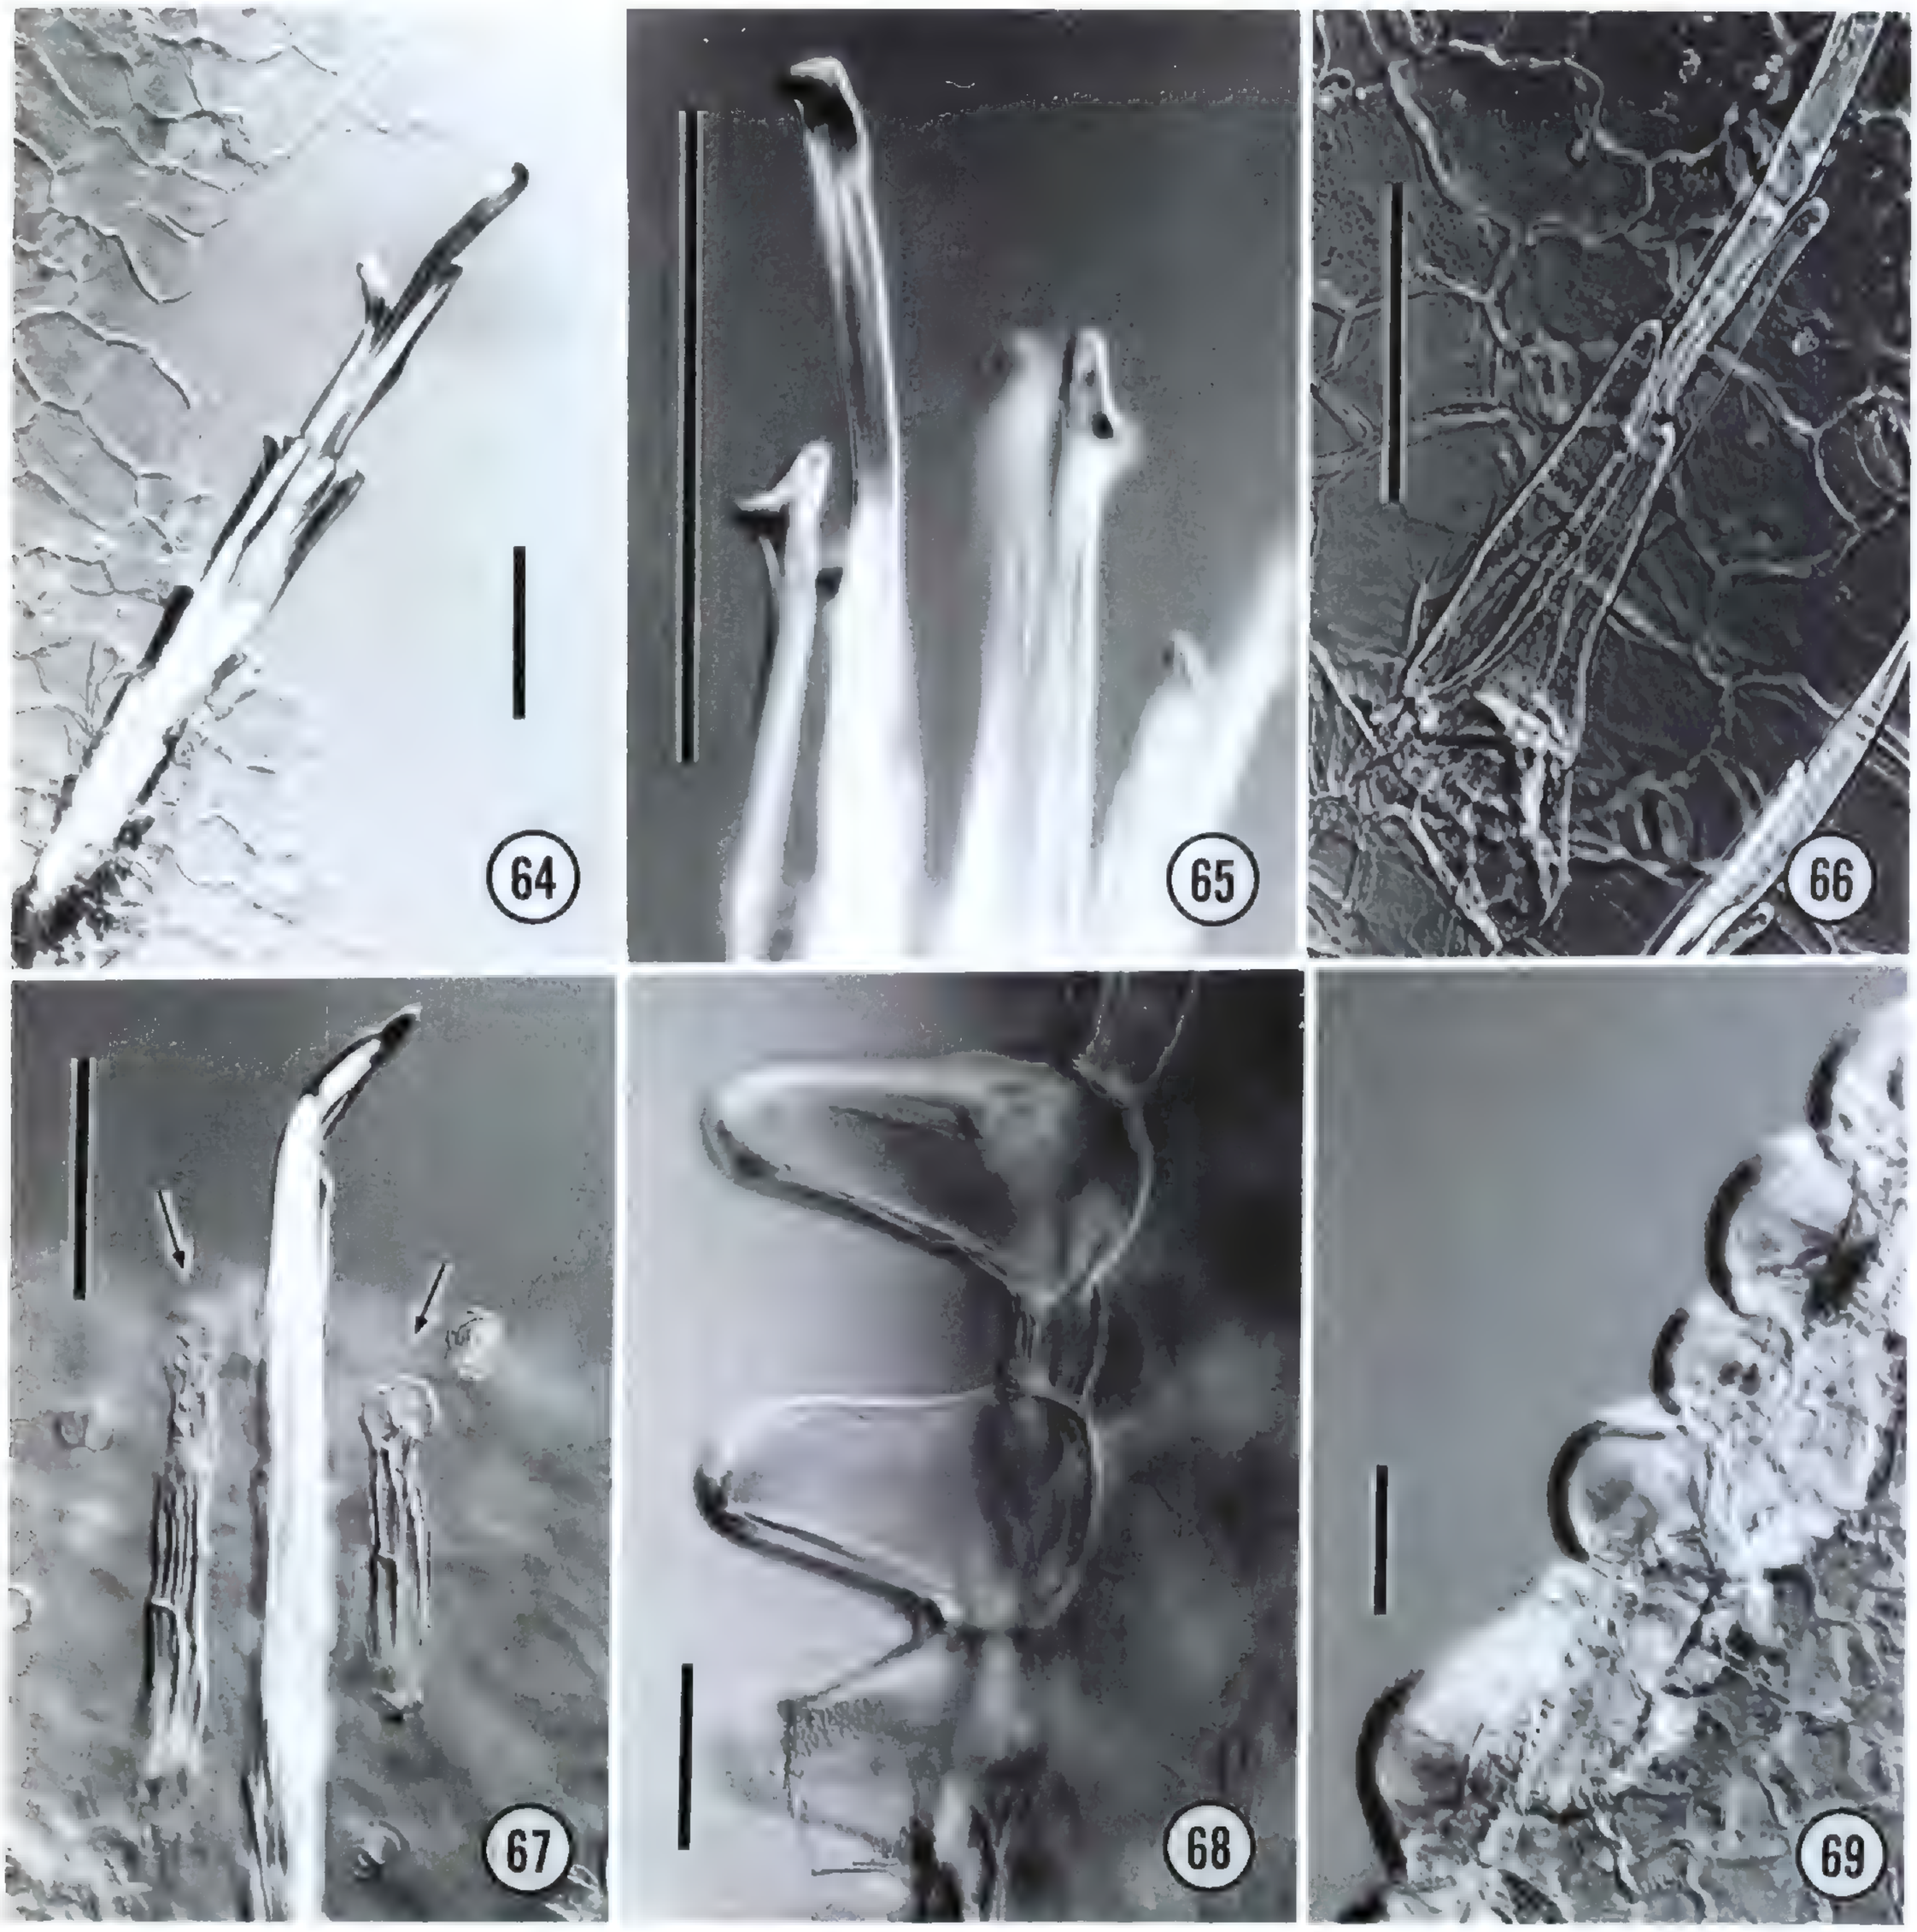
with Kelley's data, but she reported papillae in the species of *Calandrinia* sect. *Acaules*.

Figures 56–67 illustrate trichome types in *Calandrinia* and *Montiopsis*; for comparison, Figures 68 and 69 illustrate trichomes/papillae in *Rumicastrum* and *Montia*. Trichome presence and gross morphology was evaluated for all examined herbarium specimens and studied in detail in epidermal preparations (see Table 1).

All examined specimens of *C.* sect. *Calandrinia* possess unicellular ribbed trichomes (Fig. 56), as reported by Kelley (1973). The trichomes may be up to ca. 600 μm long but are sometimes merely papillar (Fig. 57). Unlike papillae in other genera (e.g., *Cistanthe*, Hershkovitz, 1991a; and *Montia*, Fig. 69), the outer tangential cell wall has a distinct U- or V-shaped process rather than a more generalized swelling. Thus, I distinguish between trichomes (process as long as or longer than broad), papillar trichomes (process broader than long), and



FIGURES 64–69.[4] Epidermal preparations of *Montiopsis* subg. *Montiopsis*, *Rumicastrum* sp., and *Montia parvifolia*.—64. Multiseriate barbed trichome in *Montiopsis* (*Montiopsis*) *capitata* (*Fischer 169*).—65. Macerated trichome of *Montiopsis* (*Montiopsis*) *umbellata* (*Joseph 3865*) showing barbed tips of individual hair cells.—66. Glandular multiseriate-multicellular trichomes (arrows) in *Montiopsis* (*Montiopsis*) *copiapina* (*Johnston 6069*).—68. Unicellular unribbed papillae in *Montia parvifolia* (*Calder et al. 14865*).—69. Unicellular unribbed papillae in *Rumicastrum* sp. (Unvouchered specimen K-242, courtesy of Walter A. Kelley.) All scale bars = ca. 100 μm.

papillae (without a distinct process). I regard as papillar trichomes papillae sensu Peralta (1988; re: *Calandrinia*) and Gerbaulet (1992; re: *Anacampseros*, etc.). The trichomes and papillar trichomes of *Calandrinia* may sparsely or densely populate the leaf margin and may occur severally adjacent (Fig. 57).

Leaves in members of *C.* sect. *Acaules* are glabrous or bear unicellular ribbed trichomes and/or papillar trichomes identical to those found in *C.* sect. *Calandrinia*, e.g., *C. carolinii* (Fig. 58). Whether these trichomes are glandular, as interpreted by Carolin (1987; see also Peralta, 1988), could not be determined in the present investigation. Structurally, however, the unicellular trichomes of *C.* sect. *Acaules* are distinct from the multicellular and obviously glandular trichomes of *Montiopsis* (see below). Trichome presence varies within species *C. affinis*, *C. carolinii*, *C. caespitosa*, and *C. compacta*. They may occur through-

TABLE 3. Leaf traits of *Calandrinia* and *Montiopsis* and their distribution in other Portulacaceae. Rare states (i.e., states characteristic of one or two species in a taxon) are indicated in parentheses. The western American Portulacaceae (cf. Hershkovitz, 1991a, 1993) and *Rumicastrum* are listed by genus and the eastern American/African Portulacaceae are listed as a single entry. Basellaceae, Cactaceae, Didiereaceae, and *Amphipetalum* are, cladistically, members of the eastern American/African group but were not included in the cladistic analysis (see Hershkovitz, 1993). Nonetheless, the data for the eastern American/African taxa reflect, to the degree known, the traits of these excluded taxa. I have not adequately investigated Hectorellaceae and hence have not included data for this family. "Brachyparacytic" stomata are here intended to include all variants (e.g., amphibrachyparacytic) except brachytetracytic/staurocytic (see Hershkovitz, 1991a). The trichome data refer to foliar trichomes, including papillar trichomes, only and not axillary trichomes present in some eastern American/African Portulacaceae (see Hershkovitz, 1993), nor papillae. Sources for data not derived from the present text are listed in Hershkovitz (1993, appendix 1).

out the abaxial leaf surface of *C. graminifolia*. Trichomes are apparently absent in *C. acaulis* from Ecuador northwards, occur occasionally in Bolivian and Peruvian specimens, and are present in all three examined Argentinian herbarium specimens ("*C. saltensis*"). In effect, trichomes occur in *C. acaulis* only in its range overlap with *C. carolinii*. My observations of variable trichome presence in section *Acaules* are consistent with Peralta (1988) but not Kelley (1973), the latter reporting the absence of trichomes in all species.

The specimens of *C.* sect. *Monocosmia* (Fig. 59) possessed only unicellular ribbed papillar trichomes, which have a distinct U-shaped emergence.

The unicellular trichomes and papillar trichomes of *C.* sects. *Calandrinia*, *Acaules*, and *Monocosmia* are distinct from those of other Portulacaceae, e.g., *Rumicastrum* sp. (Fig. 68), in bearing ribs. As I have noted, I regard unicellular epidermal emergences in some Portulacaceae, e.g., *Montia parvifolia* (Fig. 69) and *Cistanthe* spp. (Hershkovitz, 1991a), as papillae rather than trichomes.

Foliar trichomes in *M.* subg. *Dianthoideae* are multicellular and range from uniseriate (Fig. 60; only the basal cell is biseriate) to multiseriate (Fig. 61) to branched multiseriate (Fig. 62). If present, branched multiseriate trichomes typically occur along the leaf base margins and intergrade with vascularized leaf dentations (see above). The uniseriate trichomes tend to occur along the leaf margin, although in some specimens they occur occasionally on the lamina. Glandular trichomes are present or absent in *M. andicola* and *M. gayana* (Fig. 63). Some specimens of *M.* subg. *Dianthoideae* appear to be glabrous. While my observations on trichome structure in subgenus *Dianthoideae* agree with earlier reports (Kelley, 1973; Peralta, 1988), the material I examined includes what I presume to be a disproportionate number of glabrous or nearly glabrous specimens of otherwise pubescent species.

Leaves (and sepals) of all examined species of *M.* subg. *Montiopsis* bear distinctive multiseriate trichomes composed of long intertwined hair cells. Ford (1992) noted that, in some species, the tips of the individual hair cells are bent outward so that the trichome appears barbed (Fig. 64). The individual hair cells may also be barbed at the tip (Fig. 65). According to Kelley (1973), the multiseriate trichomes are several cells long, i.e., the individual hair cells are transversely divided. In the present study, individual hair cells traced to their point of origin at the leaf surface (Fig. 66) did not show evidence of transverse walls. Apparently the hair

TABLE 4. Foliar characters, character states, and scores for Portulacaceae used in the present cladistic exercise. The character numbers accord with, and the character analyses are provided in, Hershkovitz (1993: appendix 1). Polarities, where presumed, are scored as "0" in the hypothetical ancestor. The "0" designation also denotes a posteriori determined primitive states. Otherwise, the state designations are arbitrary. "X" character states are employed following Doyle & Donoghue (1986) and are analyzed as missing data in PAUP. Other missing data scores are denoted as "?" (unknown) or "V" (too variable within the OTU to determine). Character states variable within an OTU but scored for the presumed primitive state are underlined in the data matrix.

7. Leaves alternate, 0; leaves opposite, 1.
8. Leaf bases jointed, 0; leaf bases not jointed, 1.
9. Leaf bases clasping, 0; leaf bases not clasping, 1.
10. Leaf mucilage cells conspicuous and relatively numerous, 0; leaf mucilage cells none or few and not conspicuous and few, 1.
11. Ribbonlike veins absent, 0; ribbonlike veins present, 1.
12. Leaf venation not festooned brochidodromous, 0; leaf venation festooned brochidodromous, 1.
13. Fimbrial vein absent, 0; fimbrial vein present, 1.
14. Fimbrial vein becoming perpendicular to the primary vein at the apex, 0; fimbrial vein parallel to the primary vein at the apex, 1; fimbrial vein absent, X.
15. Stomata predominantly brachyparacytic and/or and similar types (see Hershkovitz, 1991a), 0; stomata predominantly parallelocytic and/or nonbrachyparacytic, 1.
16. Stomata predominantly brachyparacytic, nonbrachyparacytic, or parallelocytic, 0; stomata commonly brachytetracytic and/or staurocytic, 1.
17. Foliar trichomes absent, 0; foliar trichomes present, 1.

TABLE 4. Continued.

cells divide infrequently, if at all (cf. Becker, 1895). In any case, these trichomes sparsely populate or, in some species, densely cover the leaf surface and may be as long as ca. 3 mm. I found glandular trichomes resembling those of *M.* subg. *Dianthoideae* in only one specimen of *M.* subg. *Montiopsis* (*M. copiapina*, Fig. 67), but they have been reported in several other species (Ford, 1992; Kelley, 1973). The glandular trichomes ranged from few-celled and uniseriate to multiseriate. Unlike the eglandular trichomes, the elongate cells of the multiseriate-glandular trichomes are clearly transversely divided.

### B. PHYLOGENETIC ANALYSIS

Table 3 compares the foliar traits of *Calandrinia* and *Montiopsis* with those found in other Portulacaceae. Only those traits of *Calandrinia* and *Montiopsis* that are differentially distributed among other Portulacaceae are listed, e.g., linear leaves occur in most genera of the family and hence are not listed. Figure 70A and B compares consensus trees derived from cladistic analysis of all (from Hershkovitz, 1993) versus only nonfoliar characters, respectively. Figure 71 is a consensus derived from trees generated using weighted foliar characters. The OTU definitions, data, and character analyses are presented elsewhere (Hershkovitz,

TABLE 5. Tree statistics for Figures 70A, B and 71. Listed below are the lengths, consistency indices (CI), and rescaled consistency indices (RC) for all characters, foliar characters, and nonfoliar characters for the trees used to generate the consensuses in Figures 70A, B and 71. The statistics vary among the different trees used to generate Figure 70A when considering only the character subsets. Note that CI and RC vary inversely with respect to tree length for the character subsets for Figure 70A.

| Consensus tree | Length (all characters) | CI | RC | Length (foliar characters) | CI | RC | Length (nonfoliar characters) | CI | RC |
|---|---|---|---|---|---|---|---|---|---|
| Figure 70A | 107 | 0.449 | 0.346 | 29–32 | 0.517–0.469 | 0.441–0.385 | 75–78 | 0.440–0.423 | 0.326–0.306 |
| Figure 70B | 108 | 0.444 | 0.341 | 34 | 0.441 | 0.353 | 74 | 0.446 | 0.333 |
| Figure 71 | 121 | 0.397 | 0.284 | 25 | 0.600 | 0.537 | 96 | 0.344 | 0.210 |

1993), but, for convenience, the foliar data scores are listed in Table 4. Figures 70 and 71 do not show the speculative positions of Basellaceae, Cactaceae, Didiereaceae, or *Talinella* (cf. Hershkovitz, 1993, fig. 1). Table 5 lists the lengths, consistency indices (CI) and rescaled consistency indices (RC) of the trees on which the consensuses are based. For each treefile, the tree statistics for all, just foliar, and just nonfoliar characters are compared. Not all of the characters listed in Table 3 were included in the cladistic analysis (see Hershkovitz, 1993, appendix 1): petiolar morphology, primary vein morphology at the leaf apex, and the presence of an outer cycle of subsidiary-like cells were excluded.

Figures 70B and 71 were each independently derived by two procedures: (1) searching under various PAUP modes (Swofford, 1991; see Hershkovitz, 1993) using weights of 100 for the nonfoliar and foliar character sets, respectively, followed by weight equalization to derive comparable tree statistics; and (2) searching using only the desired character set, followed by restoration of the excluded characters and screening for the shortest trees. The aim in the latter procedure was to recover the shortest trees based on the included data that were otherwise most consistent with the excluded data. The dashed lines in Figures 70B and 71 denote nodes not supported by at least one nonfoliar or foliar character state change, respectively. These branches would be collapsed in a consensus of all trees generated using nonfoliar or foliar characters exclusively.

I aborted the searches using weighted nonfoliar characters when 9,000 trees were saved. Inasmuch as the consensus of these trees (Fig. 70B) is similar to that of trees generated using all characters equally weighted (Fig. 70A), I suspect that the number of equally parsimonious trees is actually more than an order of magnitude greater (cf. Hershkovitz, 1993). Despite their similarity, the consensuses compared in Figure 70 are based on completely different sets of trees: those yielding Figure 70A are 107 steps, and those yielding Figure 70B are, over all characters, 108 steps. Nevertheless, the unambiguous character state changes defining the nodes in Figure 70B are essentially those defining the nodes in Figure 70A (see Hershkovitz, 1993) minus those that become ambiguous when some nodes are collapsed. Hence, I do not show the unambiguous character state changes on the Figure 70B tree.

The consensus in Figure 71 is based on 490 trees found using weighted foliar characters and PAUP's tree bisection/reconnection algorithm to completion. The unambiguous foliar character state changes are indicated and numbered according to Hershkovitz (1993, appendix 1).

## DISCUSSION

### 1. TAXONOMIC SIGNIFICANCE OF FOLIAR MORPHOLOGY IN *CALANDRINIA* AND *MONTIOPSIS*

*A. Phenetic comparison of foliar traits of* Calandrinia *and* Montiopsis. Table 3 emphasizes the degree of homogeneity of foliar morphology within *Calandrinia* and *Montiopsis*, the distinctions in foliar morphology between these genera and other western American Portulacaceae, and the additional distinctions between these genera and eastern American/African Portulacaceae (cf. Hershkovitz, 1993).

*Calandrinia* is distinguished by the combination of the fimbrial vein that overtops and becomes perpendicular to the primary vein at the leaf apex, the predominance of brachytetracytic/staurocytic stomata commonly with an outer cycle of subsidiary-like cells, and unicellular-ribbed trichomes. These features are absent in some species of *Cal-*

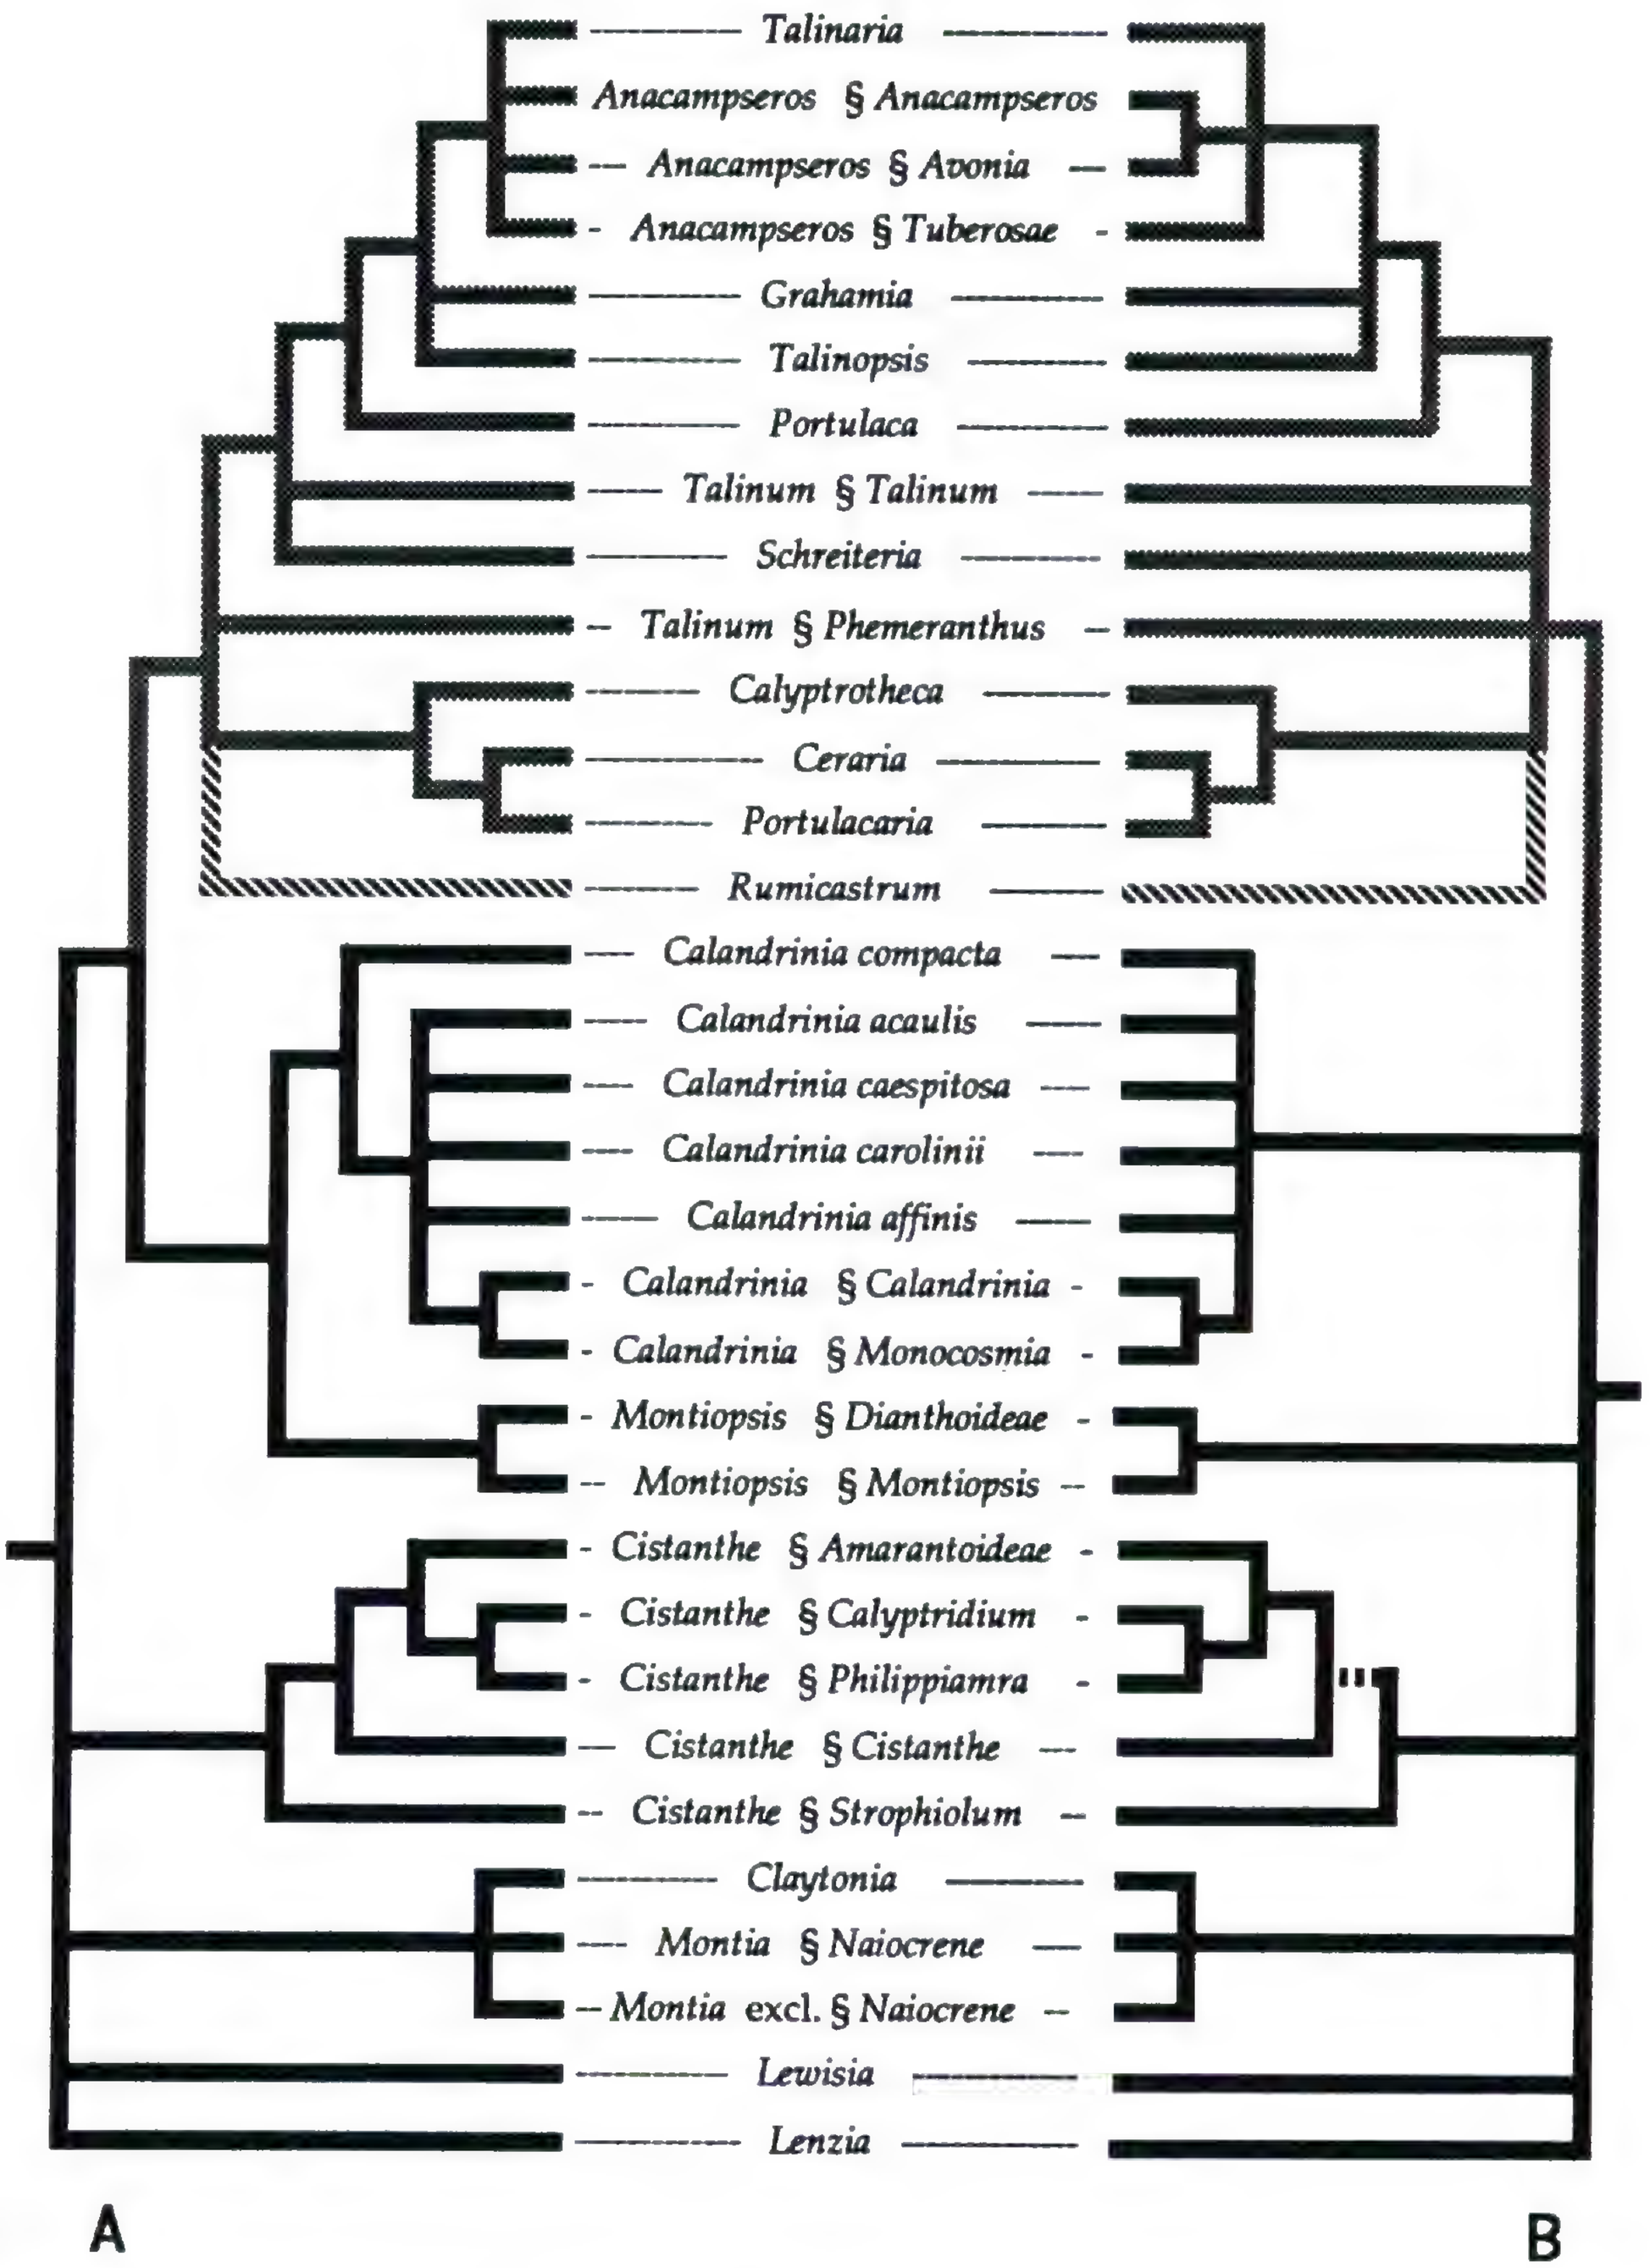

FIGURE 70. Juxtaposed consensuses of cladograms of Portulacaceae generated using all characters equally weighted versus weighted nonfoliar characters. Table 5 lists length and consistency statistics. Shaded branches delineate the eastern American/African taxa (Hershkovitz, 1993), and the diagonally hatched branch denotes Australian endemism.—70A. Consensus of cladograms of Portulacaceae generated using equally weighted foliar and nonfoliar characters. This consensus and its unambiguous character state changes are discussed and illustrated elsewhere (Hershkovitz, 1993: fig. 1). The speculated positions of Basellaceae, Cactaceae, Didiereaceae, and *Talinella*, however, are here omitted.—70B. A consensus of trees generated by 100-fold weighting of 31 nonfoliar characters from Hershkovitz (1993: table 3 and appendix 1, chars. 1–6 and 22–46). The consensus is compatible with trees generated using nonfoliar characters exclusively. All except the dashed branch are at least equivocally supported by at least one nonfoliar character state change. The dashed branch is supported only by a foliar character state change. The unambiguous character state changes in Figure 70B include those indicated elsewhere for Figure 70A (Hershkovitz, 1993: fig. 1) minus those that become ambiguous because of decreased resolution.

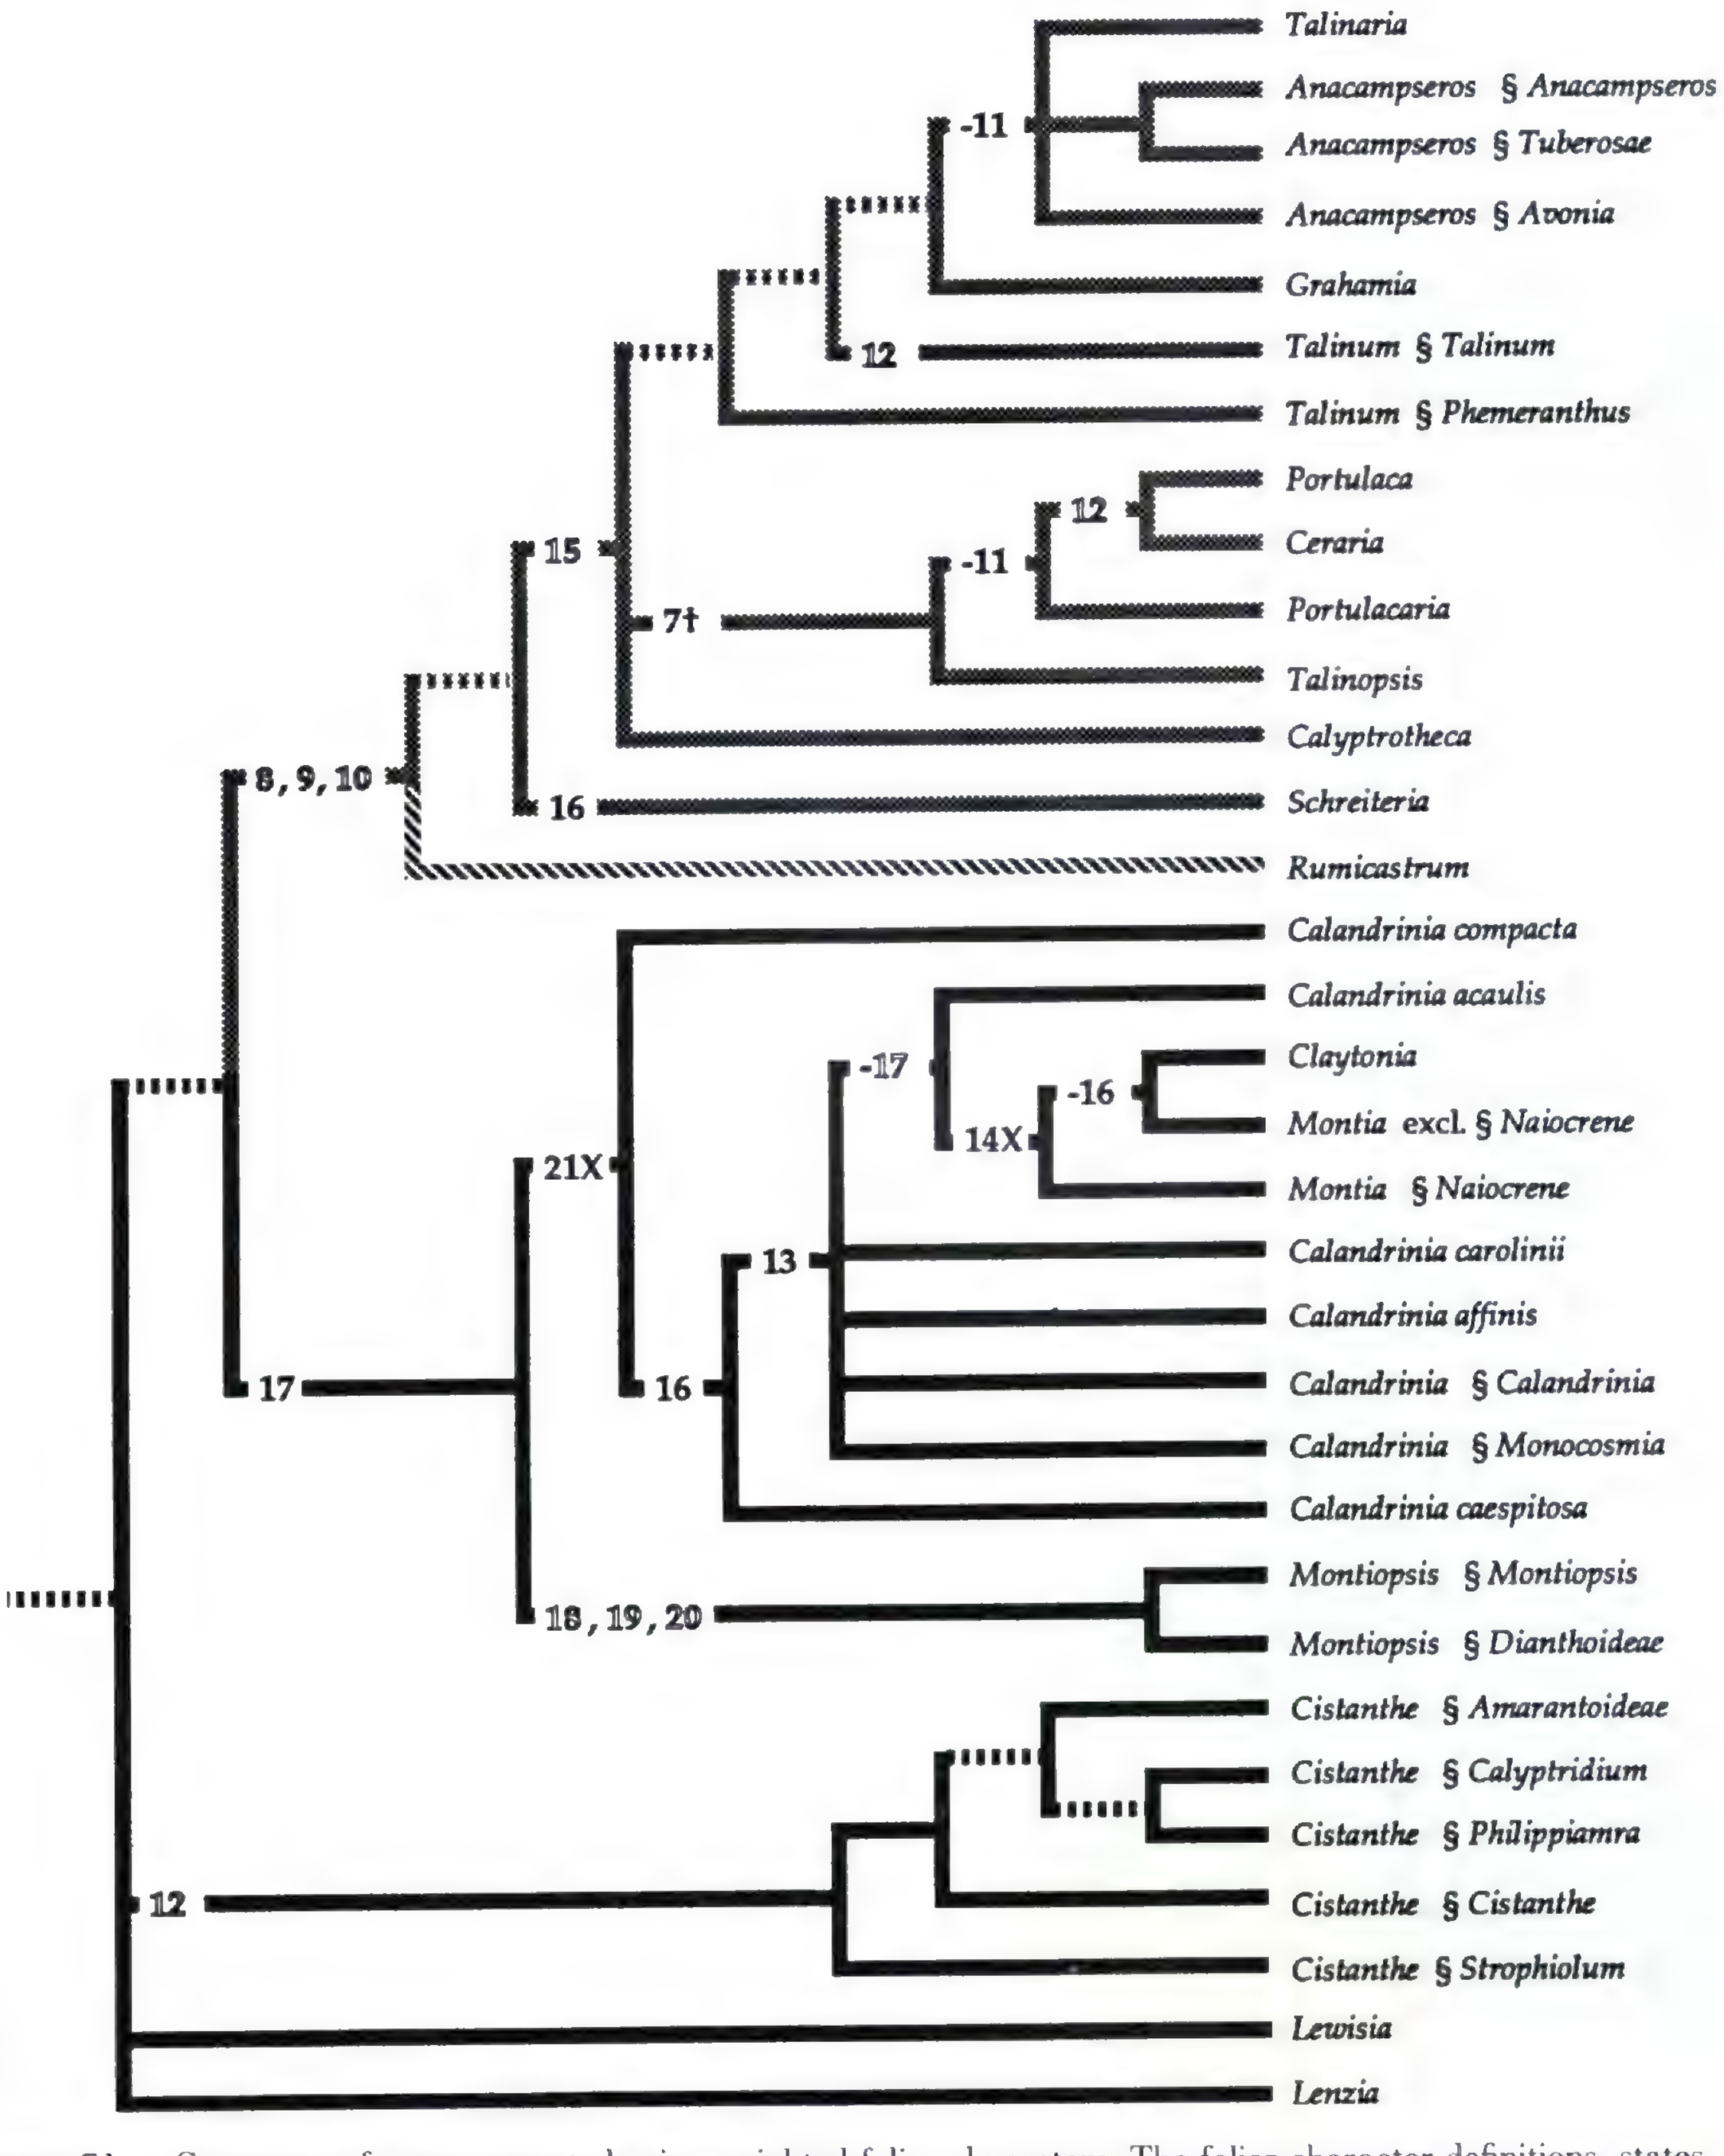

FIGURE 71. Consensus of trees generated using weighted foliar characters. The foliar character definitions, states, and OTU scores are reproduced in Table 4. Table 5 lists length and consistency statistics. Shaded branches delineate the eastern American/African taxa (Hershkovitz, 1993), and the diagonally hatched branch denotes Australian endemism. The trees were generated by 100-fold weighting of 15 foliar characters from Hershkovitz (1993: table 3 and appendix 1, chars. 7–21) and, independently, by using foliar characters exclusively, followed by reinstatement of nonfoliar characters and filtering for the shortest trees. Unambiguous foliar character state changes are indicated. Polarized characters are shown in black and unpolarized in white. "X" and "†" indicate that OTUs at adjacent branches were scored as missing data ("?") because of "X" character definitions or uncertainty (see Table 4). All except the dashed branches are at least equivocally supported by at least one foliar character state change. The dashed branches are supported only by nonfoliar character state changes.

*andrinia* sect. *Acaules*, however. Fimbrial veins, although morphologically distinct, characterize *Claytonia* and *Montia*, and brachytetracytic stomata characterize one species of the latter. Brachytetracytic stomata also regularly occur in *Montiopsis* subg. *Dianthoideae*, *Schreiteria*, and occasionally among other stomatal types in *Cistanthe* (Hershkovitz, 1991a). Trichomes occur in other Portulacaceae but are not ribbed and, in *Montiopsis* and *Amphipetalum* Bacigalupo (in Spichiger, 1988), are multicellular. Glandular or eglandular multiseriate trichomes are restricted to *Montiopsis* and represent the sole foliar distinction between this genus and other Portulacaceae.

Both *Calandrinia* and *Montiopsis* share with other western American Portulacaceae their leaf base and petiolar morphology and stomatal contact cell number. These features are generally not present in eastern American/African Portulacaceae. Well-differentiated petioles are absent in *C.* sect. *Acaules*, however. One species of *Rumicastrum* ("*Calandrinia pumila* F. Muell.") has both winged petioles and brachyparacytic stomata with four contact cells (Hershkovitz, unpublished).

The relatively pronounced diminution and/or distal ramification of the leaf primary vein in *Calandrinia* sects. *Calandrinia*, *Monocosmia*, and species of section *Acaules* may provide a synapomorphy for all or part of the genus. In some members of Portulacaceae, e.g., *Lewisia*, the primary vein is always prominent and/or unramified at the leaf apex, whereas other taxa, e.g., *Cistanthe* and various eastern American/African Portulacaceae, always have apically weak to indistinct primary veins (Hershkovitz, 1991a, unpublished). Some taxa, however, are intermediate for this feature, and evaluation of primary vein diminution is somewhat subjective.

Traits not compared in Table 3 include dentate leaf margins, the number of distinct vein orders, and the number of veinlets in the ultimate enclosures. The dentate leaf margins that characterize *Montiopsis* subg. *Dianthoideae* are here regarded as unique. Dentate leaf margins in species of *Lewisia* occur toward the apex of the leaf, rather than, as in *M.* subg. *Dianthoideae*, at the extreme base. I have not scrutinized veinlet numbers throughout Portulacaceae. Nevertheless, the paucity of freely ending veinlets might reinforce the relationship between *Calandrinia* sects. *Calandrinia* and *Monocosmia*, because veinlet numbers are higher among members of *C.* sect. *Acaules*. The poor differentiation and/or low number of distinct vein orders of *Calandrinia* characterize similar-sized leaves in species of several genera throughout Portulacaceae.

*B. Phylogenetic analysis of foliar traits of* Calandrinia *and* Montiopsis. The purpose of the cladistic exercise in this study was to evaluate the degree of taxonomic utility of foliar characters, in particular for clarifying the systematics of *Calandrinia* and *Montiopsis*. The degree of agreement between phylogenetic estimates based on foliar versus nonfoliar characters might be taken as a reliability index of each character set, and the ability of the foliar set to provide additional resolution or "break ties" in analyses based on the nonfoliar set might be taken as a measure of complementarity. If the character sets suggest conflicting phylogenetic resolutions, the data set providing the greatest degree of congruence with all characters combined might be regarded as superior. Evaluation of the utility of foliar versus nonfoliar characters requires additional considerations as well, however, including the size of the respective data sets and the degree to which each taxon has been investigated.

Superficially, the cladistic analysis suggests that the foliar data tend to misinform. The Figure 71 consensus tree derived from analysis of weighted foliar characters shows significant similarities but also departures from the consensuses of trees generated using all characters (Fig. 70A) or weighted nonfoliar characters (Fig. 70B). When measured with all characters equally weighted, the trees generated with weighted foliar characters are 13% longer than those generated with equal weightings (Table 5). In contrast, the consensuses of the Figure 70A and 70B are nearly identical even though the sets of trees used to generate each consensus are necessarily mutually exclusive. Thus, the analysis suggests that the foliar characters are somewhat dispensable. These results must be evaluated in the context of results for individual subclades and characters.

The foliar versus nonfoliar data suggest rather different relationships for *Calandrinia* and *Montiopsis*. The nonfoliar data (Fig. 70B) indicate that *Calandrinia* is monophyletic and possibly (but not necessarily) the sister group of *Montiopsis*, and that *Calandrinia* sects. *Calandrinia* and *Monocosmia* are sister groups. The foliar data (Fig. 71) indicate that *Calandrinia*—with *Claytonia* and *Montia* nested therein—is a sister group to *Montiopsis*, and that sections *Calandrinia* and *Monocosmia* may not be sister groups. In both consensuses, *Montiopsis* is monophyletic. The combined

data (Fig. 70A) agree more with the nonfoliar data, conserving only the *Calandrinia* + *Montiopsis* clade suggested by the foliar data.

Scrutiny of Figure 71 reveals that both the *Calandrinia* + *Montiopsis* clade and the inclusion of *Claytonia* and *Montia* therein are not strongly supported even by the foliar data. The sole synapomorphy of the *Calandrinia* + *Montiopsis* clade is the derivation of trichomes (char. 17), which, as I have noted, are structurally distinct in the two groups. My character definition and scoring in this case was intended to permit trichomes to be homologous in the two groups unless contradicted by other evidence. In the case of Figure 70A (see Hershkovitz, 1993) and Figure 71, it is neither contradicted nor independently supported. Likewise, the inclusion of *Claytonia* and *Montia* reflects my effort, via the use of "X" characters (Doyle & Donoghue, 1986; Hershkovitz, 1993), to permit the structurally distinct fimbrial veins (char. 13) in the two groups to be homologous and also, via recognizing *Montia* sect. *Naiocrene* as a distinct OTU, to allow the homology of brachytetracytic/tetracytic stomata (char. 16). These characters provide the sole evidence for the inclusion of *Claytonia* and *Montia* within *Calandrinia*, and brachytetracytic/staurocytic stomata must then be lost in *Claytonia* and most *Montia* species.

While the foliar evidence provides at least some support for the inclusion of *Claytonia* and *Montia* within *Calandrinia*, excluded foliar evidence might refute it. I did not include petiole presence in my analyses because all OTUs with petiolate taxa include taxa without petioles. Petioles characterize *Calandrinia* sect. *Monocosmia*, all species of section *Calandrinia* (although variable within species of the latter), *Montia* sect. *Naiocrene*, and several species of *Claytonia* and the remaining *Montia* sections. Petioles are lacking (or hardly distinct) in *Calandrinia* sect. *Acaules*. In the context of Figure 71, this evidence could provide a synapomorphy for *Calandrinia* sects. *Calandrinia* and *Monocosmia* and would appear to cause *Claytonia* and *Montia* to become, at least equivocally, a sister group of the first two or fall out of the *Calandrinia* clade altogether. The only robust clades that would remain would be those supporting a close relationship between the sections of *Calandrinia* and the monophyly of *Claytonia* + *Montia* (cf. Fig. 70B).

For other Portulacaceae, cladistic analysis of foliar versus nonfoliar characters also yields only partial congruence. Figures 70B and 71 concur in diagnosing the monophyly of *Claytonia* + *Montia*, *Montiopsis*, the eastern American/African group + *Rumicastrum*, and *Anacampseros* + *Talinaria* (see also Gerbaulet, 1992). For *Montiopsis* and the eastern American/African group + *Rumicastrum*, the foliar evidence provides substantial corroboration of nonfoliar evidence (Fig. 71; cf. Hershkovitz, 1993, fig. 1). The consensuses disagree regarding the precise relationships within the eastern American/African clade. Reconciliation of these disagreements is beyond the scope of the present paper: I have not adequately scrutinized either the taxonomy or leaf morphology of the eastern American/African group for this purpose. The apparent concurrence between Figures 70B and 71 regarding the monophyly of *Cistanthe* is artificial. Analysis with weighted foliar characters yields the result shown in the Figure 71 consensus in which brochidodromous leaf venation is a synapomorphy of *Cistanthe*. This evidence becomes equivocal using foliar characters only (i.e., by collapsing the dashed branches in Fig. 71). Thus, the foliar evidence complements the nonfoliar for diagnosing monophyly of *Cistanthe* (cf. Hershkovitz, 1993, fig. 1).

A peculiar result of the present analysis is that the *Calandrinia* + *Montiopsis* + eastern American/African group + *Rumicastrum* clade is supported in all trees generated using all (Fig. 70A) or weighted foliar characters (Fig. 71). This clade is equivocal in the nonfoliar consensus (Fig. 70B); hence one might surmise that the clade must be supported by a foliar character. In fact, the only character supporting this topology in Fig. 70A is the derivation of panaperturate pollen (see Hershkovitz, 1993). The reason that the clade appears unequivocal in the foliar weighted trees is because no evidence contradicts the homologization of trichomes in *Calandrinia* + *Montiopsis*. As a result, panaperturate pollen becomes equivocally primitive in *Montiopsis*, which then forces the homology with equivocally primitive panaperturate pollen in the eastern American/African group + *Rumicastrum*. I fortuitously discovered that scoring *Calandrinia caespitosa* as absent for trichomes is sufficient to cause, among other things, the *Calandrinia* + *Montiopsis* + eastern American/African group + *Rumicastrum* clade to become equivocal. That a minimal data modification can have such major ramifications should elicit caution in interpreting cladistic results, especially in this case because trichomes are only variably present in species of *Calandrinia* sect. *Acaules*.

It is possible that differences between the consensuses in Figures 70 and 71 reflect artifacts that might be expected given the structure of the data.

The foliar and nonfoliar data comprise, respectively, 15 and 31 characters for 33 taxa. A larger character set should yield a more reliable result, although the result should not necessarily differ from that using a smaller set. Perhaps consistent with this principle, the 31-character nonfoliar data consensus is more similar to the 46-character combined data set consensus than is the 15-character foliar data consensus. Yet, obviously contradicting the principle, the 31- and 46-character data sets yield virtually identical consensuses, despite the substantial difference in data set size.

Another consideration is the claim that, for a given number of taxa, the perceived consistency index (CI; = the number of apomorphic states in the data divided by the length of the cladogram; i.e., the degree of perceived homoplasy), should vary inversely relative to the number of characters in the data (Archie, 1989, 1990). Because the CI is often interpreted as a measure of the reliability of the data and accuracy of the tree, factors that artificially inflate the CI (in this case, a small character data base) should also distort the cladistic results. Alternatively, Sanderson & Donoghue (1989) found no decisive evidence of a relationship between the number of characters and the CI, although they agreed that the CI may not be a good indicator of cladogram accuracy. The data in Table 5 superficially appear to support the view of Archie (1989, 1990): the CI of trees generated using the smaller foliar data set is much higher than that of trees using the larger nonfoliar data set. The CI of trees generated using all 46 characters, however, is slightly greater than that of trees generated using 31 nonfoliar characters. Moreover, the CIs for individual foliar characters (i.e., the number of apomorphic states of the character divided by the number of state changes in the tree) are, in general, higher than for nonfoliar, even in trees generated using the combined data set (Table 5).

A possible artifact in the CI data arises when some characters vary in only a few OTUs, e.g., the trichome traits that are restricted to the two OTUs of *Montiopsis*. The CI for these three characters cannot possibly be lower than 0.5. In other words, irrespective of phylogeny, the maximum number of state changes for these characters is two. The CI of a binary character with ca. half of the OTUs like-scored can approach (but not equal) zero, e.g., if each apomorphic state is independently derived. Farris (1989) proposed a rescaled consistency index (RC), which adjusts for biases in character state frequencies, although Archie (1990) criticized this statistic. Because PAUP calculates RC and not Archie's (1989, 1990) proposed "homoplasy excess ratio," I list RC in Table 5. For the present data, the RCs are lower than but more or less parallel to the CIs, and the RCs of the nonfoliar rather than the foliar characters appear to be more depressed relative to the CIs. Perhaps this is not surprising: while some of the foliar character states vary among relatively few taxa, others, e.g., leaf base morphology (chars. 8, 9), have potentially very low but actually very high CIs.

More rigorous and sophisticated analyses are feasible for assessing the cladistic behavior of foliar versus nonfoliar characters in Portulacaceae, but the significance of foliar data should be clear from the evidence presented here. For example, the foliar evidence generally supports a close relationship among the sections of *Calandrinia* (the spurious results for *Claytonia* and *Montia* notwithstanding), the monophyly of *Montiopsis*, and, weakly, a sister group relationship between the last two genera (Fig. 71). These results are at least consistent with those based on nonfoliar data (Fig. 70B) and corroborate my earlier propositions (Hershkovitz, 1990, 1991b, 1993) regarding the systematics of *Calandrinia* and *Montiopsis*. Specifically, the foliar data support the close relationship of *Calandrinia* sect. *Monocosmia* to *Calandrinia* as proposed by Carolin (1987) and refute earlier taxonomic opinions on a close relationship between section *Monocosmia* and Cistanthe sect. *Calyptridium* (McNeill, 1974; Nyanyano, 1986a, 1990; Pax & Hoffmann, 1934). In supporting the coherence of *Calandrinia*, the leaf data also refute Carolin's (1987) results linking *Calandrinia* sects. *Calandrinia* and *Monocosmia* with *Rumicastrum*. The leaf data might be interpreted as supporting (or at least not refuting) Carolin's alternative proposal that *Calandrinia* sects. *Calandrinia* and *Monocosmia* are closely related to *Montia*. A close relationship between *Calandrinia* and *Claytonia* + *Montia* remains a possibility based on all characters (cf. Hershkovitz, 1993, table 4) although the precise relationship proposed by Carolin is probably incorrect. Although not the focus of the present paper, the leaf data also provide strong support for the distinction between the eastern American/African and western American Portulacaceae. Finally, analysis of the foliar versus nonfoliar data for Portulacaceae yields results consistent with opinions put forth elsewhere (e.g., Levin, 1986) that foliar characters are more conserved evolutionarily than implicit in traditional taxonomies emphasizing reproductive characters. Although the taxonomic utility of foliar characters is now widely appreciated (e.g., Cronquist, 1988: 176–184;

Takhtajan, 1991, chapter 1), the opinion that foliar and other vegetative organs "are characterized by more reversibility than reproductive organs" (Takhtajan, 1991: 21) persists. In fact, in the present study, the foliar characters proved to be more conserved than the nonfoliar in cladograms derived using all characters and about equally conserved as nonfoliar in cladograms in which the nonfoliar characters are exceedingly weighted. Of course, some foliar characters, e.g., petiole presence, were excluded from the analysis because they appear to be inherently homoplasious, but the same is true of some reproductive characters, e.g., stamen and ovule number.

## 2. DEVELOPMENTAL, FUNCTIONAL, AND EVOLUTIONARY CONSIDERATIONS OF FOLIAR MORPHOLOGY IN *CALANDRINIA* AND *MONTIOPSIS*

In my consideration of foliar morphology of *Cistanthe* (Hershkovitz, 1991a), I briefly discussed ideas put forth on the adaptive value of leaf shape, leaf venation pattern, and stomatal complex morphology. Those comments are applicable here. For *Calandrinia* and *Montiopsis*, the functional significance of trichomes must also be considered. In addition, models attempting to explain venation and epidermal patterning as a consequence of cellular-level physiological phenomena during early tissue differentiation must be reconciled in the light of detailed systematic studies of foliar morphology such as that presented here and elsewhere.

Givnish (1979) supposed that leaves not requiring much physical support should tend to have more parallel rather than pinnate venation in order to optimize vascular supply efficiency. As I noted previously (Hershkovitz, 1991a), venation in *Cistanthe* does not seem to conform to this expectation, nor does that of *Calandrinia* and *Montiopsis*. The largest/broadest leaves among these two genera are the basal leaves of *Calandrinia* sects. *Calandrinia* and *Monocosmia*—these lie more or less prostrate on the ground, hence require little internal support. Leaves of *Montiopsis* and *Calandrinia* sect. *Acaules* also seem to lack the need for much internal support because they tend to be succulent (at least relative to their dimensions) and may also lie prostrate on the ground. Yet, venation is basically pinnate in both genera, even in taxa with a more or less grasslike habit. The combination of the primary vein and well-developed fimbrial vein in *Calandrinia* sects. *Calandrinia* and *Monocosmia* and some species of section *Acaules* might be perceived as a sort of parallel venation pattern, but, in contrast to grasses and other taxa with parallel veins, the fimbrial vein is best developed toward the apex and is poorly to not at all distinct basally. The functional significance of the fimbrial vein itself is not clear. This structure could conceivably be associated with some type of leaf apical secretory function, but no obvious glandular structure was identified at the apex of these leaves. Whatever the functional significance of the fimbrial vein, some species of *Calandrinia* sect. *Acaules* appear to survive well without it.

As I noted previously (Hershkovitz, 1991a), the functional significance of stomatal complex morphology—specifically, the number, shape and arrangement of subsidiary cells—remains unknown; hence I can offer no explanation for the predominance of brachytetracytic/staurocytic stomata and partial to complete outer cycle of subsidiary-like cells in *Calandrinia* sects. *Calandrinia* and *Monocosmia* and species of section *Acaules*. Possibly the more or less radial rather than bilateral symmetry of the stomatal complex in these taxa underlies its functional significance. Again, the lack of brachytetracytic/staurocytic stomata in *C.* (*Acaules*) *compacta* and their presence in at least one species of *Montiopsis* subg. *Dianthoideae* must not be overlooked when considering function.

In the absence of ultrastructural and/or physiological evidence, the functional significance of trichomes in *Calandrinia* and *Montiopsis* remains conjectural. For example, the multiseriate trichomes composed of intertwined hair cells of *Montiopsis* subg. *Montiopsis*, because of their size, density, and collective wall thickness, might have a protective function (see, e.g., Ehleringer, 1984). The pubescence in most of the species appears sufficiently dense to substantially modify the leaf boundary layer parameters and hence possibly offer protection in the desert and xeric montane habitats where the species occur. When viewed with polarized light, these trichomes produce intricate, colorful diffraction patterns and hence must also modify the quality of solar radiation reaching the photosynthetic tissue. Such speculations on trichome function would require comparative ultrastructural, chemical, and ecophysiological study to verify (e.g., Behnke, 1984; Kelsey et al., 1984).

Foliar venation and stomatal patterning have also been considered on purely developmental grounds (Lyndon, 1990; Meinhardt, 1982; Sachs, 1989, 1991). It has been supposed that the regularity of foliar morphological patterns is a function histogenetic autocatalysis that leads to the development of veins or stomata in one locus and passive or active inhibition of such development in adjacent

loci (Meinhardt, 1982; Sachs, 1989, 1991). Computer simulations of growth in which one or two parameters corresponding to the concentration of physiological regulatory substances are modified have generated intricate patterns such as those characterizing leaf venation (Meinhardt, 1982; Mitchison, 1980).

Emphasizing the inductive effect of auxin on vascular development, Sachs's (1989, 1991) "canalization" hypothesis of vein patterning maintains that, in leaf primordia, the veins are initiated as preferred channels for draining endogenously produced auxin. As the vascular strand develops, its conductive efficiency increases both absolutely and relative to the conductive efficiency of the surrounding cells, which are then passively inhibited from differentiating as vascular tissue. As the leaf expands, and local drainage patterns induce new veins to connect to existing veins, the venation pattern is elaborated. "The difference between vein systems of various leaves would be due to different parameters of auxin formation and transport and to differences in the details of early leaf growth" (Sachs, 1989: 181). Ontogenetic causal mechanisms underlying stomatal complex patterning have also been elaborated (Lyndon, 1990; Meinhardt, 1982; Sachs, 1991).

Developmental models of foliar morphological pattern formation provide the reductionist toe-hold necessary to facilitate experimental analysis, but systematic characterization of patterns, especially when augmented by phylogenetic analysis, provides the phenomena to be explained, a means for assessing the general applicability of a particular model, and a source of natural evolutionary experiments in which developmental differences predicted from models can be studied with the lowest possible degree of interference from evolutionary artifact. The fimbrial vein in *Calandrinia* provides a case in point. Sachs's (1989, 1991) hypothesis implies that vein prominence should be proportional to the importance of the vein for auxin transport during the course of development, and that the auxin source-sink relationship between leaves and roots, respectively, should most strongly influence the attenuation pattern of at least the major veins. It is not obvious why the fimbrial vein in *Calandrinia*—often more prominent than the primary vein in the distal portion of the lamina—should be the preferred channel for auxin drainage. Moreover, the fimbrial vein is exceedingly prominent apically and indistinct basally, i.e., toward the roots. Thus, it might be appropriate to test whether this atypical structure contradicts Sachs's model or is somehow an "exception that proves the rule." The model also predicts that biochemical developmental distinctions should be detectable among the species of *Calandrinia* sect. *Acaules* according to whether or not a fimbrial vein is present in the mature tissue.

An unfortunate aspect of the developmental models is that they appear to uncouple mature tissue structure from mature tissue function. The emphasis on the independence of specific physiological events at different developmental stages is beneficial in dispelling notions of predetermination but may obscure the interdependence of these same events in phylogenetic space. Aspects of the adaptive value of leaf form such as those discussed by Givnish (1979) are undoubtedly significant in determining the survival of a phyletic line. Thus, the role of selection on the mature phenotype as a feedback on the evolution of biochemical ontogeny must be appreciated. Sachs (1991) discussed the potential role of epigenetic selection upon the evolution of pattern formation but emphasized selection during ontogeny rather than selection for functionality after differentiation is completed. Neither the mature foliar morphological patterns, nor ontogenetic studies of relatively few and not closely related species can, by themselves, reveal if and how developmental programs have been rewritten during phyletic evolution. Syntheses of information on developmental mechanisms with knowledge of the diversity of form and phylogenetic reconstructions of the relationships between different forms may thus provide a means through which general theories of development can be advanced and evaluated.

## Conclusions

Foliar morphological evidence corroborates revision of the generic limits of *Calandrinia* and *Montiopsis*. *Calandrinia* is characterized by leaves with a fimbrial vein that overtops and becomes perpendicular to the primary vein at the leaf apex, brachytetracytic/staurocytic stomata commonly with at least a partial outer cycle of subsidiary-like cells, and unicellular ribbed trichomes along the leaf margin. These traits are not universal in *Calandrinia* sect. *Acaules*. Structurally distinct fimbrial veins characterize *Claytonia* and *Montia*, and brachytetracytic stomata characterize one species of the latter. The foliar evidence that *Claytonia* and *Montia* are nested within *Calandrinia* is contradicted by nonfoliar and perhaps additional foliar characters. *Montiopsis* is characterized by its unique trichome types. Only the presence of trichomes per se supports a close relationship between *Calandrinia* and *Montiopsis*. Phylogenetic analysis of foliar characters alone strongly supports a

phylogenetic distinction between the eastern American/African and western American Portulacaceae, with the Australian endemic *Rumicastrum* belonging to the former. The analysis also indicates that foliar characters may be as well conserved evolutionarily as nonfoliar. Existing models relating leaf form to function and ontogeny are generally too rudimentary for reconciliation with the data presented here for *Calandrinia* and *Montiopsis*. Nevertheless, the existence of at least one foliar feature described here, the fimbrial vein in *Calandrinia*, would not appear to have been predicted by current models. The availability of detailed, phylogenetically analyzed systematic accounts of foliar morphology such as that presented here might be exploitable in advancing theories relating mature leaf form to function and development.

# A REVISION OF *CHIONOLAENA* (COMPOSITAE, GNAPHALIEAE)[1]

*Susana E. Freire*[2]

ABSTRACT

The neotropical genus *Chionolaena* is accepted as including the species of *Leucopholis*, which has been considered a separate genus by several authors because of its few-flowered capitula. *Chionolaena* consists of small, more or less woody shrubs with a discontinuous distribution: central Mexico, northern Colombia, and southern Brazil, with disjunct populations in Central America (Costa Rica) and northern Amazonia (southern Venezuela). The most closely related genus is *Gnaphaliothamnus* from Mexico and Guatemala. Seventeen species of *Chionolaena* are recognized, one of which, *C. mexicana*, is described for the first time. Three new combinations are made: *Chionolaena capitata*, *C. chrysocoma*, and *C. seemannii*. Descriptions, typification, synonymy, distribution maps, illustrations, indices, and a key to all taxa are presented. A cladistic analysis of *Chionolaena* was performed using morphological characters. Polarity of characters was based on outgroup comparison with the genus *Gnaphaliothamnus*. Two monophyletic groups were resolved: (1) the "*concinna* species group" (including *C. concinna* and *C. seemannii*); and (2) the "*mexicana* species group" (including *C. aecidiocephala*, *C. arbuscula*, *C. capitata*, *C. columbiana*, *C. chrysocoma*, *C. eleagnoides*, *C. isabellae*, *C. jeffreyi*, *C. latifolia*, *C. lavandulifolia*, *C. lychnophorioides*, *C. mexicana*, *C. phylicoides*, *C. sartorii*, and *C. wittigiana*). Within each group, this resolution places the Mexican species as the sister group of the South American taxa, i.e., a closer historical relationship is indicated between the Colombian and Brazilian areas than between either and the Mexican area.

*Chionolaena* DC. (including *Leucopholis*) is a genus of small shrubs found in high elevations within the neotropical region (Cabrera & Willink, 1973) from Mexico to southern Brazil. *Chionolaena* comprises 17 species characterized by dichotomously branched stems, reflexed leaves with revolute margins, central florets commonly functionally staminate, and pappus bristles with clavate cells at their tips. It is closely related to the Mexican genus *Gnaphaliothamnus* Kirp.

The last complete taxonomic treatment of this genus was by J. G. Baker (1882), who recognized nine species. Seven species were published by various authors under *Chionolaena* since the appearance of Martius's *Flora Brasiliensis*. In addition to problems with delimitation of species of *Chionolaena*, the generic limits became unclear.

The aims of this revision are to clarify generic and specific limits, to interpret species interrelationships using cladistic methods, and to compare the results of cladistic analysis with the geographic distribution of the genus.

## MATERIALS AND METHODS

This study was based on specimens from the following herbaria: BM, C, COL, E, G, GH, HBG, K, LP, M, MO, NY, P, RB, S, U, UC, US, and W (see List of Exsiccate at end of article). Floral and vegetative parts were dissected and observed after boiling in water. Cross sections of leaves and stems were made by free hand and stained with 2% safranin. All drawings were made by the author from herbarium material.

Information on flowering periods, habitat, and color of corollas was taken from herbarium labels. Species descriptions are presented alphabetically.

The applied cladistics methods were summarized in Nelson & Platnick (1981) and Wiley (1981). Identification of apomorphic characters was based on the outgroup comparison (Platnick, 1979; Watrous & Wheeler, 1981) with *Gnaphaliothamnus* as the outgroup. Table 1 shows the characters and character states used in the cladistic analysis. Five characters have more than two states (4, 6, 8, 9, 10). These characters were treated as nonadditive.

[1] I thank Arne Anderberg, Angel L. Cabrera, Jorge V. Crisci, Juan J. Morrone, J. Strother, and two anonymous referees for review and/or discussion of the manuscript. I also thank Angel L. Cabrera for checking the Latin description of *Chionolaena mexicana*. My gratitude is expressed to all the curators of the herbaria listed in the text, who kindly loaned material. The present study was completed at the Swedish Museum of Natural History during my tenure as a fellow of the Consejo Nacional de Investigaciones Científicas y Técnicas de Argentina. I am grateful to the officers of both of these institutions for support of my work.

[2] Departamento Científico de Plantas Vasculares, Museo de La Plata, 1900 La Plata, Argentina.

TABLE 1. Characters and character states.

| Characters | Character states |
|---|---|
| 1. Adaxial leaf surface | tomentose (0); glabrous (1) |
| 2. Leaf margin | slightly revolute (0); conspicuously revolute (1) |
| 3. Stem branching | dichotomous (0); subdichotomous (1) |
| 4. Type of capitulescence | corymbs (0); umbels (a); solitary (b) |
| 5. Corymbophore | absent (0); present (1) |
| 6. Type of capitula | heterogamous (0); homogamous (with perfect florets) (a); nearly unisexual (b); homogamous (with unisexual florets) (c) |
| 7. Inner bracts | obtuse (0); acute (1) |
| 8. Involucre shape | obdeltate (0); narrowly oblong (1 4 mm wide) (a); broadly campanulate (12 mm wide (b) |
| 9. Relation of female to staminate florets in heterogamous capitula | pistillate florets outnumbering the functionally staminate, 5:1 (0); pistillate florets slightly more numerous than functionally staminate florets, 1.1:1–2.5.1 (a); pistillate florets slightly more numerous than functionally staminate or functionally staminate florets slightly more numerous than pistillate (b); functionally staminate florets slightly more numerous than or equaling pistillate, 1:1–2:1 (c) |
| 10. Achene pubescence | shortly pubescent (0); glabrous (a); villous (b) |
| 11. Achenial hairs | obtuse at the tip (0); acute at the tip (1) |
| 12. Pappus bristles | free (0); fused at base into a ring (1) |
| 13. Apical cells of pappus bristles | linear (0); clavate (1) |

In the data matrix (Table 2), plesiomorphic characters were coded with 0, apomorphic ones with 1 (multistate characters with a, b, and c), and unknown characters with question marks. The data matrix was analyzed using the phylogenetic program Hennig86 version 1.5 (Farris, 1988). The options used were "mhennig," for constructing multiple initial cladograms, followed by "bb" (branch breaker). Furthermore, the successive weighting procedure was applied, which calculates weights from the best fits to the most parsimonious trees, using rescaled consistencies (rc), which are the products of the character consistency (c) and the character retention index (r). The product is scaled to lie in the range 0–10. The weighting procedure is repeated on successively produced trees until the trees no longer change (Farris, 1989).

TABLE 2. Data matrix. The character numbers correspond to the numbers used in the text and in the cladograms. Question marks indicate missing information.

| | Character | |
|---|---|---|

## HISTORICAL SURVEY

*Chionolaena* was first described by de Candolle (1836) on the basis of the Brazilian species *C. arbuscula* from a Vauthier collection. The genus was characterized by its solitary, heterogamous, many-flowered heads in which the central florets were functionally staminate.

In 1843 Gardner created the genus *Leucopholis* on the basis of the Brazilian species *L. phylicoides* with few-flowered, congested, homogamous capitula.

In 1882 Baker placed *Leucopholis* in a section of *Chionolaena*, which is characterized by having capitula with 8–10 florets, in contrast to section *Euchionolaena* with its many-flowered capitula. Six species were listed under section *Euchionolaena*: *C. arbuscula*, *C. lychnophorioides*, *C. gla-*

*ziovii*, *C. glomerata*, *C. isabellae*, and *C. wittigiana*, of which the last four were new. The section *Leucopholis* included three species: *C. latifolia*, *C. phylicoides*, and *C. longifolia*, of which the last was new.

Since 1882, seven species have been added to *Chionolaena*. The first two, *C. eleagnoides* and *C. sartorii*, were described by Klatt (1887: 88) based on Liebman collections from Mexico. The next year, Wawra (1888, 2: 30) described *C. innovans* (presently placed in synonymy of *C. isabellae*). In 1893, B. D. Jackson transferred the Mexican species *Elichrysum lavandulaefolium* Kunth to *Chionolaena*. Blake (1935: 312) described *C. columbiana* from Mexico. It was approximately 50 years before the next species of *Chionolaena*, *C. jeffreyi* H. Robinson (1984: 121) from Brazil and *C. breweri* (Steyermark (1984: 26) (presently placed in synonymy of *C. latifolia*) from Venezuela, were described.

Cabrera (1961) maintained the generic status for *Leucopholis*. He noted that members of this genus are distinguishable by their few-flowered, homogamous heads.

In the present study, *Leucopholis* is not recognized. The species of *Chionolaena* show variation in the number of the flowers and in the proportion of pistillate to functionally staminate florets (including homogamous heads). It is evident that distinction between these genera is impossible based on sexuality alone.

Dillon & Sagástegui (1990) proposed *Pseudoligandra* for the Colombian species *Oligandra chrysocoma* Wedd. According to the cladistic analysis, this new genus cannot be accepted, i.e., *Oligandra chrysocoma* is a derived species with its closest relatives within *Chionolaena*. If *Pseudoligandra* is treated as a separate genus, *Chionolaena* becomes paraphyletic.

## Delimitation and Generic Relationships

*Chionolaena* belongs to Gnaphalieae (sensu Anderberg, 1989; Bremer, 1987) of the Compositae. Merxmüller et al. (1977) considered *Chionolaena* to belong within the "*Lucilia* group" (i.e., *Lucilia*, *Belloa* (= *Lucilia*, Freire, 1986), *Berroa*, *Chevreulia*, *Facelis*, *Gnaphaliothamnus*, *Leucopholis*, *Luciliopsis*, *Mniodes*, and *Raouliopsis*) principally on the basis of its style branches with dorsal sweeping hairs.

*Chionolaena* is distinguished from other genera of Gnaphalieae by its dichotomously branched stems, deflexed leaves (at maturity) with revolute margins, absence of stem phloem fibers, undivided stereome (i.e., lower part uniformly thickened) and white opaque lamina of the inner involucral bracts, often purple upper corollas, functionally staminate hermaphroditic florets, and basally fused pappus bristles with clavate apical cells. *Leucopholis* consistently differs from *Chionolaena* only in having few-flowered capitula. The genus *Leucopholis* is therefore not recognized (see Historical Survey).

Preliminary results from cladistic analysis of Gnaphalieae indicate that *Gnaphaliothamnus* is the sister group of *Chionolaena* (Anderberg, 1989; Anderberg & Freire, 1989). It differs from *Chionolaena* in having free pappus bristles with linear apical cells.

## Morphology

### Habit

The stems are dichotomously branched, i.e., at the apex of each stem there is a terminal aborted primordium or, eventually, a terminal capitulescence. When the capitulescence matures, axillary buds develop, producing a dichotomous growth pattern. In a few species (*C. concinna* and *C. seemannii*), however, only a single bud develops at the base of the capitulescence, and the resulting growth is subdichotomous, leaving the capitulescence conspicuously lateral.

### Trichomes

Throughout *Chionolaena* two types of trichomes occur together on the leaves and stems: nonglandular uniseriate hairs (Fig. 1D) and glandular hairs (Fig. 1C). The former were described as "aseptate flagellate hairs" by Ramayya (1962) and consist of 1–3 small, basal cells and a long, basally swollen terminal cell. Glandular hairs consist of a unicellular basal foot and a uniseriate or biseriate row of cells. Only glandular hairs were found on the abaxial surfaces of corolla apices.

### Capitulescence

The arrangement of the capitula in *Chionolaena* varies (Fig. 1). Heads may be solitary and terminal or densely clustered in umbelliform cymes (i.e., "umbels"). Sometimes these umbelliform clusters are arranged in "corymbs."

In most species of *Chionolaena* the upper flowering branches are leafy. In some species, e.g., *C. columbiana* and *C. isabellae* (Fig. 1a, b), the capitulescence is supported by a leafless slender stem, i.e., a peduncle, termed "corymbophore" by Lundgren (1972) for *Anaxeton*.

## CAPITULESCENCE

| solitary | umbel | corymb | with corymbophore |
|---|---|---|---|
| |  |  |  a b |

CAPITULA

The capitula are either heterogamous with functionally staminate florets and pistillate florets, homogamous with perfect florets, or homogamous-unisexual with functionally pistillate or staminate hermaphroditic florets.

The heterogamous condition predominates in *Chionolaena*. Only two species have homogamous capitula: *C. isabellae*, with all perfect florets, and *C. phylicoides*, with unisexual capitula.

Four species of *Chionolaena* are subdioecious: *C. arbuscula*, *C. concinna*, and *C. lavandulifolia* have nearly unisexual capitula in different plants; *Chionolaena aecidiocephala* has two types of capitula, homogamous capitula with all flowers functionally male and heterogamous capitula with pistillate, female flowers as well as male central flowers.

FLORETS

Most species have functionally staminate central florets and filiform, pistillate, peripheral florets. Only one species, *C. aecidiocephala*, shows reduction in the fertility of the staminate florets, i.e., anthers without pollen (neuter florets). All species have fertile pistillate florets.

The proportion of pistillate to functionally staminate florets differs slightly or sometimes markedly. In six species (*C. arbuscula*, *C. capitata*, *C. eleagnoides*, *C. jeffreyi*, *C. latifolia*, and *C. wittigiana*) the functionally staminate florets commonly equal or slightly exceed the pistillate in number (ca. 1 : 1–2 : 1). In other species (*C. chrysocoma*, *C. columbiana*, *C. concinna*, *C. lavandulifolia*, *C. lychnophorioides*, *C. mexicana*, and *C. sartorii*) the pistillate florets are slightly more numerous than the functionally staminate florets (ca. 1.1 : 1–2.5 : 1). In only two species, *C. aecidiocephala* and *C. seemannii*, the female florets outnumber the functionally staminate florets (ca. 5 : 1).

ACHENES

In *Chionolaena* only the pistillate florets are capable of producing achenes, except in *C. isabellae*, which has perfect florets. The sterile ovaries of the functionally staminate florets are usually flattened, without an embryo, and sometimes contracted toward the middle or strongly reduced. Differences between the fertile achene and the sterile ovary are further addressed in the systematic treatment below.

The achenes are usually oblong or oblong elliptic. Within the subdioecious species, only *C. aecidiocephala* has slightly dimorphic achenes, i.e., the central-floret ovary of heterogamous capitula is longer than the central-floret ovary from homogamous capitula.

Within the genus, the achenes may be pubescent or glabrous. *Chionolaena columbiana*, *C. eleagnoides*, *C. chrysocoma*, and, usually, *C. lavandulifolia* have glabrous achenes. The hairs are always 3-cellular, with two parallel elongated cells and a shorter, lateral, basal cell with a thickened outer wall. This "duplex hair" (Hess, 1938) is commonly present in many other genera of the Compositae. In contrast with all other *Chionolaena* species having pubescent achenes, *C. arbuscula*, *C. isabellae*, *C. lychnophorioides*, and *C. wittigiana* have achenial hairs acute at the tip (Fig. 1F). In the remaining species these hairs are obtuse. Furthermore, there is variation in achenial hair length; the four species listed above and *C. phylicoides*, *C. latifolia*, *C. jeffreyi*, and *C. capitata* have sericeous, villous achenes with hairs ca. 0.3 mm long, whereas *C. aecidiocephala*, *C. lavandulifolia* (when hairy), *C. seemannii*, and *C. sartorii* have hairs ca. 0.1 mm long (Fig. 1G).

CHROMOSOME NUMBER

Gametic chromosome number has been investigated in one species of *Chionolaena*, i.e., *C. la-*

Diagrams of capitulescence types in *Chionolaena*: solitary (*C. arbuscula*, *C. jeffreyi*, *C. lychnophorioides*); umbel (*C. aecidiocephala*, *C. capitata*, *C. chrysocoma*, *C. latifolia*, *C. lavandulifolium*, *C. phylicoides*); corymb (*C. concinna*, *C. eleagnoides*, *C. mexicana*, *C. sartorii*, *C. seemannii*, *C. wittigiana*); capitulescence supported by corymbophore (a, *C. columbiana*; b, *C. isabellae*).

*vandulifolia* (= *Gnaphalium lavandulifolium*), which was found to have $n = 14$ by De Jong & Longpre (1963). This number suggests tetraploidy, based on $x = 7$ in Gnaphaliinae (Merxmüller et al., 1977).

## Cladistics

*Chionolaena* and its sister group, *Gnaphaliothamnus*, form a larger monophyletic group that is characterized by having dichotomously branched stems without phloem fibers, reflexed leaves (at maturity) with revolute margins, an undivided stereome in the inner bracts, and commonly functionally staminate central florets. *Chionolaena* is morphologically distinct because its pappus bristles are fused at the base into a ring and have clavate cells at their tips.

Thirteen apomorphic character states were found (Table 1) by outgroup comparison (Hennig, 1966; Platnick, 1979; Watrous & Wheeler, 1981) using the monotypic genus *Gnaphaliothamnus* as outgroup. Thirty-five equally parsimonious cladograms were generated from the data matrix. All have 39 steps, a consistency index of 0.51, and a retention index of 0.62. If the synapomorphies for the whole genus (characters 12 and 13) are excluded, the consistency index is 0.48. When the successive weighting procedure was applied, 11 minimum length trees resulted after the second round of weighting, with length 118, a consistency index of 0.68, and a retention index of 0.75. Again, if the synapomorphies for the whole genus are ignored, the consistency index is 0.62.

The strict consensus tree of the 11 cladograms (Fig. 2) shows that there are three monophyletic groups: (1) the "*concinna* species group" (including *C. concinna* and *C. seemannii*); (2) the "*eleagnoides* species group" (including *C. eleagnoides*, *C. columbiana*, and *C. isabellae*) and (3) the "*sartorii* species group" (including *C. sartorii*, *C. lavandulifolia*, *C. aecidiocephala*, *C. jeffreyi*, *C. capitata*, *C. wittigiana*, *C. lychnophorioides*, *C. arbuscula*, *C. latifolia*, *C. chrysocoma*, and *C. phylicoides*). *Chionolaena mexicana* appears to be isolated.

As an example of how characters may be distributed, I have presented one of the 11 equally parsimonious cladograms (Fig. 3). The cladogram chosen shows two monophyletic groups: (1) the "*concinna* species group" (including *C. concinna* and *C. seemannii*) and (2) the "*mexicana* species group" (including *C. mexicana*, *C. eleagnoides*, *C. columbiana*, *C. isabellae* *C. sartorii*, *C. lavandulifolia*, *C. aecidiocephala*, *C. jeffreyi*, *C. capitata*, *C. latifolia*, *C. chrysocoma*, *C. phylicoides*, *C. wittigiana*, *C. arbuscula*, and *C. lychnophorioides*).

The Mexican species *C. concinna* and *C. seemannii* have stems subdichotomously branched (character 3). Fifteen species comprise the "*mexicana* species group," which is defined by the slightly more numerous pistillate florets than functionally staminate florets (character 9a). Two species groupings appear within this last group: the "*eleagnoides* species group" (including *C. eleagnoides*, *C. columbiana*, and *C. isabellae*") and the "*sartorii* species group" (including *C. sartorii*, *C. lavandulifolia*, *C. aecidiocephala*, *C. jeffreyi*, *C. capitata*, *C. latifolia*, *C. chrysocoma*, *C. phylicoides*, *C. wittigiana*, *C. arbuscula*, and *C. lychnophorioides*). *Chionolaena eleagnoides* from Mexico, *C. columbiana* from Colombia, and *C. isabellae* from Brazil have glabrous achenes (character 10a). *Chionolaena columbiana* and *C. isabellae* appear together united by capitula supported by a corymbophore (character 5). The second large monophyletic group, "*sartorii* species group," is justified by the acute inner bracts (character 7). *Chionolaena sartorii* is the sister species of the other "*sartori* group" taxa. The latter species are united by umbelliform clusters of capitula (character 4a). There are two monophyletic groups within the last group. The Mexican species *C. lavandulifolia* and *C. aecidiocephala* share capitula nearly unisexual (character 6b). The second monophyletic group is formed by the mostly Brazilian species *C. jeffreyi*, *C. capitata*, *C. latifolia*, *C. chrysocoma*, *C. phylicoides* *C. wittigiana*, *C. arbuscula*, and *C. lychnophorioides*. They are united by villous achenes (character 10b) and the functionally staminate florets slightly more numerous than or equaling pistillate florets (character 9c). The relationships among *C. capitata*, *C. jeffreyi*, and *C. latifolia* are unclear. *Chionolaena arbuscula* and *C. lychnophorioides* appear together united by the solitary capitula (character 4b). In some solutions, *C. arbuscula* and *C. wittigiana* appear together, whereas in other solutions *C. arbuscula* is placed as the sister species of *C. lychnophorioides* and *C. wittigiana*. *Chionolaena wittigiana*, *C. arbuscula*, and *C. lychnophoriodes* have achenial hairs acute at the tip (character 11). In all cases *C. chrysocoma* and *C. phylicoides* appear together, sharing conspicuously revolute leaf margins (character 2).

The sections distinguished by Baker (1882), section *Euchionolaena* (*C. arbuscula*, *C. isabellae*,

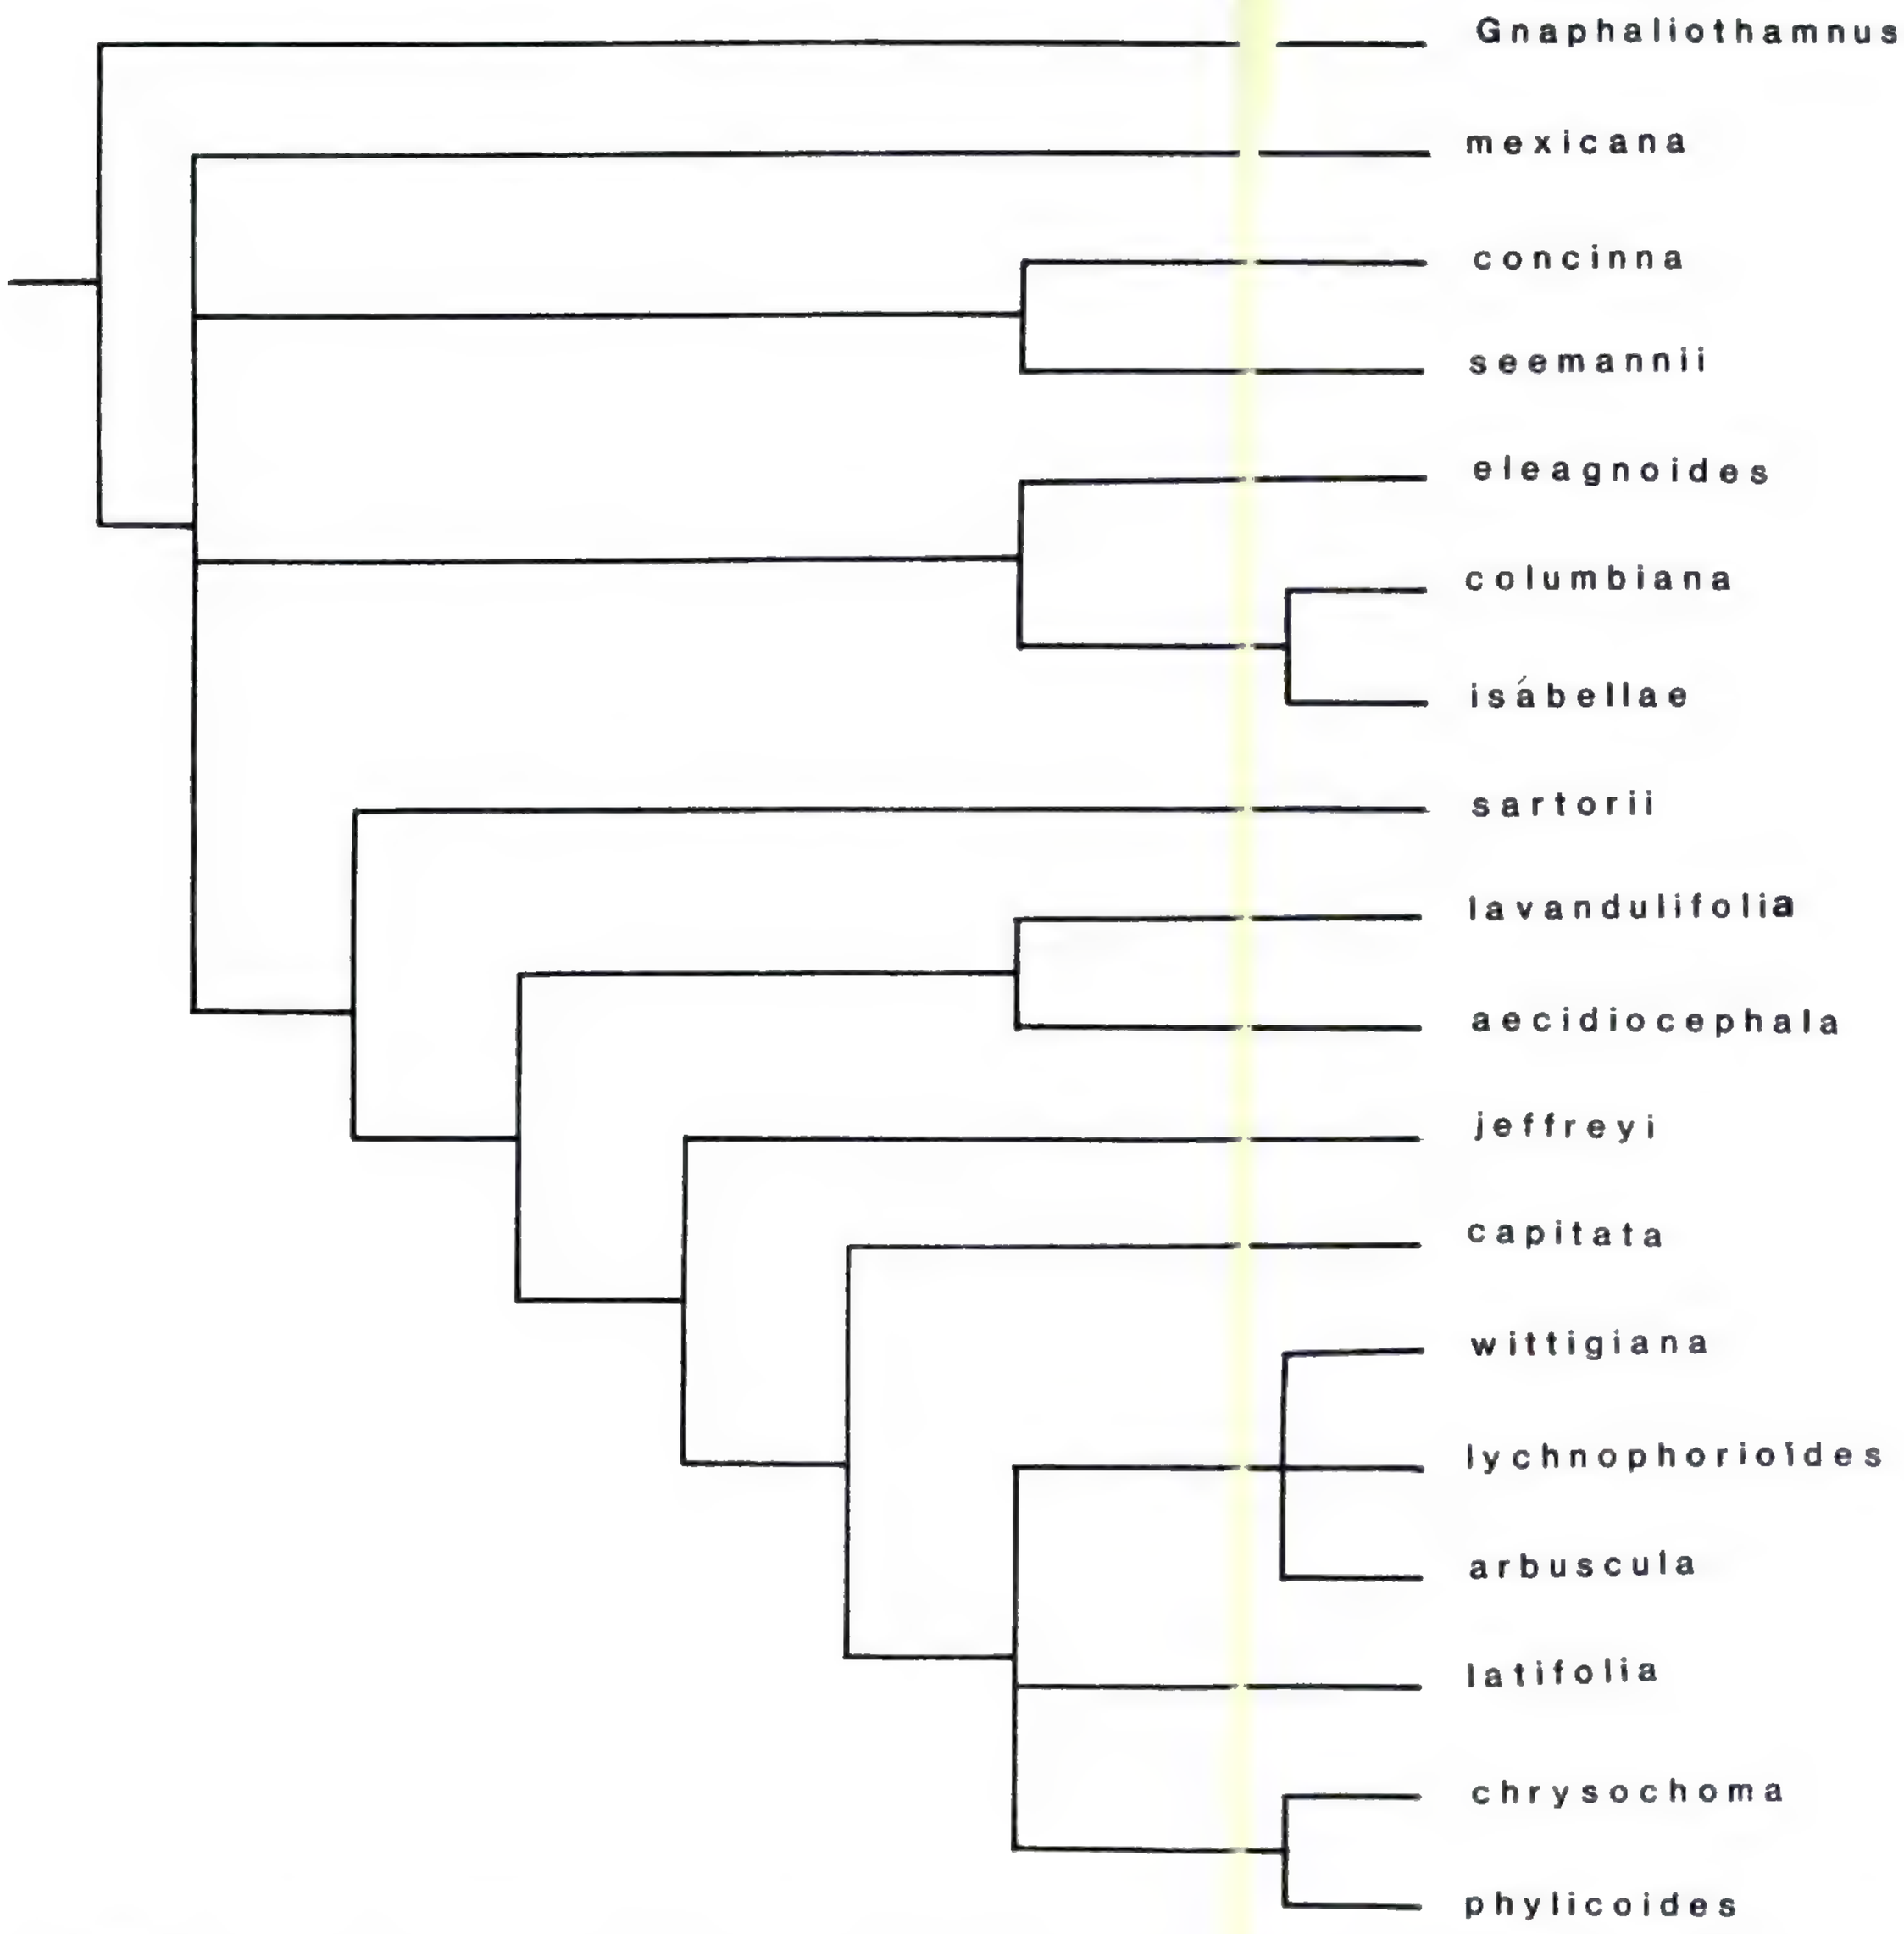

FIGURE 2. The strict consensus tree of relationships among species of *Chionolaena* for all equally parsimonious trees.

*C. lychnophorioides, C. wittigiana*) and section *Leucopholis* (*C. phylicoides, C. latifolia*) do not represent monophyletic groups. The character by which these sections have been separated (number of florets per capitulum) is variable intragenerically and also sometimes infraspecifically.

## BIOGEOGRAPHY

The total range of *Chionolaena* (Fig. 4A) comprises the montane habitats of America within the neotropical region (Caribbean, Amazonian, and Chaqueño dominions) as distinguished by Cabrera & Willink (1973).

*Chionolaena* has a discontinuous distribution; it is present in central Mexico, Central America (Costa Rica), northern Colombia, southern Brazil, and northern Amazonia (southern Venezuela). Plant species with similar ranges are frequent, e.g., *Agarista* (Judd, 1984), *Heliconia* (Andersson, 1985), *Maranta* (Andersson, 1986), and ferns (Tryon, 1962, 1970; Conant, 1983). The floristic relationships among the highlands of Mexico and Amazonas and the Andean region have been expressed by Hemsley (1879–1880, vol. 4: 228) and Epling (1940) in Rzedowski (1965).

The monotypic *Gnaphaliothamnus*, the sister

group of *Chionolaena*, has a Mexican and Central American (Guatemala) distribution.

The 17 species of *Chionolaena* are distributed as follows, according to Cabrera & Willink (1973): seven species (*C. aecidiocephala*, *C. concinna*, *C. eleagnoides*, *C. lavandulifolia*, *C. mexicana*, *C. sartorii*, and *C. seemannii*) are narrowly endemic to the mountainous areas of central Mexico (most being known from a single locality) in the "Mesoamerican Mountain" Province within the Caribbean Dominion. *Chionolaena lavandulifolia* has disjunct populations in central Costa Rica as well. Two species (*C. columbiana* and *C. chrysocoma*) are confined to the northern Andes of Colombia, on the Sierra de Santa Marta and the Sierra de Perijá, in the "Guajira" Province within the Caribbean Dominion. The remaining species are endemic to the mountains of southern Brazil in the Chaqueño Dominion ("Caatinga" Province: *C. jeffreyi*) and Amazonian Dominion ("Amazonian" Province: *C. latifolia*; "Cerrado" Province: *C. arbuscula* and *C. lychnophorioides*; "Paranense" Province: *C. isabellae*, *C. capitata*, *C. wittigiana*, and *C. arbuscula*; "Atlantica" Province: *C. capitata*, *C. latifolia*, *C. phyllicoiodes*). Only *C. latifolia* has a disjunct distribution, being also recorded from Cerro Marahuaca in Venezuelan Guayana.

In order to formulate biogeographic hypotheses for the central Mexican, Colombian Andean, and southern Brazilian areas in the neotropical region, cladistic analysis of *Chionolaena* was used. Additional cladistic analyses of other taxa in this region will allow testing the following results.

In the area cladograms (Fig. 4B, C) based on the consensus tree (Fig. 2), the name of each taxon was replaced by an abbreviation of the area in which it occurs. The first events leading to the separation of the ancestral population of *Chionolaena* are unclear. The three monophyletic groups, the "*concinna* species group," the "*eleagnoides* species group," and the "*sartorii* species group," identified in the consensus tree (Fig. 2) can, however, be used to analyze the relationships between the geographical areas of each taxon. Two of these groups, the "*eleagnoides* species group" and the "*sartorii* species group" are today sympatric and present similar vicariant patterns, which can be presumed to have developed simultaneously.

In the "*eleagnoides* species group," two principal vicariant events can be postulated. The first event could have split a large and continuous population into northern (evolving into a Mexican taxon, i.e., *C. eleagnoides*) and southern (evolving into South American taxa) populations. The second event could have separated a small population in the Colombian area (evolving into *C. columbiana*) from the more southern population, which evolved into the Brazilian taxon (*C. isabellae*) (Fig. 4D).

In the "*sartorii* species group," a Mexican population (evolving into *C. sartorii*, *C. lavandulifolia*, and *C. aecidiocephala*) may have first split off from the main population. Subsequently, a large Brazilian population (evolving into *C. jeffreyi*, *C. capitata*, *C. latifolia*, *C. wittigiana*, *C. arbuscula*, and *C. lychnophorioides*) could have become isolated from the rest of the main population. The remaining population may have then extended its range toward the southeast and split off another Brazilian population (evolving into *C. phylicoides*) leaving behind a Colombian population (evolving into *C. chrysocoma*).

To summarize, although the sequential events involved in this group are unclear because the phylogeny is unresolved, it is clear that a closer biogeographical relationship exists between the Colombian Andean and southern Brazilian areas than between either and the central Mexican area.

## Systematic Treatment

*CHIONOLAENA*

**Chionolaena** DC., Prodr. 5: 397. 1836. TYPE: *Chionolaena arbuscula* DC.

*Leucopholis* Gardner, London J. Bot. 2: 10. 1843. TYPE: *Leucopholis phylicoides* Gardner.

*Pseudoligandra* Dillon & Sagást., Taxon 39: 125. 1990. TYPE: *Pseudoligandra chrysocoma* (Wedd.) Dillon & Sagást.

Shrubs or subshrubs. Stems erect or ascendent, dichotomously or subdichotomously branched, woolly tomentose and leafy when young but later glabrous and leafless with marked leaf scars in the lower parts. Vascular cylinder without phloem fibers, surrounded by a distinct endodermis (Fig. 1A). *Leaves* sessile, closely set or spreading, sub-

decussate, in four distinct rows; erect in the upper part of the stem, becoming reflexed with age (only one species has appressed leaves); midrib prominent; margins entire, slightly or conspicuously revolute (Fig. 1B); mucronate; adaxially glabrous or tomentose, abaxially densely lanate and whitish, with glandular and nonglandular hairs (Fig. 1C, D). Epidermis with cyclocitic stomata surrounded by 4–6 subsidiary cells scattered on the abaxial surface (Fig. 1E); cuticle thick. *Capitula* shortly pedunculate in dense umbels or corymbose capitulescences, sometimes solitary, terminal on the main stems, sometimes supported by a slender peduncle (Fig. 1). Heterogamous or homogamous. *Involucres* narrowly oblong, campanulate or broadly campanulate; bracts imbricate, membranaceous, generally yellowish brown, entire; outer ones broadly ovate to linear-ovate, acute, obtuse or acuminate at the apex, pubescent adaxially; innermost bracts narrow, linear or obovate, obtuse or acute at the apex, glabrous with white opaque lamina and lower part uniformly thickened (i.e., stereome undivided). *Receptacle* glabrous, flat or somewhat convex, epaleate. *Florets* 5 to ca. 100; corollas white-cream, often red-tipped; pistillate florets (when present) fewer than, equaling, or more numerous than the hermaphroditic ones. *Pistillate florets* fertile; corollas filiform, minutely bilabiate, lobes with biseriate glandular hairs. Styles bifid; style branches erect to spreading, linear, glabrous, rounded; stylopodium indistinct. *Achenes* narrowly oblong or narrowly elliptic, glabrous or pubescent with long or short duplex hairs (Fig. 1F, G). *Pappus* bristles as in hermaphroditic florets but with apical cells slightly inflated, not clavate. *Hermaphroditic florets* functionally staminate (occasionally functionally pistillate, neuter, or fully fertile); corollas tubular, slightly expanded at top, 5-lobed, the lobes papillose with biseriate glandular hairs. Styles shortly bifid or sometimes undivided; the branches rounded truncate or acute; with apically obtuse sweeping hairs, commonly the sweeping hairs occurring almost to the stylar partition; abaxial faces with two parallel stigmatic areas constituted by small and rounded papillae (Fig. 1J); stylopodium and stylophore (between the ovary and the stylopodium) developed. *Anthers* 5, caudate, with ovate apical appendages, thickenings in endothecial tissue, antheropodium (collar) distinct, tails slightly shorter than, equaling, or longer than the antheropodium. *Ovaries* flattened, often strongly contracted with embryo not developed. *Pappus* bristles ± thick, barbellate with clavate (occasionally slightly inflated) apical cells (Fig. 1I); fused at the base into a single ring and connate in groups of different lengths (Fig. 1H); equaling the corolla.

The name of the genus seems to refer to the snow white and cottony tomentum on the lower surface of the leaves (from Greek, "chionos" = snow, "laenos" = cloak or mantle).

*Distribution.* Seven species from the central region of Mexico; two species confined to the northern area of Colombia; and eight species in southern Brazil.

*Local name.* The name "Arnica" is applied to some Brazilian species (Glaziou, 1910), viz, *C. arbuscula* var. *hololeuca* (= *C. capitata*), *C. innovans* (= *C. isabellae*), *C. wittigiana*, and *C. glomerata* (= *C. latifolia*).

KEY TO THE SPECIES OF *CHIONOLAENA*

1a. Capitula solitary (occasionally arranged in terminal, small, loose umbels).
  2a. Subshrub with ascending stems; leaves with lamina conspicuously narrowed at the base; achene hairs obtuse at the apex ..... 9. *C. jeffreyi*
  2b. Shrubs erect, rigid, woody; leaves not notably narrowed at the base; achene hairs acute at the apex.
    3a. Leaves narrowly linear, 0.7–1 mm wide, margins conspicuously revolute ..... 2. *C. arbuscula*
    3b. Leaves broadly linear, 1.2–3 mm wide, margins slightly revolute ..... 12. *C. lychnophorioides*
1b. Capitula arranged in clusters or corymbs.
  4a. Capitula arranged in dense umbels.
    5a. Umbels supported by a peduncle at maturity ..... 4. *C. columbiana*
    5b. Umbels sessile at maturity.
      6a. Involucres narrowly oblong.
        7a. Leaves with lower lamina completely concealed by the revolute margins.

(Names of taxa were substituted by abbreviations of geographical areas.)—C. Reduced area cladogram. Groups of taxa occurring in the same area were reduced to a single branch in the cladogram.—D. Postulated distribution of the ancestral population after the two principal vicariant events. (MEX = Mexican area, COL = Colombian area, BRA = Brazilian area.)

8a. Leaves reflexed; achenes pubescent; capitula homogamous (unisexual) ..... 14. *C. phylicoides*
8b. Leaves closely appressed to stem; achenes glabrous; capitula heterogamous ..... 6. *C. chrysocoma*
7b. Leaves with lower surface visible (leaf margins slightly revolute).
9a. Leaves elliptic, 1.5–4 cm long, adaxial face glabrous ..... 10. *C. latifolia*
9b. Leaves linear, 5–13 mm long, adaxial face tomentose ..... 3. *C. capitata*
6b. Involucres obdeltate.
10a. Erect, rigid shrub; leaves suborbicular ..... 1. *C. aecidiocephala*
10b. Caespitose shrub; leaves linear-elliptic ..... 11. *C. lavandulifolia*
4b. Capitula arranged in corymbs.
11a. Leaves broadly obovate, 11–12 mm wide; achenes glabrous ..... 7. *C. eleagnoides*
11b. Leaves obovate, linear, or elliptic (when obovate 3–7 mm wide); achenes pubescent.
12a. Achenes sericeous; achene hairs acute or subacute.
13a. Leaves narrowly obovate; corymbs lax, supported by a peduncle at maturity ..... 8. *C. isabellae*
13b. Leaves linear; corymbs dense, sessile ..... 17. *C. wittigiana*
12b. Achenes with short obtuse hairs.
14a. Leaves linear to elliptic.
15a. Subshrub weakly woody, caespitose; leaves narrowly linear, 1–2 cm long, 1 mm wide; corymbs of 3–4 capitula ..... 15. *C. sartorii*
15b. Shrub woody, rigid, ascendent; leaves linear-elliptic, 3.5–4.5 cm long, 4–5 mm wide; corymbs of many capitula (up to 10) ..... 16. *C. seemannii*
14b. Leaves obovate.
16a. Dichotomously branched, rigid shrub; capitulescence terminal at maturity; leaves slightly attenuate at the base ..... 13. *C. mexicana*
16b. Subdichotomously branched subshrub; capitulescence lateral at maturity; leaves subpetiolate ..... 5. *C. concinna*

**1. Chionolaena aecidiocephala** (Grierson) Anderberg & Freire, Notes Roy. Bot. Gard. Edinburgh 46(1): 37–41. 1989. *Anaphalis aecidiocephala* Grierson, Notes Roy. Bot. Gard. Edinburgh 31: 389, fig. 1972. *Gnaphalium aecidiocephalum* (Grierson) L. O. Williams., Phytologia 25: 459. 1973. TYPE: Mexico. Oaxaca: Ixtlán, Comaltepec, Cerro de Humo Chico, in grass in sun, 3,050 m, 2 Mar. 1968, *MacDougall 4129* (holotype, E; isotype, S). Figure 5.

Erect, multibranched, rigid shrub, 10–20 cm high. *Leaves* suborbicular, obtuse, 2.5–5 mm long, 1.5–3 mm wide with slightly revolute margins, tomentose adaxially, densely whitish lanate abaxially. *Capitula* homogamous and heterogamous, arranged in dense umbels sessile and terminal on the upper branches. *Involucre* obdeltate. Involucral bracts ca. 32; outer bracts ovate, obtuse, 3–4 mm long, 2–2.5 mm wide, purple at the tip; inner bracts linear, slightly obtuse, 6–8 mm long, 0.8–1.2 mm wide, purplish above stereome. *Florets* 29–35, pistillate florets more numerous than the functionally staminate or all functionally staminate in homogamous capitula. *Pistillate florets* (0–)25–26; corollas 4 mm long; achenes elliptic, 1–1.5 mm long, 0.25–0.40 mm wide, pubescent with short, apically obtuse, duplex hairs. *Functionally staminate florets* 5 (and functionally neuter in heterogamous capitula), 29–35 (in homogamous capitula); corollas 3.5–4 mm long; style branches rounded, 0.2 mm long; fertile anthers 2 mm long with tails slightly shorter than antheropodium; sterile anthers 1.5 mm long, tails slightly exceeding antheropodium and without pollen grains; ovaries sterile, flattened, 0.5–0.8 mm long, 0.25–0.30 mm wide, shortly pubescent as in pistillate florets.

*Distribution.* Known only from the type locality, i.e., mountains of Oaxaca in Mexico, growing between 2,700 and 3,050 m. Flowering collection was made in March.

*Additional specimen examined.* MEXICO. OAXACA: Ixtlán, Comaltepec, in grass in sun, Cerro de Humo Chico, 10,000 ft., *T. MacDougall*, 6 Jan. 1961 (E).

*Chionolaena aecidiocephala* is distinguished from other Mexican species of the genus by its

suborbicular leaves and purplish bracts. It is closely related to *C. lavandulifolia*: both species have obtuse outer bracts and the capitula arranged in dense umbels.

**2. Chionolaena arbuscula** DC., Prodr. 5: 397. 1836. TYPE: Brazil. Minas Gerais: Marianne, 1833, *M. Vauthier 298* (lectotype, selected here, G; isolectotype, GH, photograph at LP). Figure 6.

Erect, rigid shrubs, with thin woody stems, 50 cm high. *Leaves* narrowly linear, 1–2 cm long, 0.7–1 mm wide with conspicuously revolute margins, glabrous on adaxial side, abaxial surface densely woolly. *Capitula* heterogamous, solitary on the upper branches, sometimes arranged in small, loose, terminal umbels at the ends of the leafy stems. *Involucre* narrowly oblong. Involucral bracts 12–52; outer bracts linear-ovate, acute, 3–3.5 mm long, 1 mm wide, with few long woolly hairs; inner bracts linear elliptic, acute, 3–6 mm long, 0.3–0.5 mm wide. *Florets* 32–65, functionally staminate florets commonly more numerous than the pistillate, occasionally equaling or fewer. *Pistillate florets* 10–32; corollas 1.8–2.4 mm long; achenes oblong, 0.7–1.2 mm long, 0.2–0.5 mm wide, sericeous with long, apically acute, duplex hairs. *Functionally staminate florets* 21–47; corollas 1.8–3.5 mm long; style branches acute, 0.15–0.40 mm long; anthers 1–1.5 mm long with tails shorter than the antheropodium; ovaries sterile, pubescence as in pistillate florets.

*Distribution.* Restricted to the state of Minas Gerais in southeastern Brazil. It occurs in the planalto, which has a temperate climate and a well-marked dry season. *Chionolaena arbuscula* usually grows adjacent to waterfalls on gray, sandy soils at 1,500 m. Flowering collections were made in May, August, January, and February.

*Additional specimens examined.* BRAZIL. MINAS GERAIS: Serra de Itatiaia, *Claussen*, 1839 (GH); Serra do Espinhaço, campo and gallery margin with outcrops, gray sandy soil, ca. 12 km W of Barão de Cocais, base of Serra da Caraça, ca. 1,500 m, periodically flooded crevices adjacent to waterfall, 28 Jan. 1971, *Irwin et al. 29310* (NY); Serra do Espinhaço, riacho margin, cerrado, sedge meadow (brejo) sandstone outcrops and gallery forest, ca. 10 km W of Barão de Cocais gray sandy soil, ca. 1,500 m, 24 Jan. 1971, *Irwin et al. 29023* (NY); Environs de Rio de Janeiro et d'Ouro-Preto-Brésil, 6 Aug. 1885, *Glaziou 14959* (NY); Serra de Ouro Preto, Apr. 1892, *Ule 2602* (HBG); prope Itambe do Matto dentro et in Serra de Piedade, *Martius 843* (M); Serra do Caraça, 1880, *Glaziou 11036* (G), 25 Mar. 1957, *E. Pereira 2637*, *Pabst 3473* (both RB); Serra de Ibitipoca, 15 May 1970, *Krieger & Urbano 8649* (RB); Campos de Ouro Branco, 26 Nov. 1922, *Campos Porto 1218* (RB); Serra do Curral, Belo Horizonte, 20 May 1952, *P. L. Roth 1401* (RB). Sine loco. BRASILIA: *Schuch s.n.* (NY), *Martius 829* (M); in 1903, *L. Damazio 1159* (RB).

*Chionolaena arbuscula* is closely related to *C. lychnophorioides*: both species are erect, rigid, woody shrubs with solitary capitula and achene hairs acute at the apex. *Chionolaena arbuscula* is easily distinguished by its narrowly linear leaves with conspicuous revolute margins and capitula with male florets outnumbering female florets.

**3. Chionolaena capitata** (Baker in Martius) Freire, comb. nov. *Achyrocline capitata* Baker in Martius, Fl. Bras. 6: 117, tab. 39. 1882. *Leucopholis capitata* (Baker) Cufod., Feddes Repert. 31: 329. 1933. SYNTYPES: Brazil. Minas Gerais: Serra de Itatiaia, *Sello 859* (not seen); Rio de Janeiro: *Glaziou 4843* (K, S, US), *Glaziou 5899* (lectotype, selected here, S), *Glaziou 6593* (US), *Glaziou 7723* (G). Figure 7.

*Chionolaena arbuscula* DC. var. *hololeuca* Baker ex Glaz., Mém. Soc. Bot. France 1: 406. 1910. SYNTYPES: Brazil. Rio de Janeiro: Serra de Itatiaia, entre les rochers, *Glaziou 4842* (not seen), *Glaziou 4843* (lectotype, selected here, S; isolectotypes, K, US), *Glaziou 6593* (US), *Glaziou 8768* (G, K).

Weakly woody shrub with multibranched, erect stems, 20–60 cm high. *Leaves* linear, 5–13 mm long, 0.6–1 mm wide with slightly revolute margins, tomentose adaxially, densely lanate abaxially. *Capitula* heterogamous (occasionally homogamous), arranged in dense umbels sessile and terminal on the upper branches. *Involucre* narrowly oblong. Involucral bracts 16–25; outer bracts ovate to linear-ovate, acute, 1.5–3.5 mm long, 0.5–1.5 mm wide; inner bracts linear, acute, 4–8 mm long, 0.4–1 mm wide. *Florets* 5–11, functionally staminate florets slightly more numerous than the pistillate, sometimes equaling, or all functionally

staminate. *Pistillate florets* (0–)2–4; corollas 1.5–4 mm long; achenes oblong-elliptic, 0.5–1.2 mm long, 0.25–0.50 mm wide, pubescent with long, apically obtuse, duplex hairs. *Functionally staminate florets* 2–8; corollas 1.8–3.5 mm long; style branches truncate or rounded, rarely subacute, 0–0.4 mm long; anthers 1–1.8 mm long with tails equaling antheropodium; ovaries sterile, contracted toward middle, 0.3–0.8 mm long, 0.15–0.40 mm wide, pubescence as in pistillate florets.

*Distribution.* Restricted to the states of Minas Gerais, Rio de Janeiro, and Paraná of southeastern Brazil. *Chionolaena capitata* is found in the planalto, which has a temperate climate and a slightly to well-marked dry season. It often grows in rocky places, between 2,300 and 2,850 m. Flowering collections were made from April to October.

*Additional specimens examined.* BRAZIL. MINAS GERAIS: Serra do Caparaó, Pico de Calçado, 2,850 m, 25 Sep. 1941, *A. C. Brade 17013* (NY); Pico Luis Ignasio, 2,300 m, 9 Sep. 1941, *A. C. Brade 16898* (NY); slope of Pontão Crystal?, in rocks, 30 Apr.–4 May 1925, *Chase 9708* (GH); Subida Agulhas Negras, ca. 2,400 m, 16 Aug. 1969, *Sucre 5765* (COL). PARANA: *Dusén s.n.* (S). RIO DE JANEIRO: Itatiaia, 2,300 m, Aug. 1933, *Brade 12659* (NY); 2,300–2,400 m, 23 Aug. 1960, *O. Handro 9423* (NY); 2,350 m, terreno pedregoso, 29 Apr. 1977, *Joly C. A. et al. 6790* (NY); 2,400 m, 4/10 June 1913, *F. Tamandaré 6384* (S); Agulhas Negras, 3,000 m, 4/10 June 1913, *F. Tamandaré & A. C. Brade 6383* (S), 19/27 July 1901, *Hemmendorff 633* (S); Municipio Rezende, Parque Nacional de Itatiaia, planalto, proximo do abrigo Rebonças, campos de altitude 2,400 m, 9 Oct. 1981, *Martinelli 7762* (RB); Pedra do Altar, 2,400 m, 1937, *A. C. Brade 15599* (NY); "Felsritzen des Kegels," (Wawra 396 (NY); planalto, km 16 de la carretera, ca. 2,300 m, 25/26 May 1961, *Cabrera & Fabris 14212* (GH, LP); Serra da Pedra assentado, Retiro, 5 June 1902, *Dusén 468* (S); Rio Bonito, Bracaña, 4 July 1978, *Lua & Nogueira 30* (RB); Serra do Itatiaia, 26 Dec. 1895, *Ule 3913* (HBG).

*Chionolaena capitata* is recognized by its adaxially and abaxially pubescent, linear leaves and dense umbellate clusters of capitula.

Glaziou (1910) mentioned the variety *hololeuca* ex Baker and cited the following specimens *4842*, *4843*, *6593*, and *8768*. Analysis of these specimens, except *4842*, shows that they belong to *C. capitata* because they have small leaves and few-flowered capitula arranged in dense umbels. Furthermore, the specimens *Glaziou 4843* and *6593* form part of the type material cited by Baker (1882) for *Achyrocline capitata* (= *Chionolaena capitata*).

4. **Chionolaena columbiana** S. F. Blake, J. Wash. Acad. Sci. 25: 312. 1935. TYPE: Colombia. Paramos of the Sierra Nevada de Santa Marta, about 30 mi. inland from Dibulla, ca. 4,390 m, July 1932, *William Seifriz 494* (holotype, US). Figure 8.

Caespitose shrub with weakly woody stems, 15–30 cm high. *Leaves* linear-obovate 1.3–4.5 cm long, 3–4.5 mm wide with slightly revolute margins, tomentose adaxially, densely lanate abaxially. *Capitula* heterogamous, arranged in dense umbels surrounded by leaves of the same shape as the stem leaves, umbels supported at maturity by a woolly, thin peduncle with a few scattered, generally rather small leaves. *Involucre* obdeltate. Involucral bracts 25–27; outer bracts ovate, acuminate, 4 mm long, 1.5 mm wide; inner bracts linear elliptic, obtuse, 3–5 mm long, 0.5–1 mm wide. *Florets* 13–20, pistillate florets slightly more numerous than the functionally staminate. *Pistillate florets* 7–9; corollas 1–2.8 mm long; achenes oblong, 0.3–0.8 mm long, 0.15–0.20 mm wide, glabrous. *Functionally staminate florets* 6–8; corollas 1.5–3 mm long; style branches rounded, 0.3–0.4 mm long; anthers 1 mm long with tails equaling antheropodium; ovaries sterile, flattened, 0.3–0.7 mm long, 0.15–0.20 mm wide, glabrous.

*Distribution.* Restricted to northern Colombia on the Sierra de Santa Marta and the Sierra de Perijá. It grows in rocky places, between 3,000 and 3,900 m. Flowering collections were made from April to November.

*Additional specimens examined.* COLOMBIA. MAGDALENA: Cordillera Oriental, Sierra de Perijá, 12 km ENE of Manaure, 48 km E of Valledupar, 1 km from the Venezuelan border, 3,000 m, 5 Feb. 1945, *M. L. Grant 10864* (NY, US); Sierra de Perijá, plain between Cerro Venado and Cerro Avión, paramo 3,270–3,350 m, 8 Nov. 1959, *Cuatrecasas & Castañeda 25115* (US); Sierra Perijá, Tres Tetas (south peak, 3,000 m, 28 Apr.–4 May 1942, *Carriker 15* (US); Mun. La Paz, frontera colombo–venezolana, Serranía de Perijá, entre los cerros El Venado y El Avión, 3,200–3,600 m, 3 Mar. 1959, *Romero & Castañeda 7356* (MO); Sierra Nevada de Santa Marta, 1 km S of laguna Río Frío, 3,800 3,900,

ca. 10°55′N, 73°53′W, 30 July 1972, *J. H. Kirkbride Jr. & E. Forero 1803* (MO, NY, RB, US); Sierra Nevada de Santa Marta, Transecto del Buritaca (Filo La Cumbre), 3,850 m, 19 Aug. 1977, *Rangel et al. 988* (U); Sierra Nevada de Santa Marta, alrededores de cabeceras de Río Ancho, Paramo de Macotama, on rock outcrop of high ridge SE of campsite at joining of two streams, 3,840 m, 13 Feb. 1959, *Barclay & Juajibioy 6927* (US).

*Chionolaena columbiana* is closely related to *C. isabellae* from southern Brazil: both species have obovate leaves and pedunculate capitulescences, but the former differs by its densely umbellate clusters of capitula and acuminate outer bracts.

**5. Chionolaena concinna** (A. Gray) Anderberg & Freire, Notes Roy. Bot. Gard. Edinburgh 46(1): 37–41. 1989. *Gnaphalium concinnum* A. Gray, Proc. Amer. Acad. Arts 15: 34. 1879. *Anaphalis concinna* (A. Gray) Grierson, Notes Roy. Bot. Gard. Edinburgh 31: 392. 1972. TYPE: Mexico. San Luis Potosí: 22°N, alt. 6,000–8,000 ft., in 1878, *Parry & Palmer 423* (lectotype, designated by Anderberg & Freire (1989), GH; isolectotypes, BM, E). Figure 9.

Subshrub, with thin, subdichotomously branched stems, 20–40 cm high. *Leaves* obovate, subpetiolate, obtuse, 1.5–2.5 cm long, 4–7 mm wide with slightly revolute margins, tomentose adaxially, densely whitish lanate abaxially. *Capitula* heterogamous, arranged in sessile and terminal corymbs that later become deeply lateral. *Involucre* obdeltate. Involucral bracts 30–34; outer bracts ovate, acute, 4 mm long, 1.5 mm wide; inner bracts stipitate, obtuse, 6 mm long, 0.5 mm wide. *Florets* 36–42, pistillate florets slightly more numerous than, ± equaling, or slightly fewer than the functionally staminate. *Pistillate florets* ca. 20; corollas 2.5–2.9 mm long; achenes elliptic, 0.6–0.8 mm long, 0.3 mm wide, pubescent with short, apically obtuse, duplex hairs. *Functionally staminate florets* 16–22; corollas 1.5–3 mm long; style branches truncate, 0.4 mm long; anthers 1.5 mm long with tails equaling antheropodium; ovaries sterile, strongly contracted, 0.2–0.6 mm long, 0.10–0.15 mm wide, pubescence as in pistillate florets.

*Distribution.* Restricted to central Mexico. Known only from the original site, which is at 22°N between 1,800 and 2,400 m. Flowering collections were made in September.

*Additional specimen examined.* MEXICO. SAN LUIS POTOSI: Sep. 1879, *Schaffner 222* (BM, GH).

*Chionolaena concinna* is distinguished from other Mexican species of the genus by its slender, subdichotomously branched stems and obovate leaves.

**6. Chionolaena chrysocoma** (Wedd.) Freire, comb. nov. *Oligandra chrysocoma* Wedd., Chlor. Andina I: 158. 1855. *Pseudoligandra chrysocoma* (Wedd.) Dillon & Sagást., Taxon 39: 125. 1990. TYPE: Colombia. Nouvelle Grenade, prov. de Río Hacha, Sierra Nevada, 3,800 -4,300 m, 1852, *Schlim 809* (holotype, P). Figure 10.

Erect, rigid, multibranched shrub, 30–40 cm high. *Leaves* closely appressed to stem, linear, acute, 4–6 mm long, 0.8–1 mm wide, glabrous adaxially, densely whitish lanate and completely concealed by the revolute margins abaxially. *Capitula* heterogamous, arranged in dense umbels sessile and terminal on the upper branches. *Involucre* narrowly oblong. Involucral bracts 21–31; outer bracts linear-ovate, acute, 4–4.5 mm long, 0.5–0.8 mm wide; inner bracts linear elliptic, slightly acuminate, 5–6 mm long, 0.6–0.2 mm wide. *Florets* 9–13, pistillate florets slightly more numerous than the functionally staminate. *Pistillate florets* 4–8; corollas 2.2–3.2 mm long; achenes oblong, 0.6–0.8 mm long, 0.25–0.30 mm wide, glabrous. *Functionally staminate florets* 3–6; corollas 2–4 mm long; style branches rounded to obtuse, 0.2–0.4 mm long; anthers 1.5 mm long with tails equaling antheropodium; ovaries sterile, flattened, 0.4–0.7 mm long, 0.2 mm wide.

*Distribution.* Restricted to northern Colombia on the Sierra de Santa Marta. This species grows at the highest elevations of any species in the genus (between 3,300 and 4,300 m). Flowering collections were made in March and August.

*Additional specimen examined.* COLOMBIA. MAGDALENA: Sierra Nevada de Santa Marta, Transecto del Buritaca, Filo La Cumbre, 3,300 m, Aug. 1977, *O. Rangel & A. Cleef 934* (US).

←

FIGURE 8. *Chionolaena columbiana* S. F. Blake.—A. Portion of plant.—B. Leaf adaxial surface.—C–F. Involucral bracts.—G. Pistillate floret.—H. Functionally staminate floret.—I. Achene of pistillate floret.—J. Ovary of functionally staminate floret.—K. Stamen.—L. Style of pistillate floret.—M. Style of functionally staminate floret. Below: Colombian distribution. A—M, *Kirkbride & Forero 1803* (MO).

*Chionolaena chrysocoma* is distinguished from other species of the genus by its appressed leaves. It is similar to *C. phylicoides*: both species exhibit narrowly oblong involucres, capitula arranged in dense umbels, and lower leaf surfaces completely concealed by the revolute margins.

7. **Chionolaena eleagnoides** Klatt, Leopoldina 23: 88. 1887. *Gnaphalium eleagnoides* (Klatt) S. F. Blake, Contr. U.S. Natl. Herb. 23: 1511. 1926. [*Gnaphalium hypochaionaeum* Sch. Bip. ex Klatt, Leopoldina 23: 88. 1887, sub *C. eleagnoides*, as synonym, nomen nudum.] TYPE: Mexico. Pelado, Aug. 1841, *Liebman 316* (holotype, C; isotypes (fragment), GH; photograph ex C in US). Figure 11.

Moderately branched shrub with weak, woody stems. *Leaves* broadly obovate, narrowed at the base, 3–4.5 cm long, 11–12 mm wide with slightly revolute margins, adaxially arachnoid pubescent, densely whitish lanate abaxially. *Capitula* heterogamous, arranged in corymbs sessile and terminal to the stems. *Involucre* obdeltate. Involucral bracts ca. 42; outer bracts ovate, obtuse, 2.5 mm long, 1.5 mm wide; inner bracts oblong obovate, 3 mm long, 1 mm wide. *Florets* 30–34, functionally staminate florets slightly more numerous than pistillate or equaling them. *Pistillate florets* 15–16; corollas 1.5–2.5 mm long; achenes oblong, 0.5 mm long, 0.25 mm wide, glabrous. *Functionally staminate florets* 15–18; corollas 1.2–2.5 mm long; style branches rounded, 0.2 mm long; anthers 1.8–2 mm long with tails equaling antheropodium; ovaries sterile, flattened, 0.3 mm long, 0.2 mm wide, glabrous.

*Distribution.* Known only from the type locality at Pelado, Mexico, at 3,600 m. Flowering collections were made in August.

*Chionolaena eleagnoides* is recognized by its broad, obovate leaves with slightly revolute margins.

8. **Chionolaena isabellae** Baker in Martius, Fl. Bras. 6: 130, tab. 46. 1882. SYNTYPES: Brazil. Rio de Janeiro: Serra de Itatiaia, 22 Jan. 1873, *Glaziou 6601* (lectotype, selected here, S; isolectotypes, G, UC); Serra de Itatiaia, 10 Jan. 1876, *Glaziou 4840* (NY, S). Figure 12.

*Chionolaena glaziovii* Baker in Martius, Fl. Bras. 6: 130. 1882. TYPE: Brazil. Minas Gerais: sommet de la Sierra de Tirapitinoja, 2,120 m, 20 Nov. 1876, *Glaziou 8769* (lectotype, selected here, P; isolectotypes, G, S).

*Chionolaena innovans* Wawra, Itin. Princ. S. Coburgi 2: 30. 1888. TYPE: Brazil. Itatiaia, Gipfel des Kegels, 1879, *Wawra 420* (holotype, W).

Erect, rigid, multibranched shrub, 15–40 cm high. *Leaves* narrowly obovate, 1.3–2.2 cm long, 3–5 mm wide with slightly revolute margins, tomentose adaxially, densely lanate and whitish abaxially. *Capitula* homogamous, arranged in dense umbels, these umbels aggregated in spreading corymbs terminal to the stems supported at maturity by a peduncle, 1.5–2.5 cm long, wholly devoid of leaves. *Involucre* obdeltate. Involucral bracts 18–28, yellow; outer bracts broadly ovate, obtuse, 2.5–3 mm long, 1.5–2 mm wide; inner bracts linear oblong, obtuse, 4–5 mm long, 0.4–1 mm wide. *Florets* 12–31, all perfect (apparently with embryo developed); corollas 2–3.2 mm long; style branches rounded, 0.3–0.5 mm long; anthers 1–1.3 mm long with tails equaling or slightly exceeding antheropodium; achenes oblong, 0.5–0.9 mm long, 0.2–0.4 mm wide, pubescent with long, apically acute, duplex hairs.

*Distribution.* Restricted to the states of Minas Gerais and Rio de Janeiro of southeastern Brazil. This species occurs between 2,000 and 3,000 m.

*Chionolaena isabellae* is closely related to *C. columbiana*: both species have obovate leaves and a capitulescence supported by a slender peduncle. *Chionolaena isabellae* is distinguished from *C. columbiana* by its corymbosely arranged, homogamous capitula and its villous achenes with apically acute, duplex hairs.

**9. Chionolaena jeffreyi** H. Robinson, Phytologia 55: 121. 1984. TYPE: Brazil. Municipio de Rio Contas, Pico das Almas a 18 km NW de Rio de Contas, 1,600–1,850 m, 24 July 1979, *R. M. King et al. 8141* (holotype, RB not seen; isotypes, CEPEC not seen, MO not seen, US). Figure 13.

Subshrub, weakly woody, multibranched, with slender ascendent stems, 10–20 cm high. *Leaves* linear-elliptic, narrowed at the base, 3 8 mm long, 1–2 mm wide with slightly revolute margins, tomentose adaxially, densely lanate abaxially. *Capitula* heterogamous, solitary on the upper branches. *Involucre* obdeltate. Involucral bracts 20–25; outer bracts 3.5 mm long, 1.2 mm wide; inner bracts 4.5 mm long, 1 mm wide. *Florets* 23–26, pistillate florets slightly fewer than the functionally staminate. *Pistillate florets* 8–11; corollas 2–2.5 mm long; achenes oblong elliptic, 0.7–0.8 mm long, 0.3 mm wide, pubescent with long, apically obtuse, duplex hairs. *Functionally staminate florets* 15–25; corollas 2–2.8 mm long; style branches rounded, 0.2 mm long; anthers 0.7–1 mm long with tails equaling or slightly exceeding anthheropodium; ovaries sterile, 0.15 mm long, 0.20 mm wide, pubescence as in pistillate florets.

*Distribution.* *Chionolaena jeffreyi* is the only species endemic to the state of Bahia in Brazil, where the climate is temperate with long dry periods. This species is found growing in damp, shady places, between 1,600 and 1,850 m. Flowering collections were made in March and July.

*Additional specimen examined.* BRAZIL. BAHIA: middle and upper NE slopes of the Pico das Almas ca. 25 km WNW of the Vila do Rio de Contas, sandstone conglomerate metamorphic and quartzite rock outcrop with associated scrubby vegetation with damp flushes and grassland and marsh in some areas, ca. 41°57′W, 13°33′S, 1,600–1,850 m, 19 Mar. 1977, *R. M. Harley et al. 19677* (paratypes, NY, RB—2 sheets, U, US).

*Chionolaena jeffreyi* is distinguished from other species of the genus because of its short petiolate, elliptic leaves, solitary capitula, and weakly woody, ascendent stems.

**10. Chionolaena latifolia** (Benth.) Baker in Martius, Fl. Bras. 6: 132, tab. 43, fig. 2. 1882. *Leucopholis latifolia* Benth., Hooker's Icon. Pl. vol. 12: 14. 1876. TYPE: Brazil. Rio de Janeiro: Itatiaia, 2,400 m, 9 July 1872, *Glaziou 4841* (holotype, P; isotype, S). Figure 14.

*Chionolaena glomerata* Baker in Martius, Fl. Bras. 6: 130. 1882. SYNTYPES: Brazil. Rio de Janeiro: Itatiaia, 6 July 1871, *Glaziou 4851* (lectotype, selected here, P; photograph ex P in GH); Itatiaia, 9 July 1872, *Glaziou 5896* (excluded here, P).

B-C 5 mm

D-G 3 mm

H-I 2 mm

J-N 1 mm

Erect, rigid shrub, moderately branched with densely leafy stems, 15–80 cm high. *Leaves* oblong-elliptic or linear-elliptic, acute, 1.5–4 cm long, 3–5 mm wide with slightly revolute margins, glabrous and bright adaxially, densely lanate and whitish abaxially. *Capitula* heterogamous, arranged in dense umbels, sessile and terminal on the upper branches, these umbels sometimes aggregated corymbosely. *Involucre* narrowly oblong. Involucral bracts 15–21; outer bracts ovate, acuminate, 3–4 mm long, 1–1.5 mm wide; inner bracts linear, subacute, 4–6.5 mm long, 0.5–1 mm wide. *Florets* 5–14, pistillate slightly fewer than the functionally staminate. *Pistillate florets* 2–6; corollas 2–3 mm long; achenes oblong to oblong-elliptic, 0.6–1.2 mm long, 0.2–0.4 mm wide, pubescent with long, apically obtuse, duplex hairs. *Functionally staminate florets* 3–9, corollas 2–3 mm long; style branches truncate, 0.2–0.4 mm long; anthers 0.8–1.3 mm long with tails slightly exceeding or equaling antheropodium; ovaries sterile, oblong, flattened, 0.6–1 mm long, 0.2–0.4 mm wide, pubescence as in pistillate florets.

*Distribution.* *Chionolaena latifolia* grows on open rocky slopes, between 2,300 and 3,000 m. This species has a discontinuous distribution, confined to northern Amazonia and southeastern Brazil. Similar distributions are frequent among other plant species (Harling, 1958; Maas, 1972; Andersson, 1977). Flowering collections were made between October and March.

*Additional specimens examined.* BRAZIL. MINAS GERAIS: Itatiaia, 2,400 m, 10 Jan. 1876, *Glaziou 5903* (cited by Baker for *Chionolaena latifolia*; NY, S); near summit of Mt. L. Liesner 17987* (U).

*Chionolaena latifolia* is an easily recognized species with characteristic foliage, i.e., elliptic leaves with glabrous, bright adaxial surfaces and slightly revolute margins.

Steyermark and Maguire (Steyermark, 1984) described *C. breweri* from Venezuela. This species was said to differ from *C. latifolia* in the width of the capitulescence, size of the capitula, and habit. Because this variation is continuous and not correlated with distribution, these species are treated here as conspecific.

I have excluded the sterile syntype of *Chionolaena glomerata, Glaziou 5896*, from this species and placed it under *C. wittigiana* because of its foliage. This specimen has linear leaves with adaxially tomentose surfaces, whereas the leaves of *C. glomerata* (= *C. latifolia*) are elliptic with glabrous, bright adaxial surfaces.

Gray Herb. n.s. 52: 21. 1917, hom. illeg., non *Gnaphalium lavandulaefolium* Willd., Sp. Pl. 3: 1868, 1804, which is *Elichrysum lavandulaefolium* (Willd.) D. Don., Mem. Wern. Nat. Hist. Soc. 5: 550, 1826. TYPE: Mexico. Crescit in frigidis Andium Mexicanorum in nobilissimo monte Nauhcampatepetle juxta urbem Perote, alt. 1720 hex. h. Floret Martio Herb. HBK (holotype, P not seen; photograph at GH, LP-neg.no.37976, distributed by F). Figure 15.

Caespitose, multibranched shrub with weakly woody stems, 10–25 cm high. *Leaves* linear-elliptic, acute, 7–18 mm long, 1.5–3.5 mm wide with margins sometimes slightly revolute, tomentose adaxially, densely lanate and whitish abaxially. *Capitula* heterogamous, commonly arranged in dense umbels sessile and terminal on the upper branches, sometimes in a compact corymb. *Involucre* obdeltate. Involucral bracts 25–44; outer bracts broadly ovate, obtuse, 3–4 mm long, 1–2 mm wide, dark brown at the tip; inner bracts linear-oblong, obtuse, 6.5–9 mm long, 0.5–1 mm wide, dark brown above the stereome. *Florets* 11–48, pistillate more numerous or slightly more numerous than the functionally staminate, sometimes slightly fewer than the functionally staminate. *Pistillate florets* 6–24; corollas 3–4.5 mm long; achenes oblong elliptical, 0.7–1.9 mm long, 0.3–0.6 mm wide, glabrous, occasionally shortly pubescent with apically obtuse, duplex hairs. *Functionally staminate florets* 5–13; corollas 3–5 mm long; style branches rounded or subacute, 0.2–0.4 mm long; anthers 1.5–2.2 mm long with tails shorter than anther-opodium; ovaries sterile, flattened, 0.25–0.70 mm long, 0.1–0.4 mm wide, glabrous, occasionally with short pubescence as in pistillate florets. Pappus bristles with apical cells slightly swollen and acute at the apex.

*Distribution.* *Chionolaena lavandulifolia* has a highly disjunct distribution, i.e., it occurs in the central mountains of Mexico and in the central parts of Costa Rica. This species is found among rocks in sandy, gravelly soil and volcanic sand on open exposures, commonly on summits between 3,150 and 4,200 m. Flowering collections were made between July and March, except in November and December.

*Additional specimens examined.* MEXICO. MEXICO: summit ledges, Nevado de Toluca, 2 Sep. 1882, *Pringle 4223* (M, UC); Nevado de Toluca, Alpine Region, 4,000 m, 27 Mar. 1954, *Troll 721* (M); Ixtaccihuatl, S side of mtn. at La Joya, ca. 4,015 m, "in crevices at base of cliff, occasional," 8 Aug. 1960, *Beaman 3511* (UC); 4,000 4,050 m, "under rock ledge," 30 July 1958, *Beaman 1961* (UC); La Joya de Alcalican, extremo SW del Ixtaccihuatl, municipio de Amecameca, "pradera alpina," 3,900 m, 13 Nov. 1977, *Rzedowski 35551* (UC); Ixtaccihuatl, 12,000 13,000 ft., Sep.—Oct. 1905, *Purpus 1523* (UC). *s.n.* (in rocky area on Itacolumy mountain, Aug. 1824, LE not located); *Claussen 184* (Minas Gerais, Crarassa, lectotype, selected here, P; negative at LP). Figure 16.

Erect, rigid shrub, moderately branched, 15–35 cm high. *Leaves* linear, acute, 1.3–3.3 cm long, 1.2–3 mm wide with slightly revolute margins, adaxially arachnoid pubescent, densely lanate and whitish abaxially. *Capitula* heterogamous, solitary on the upper branches, occasionally arranged in terminal, small, loose umbels at the ends of the leafy stems. *Involucre* broadly campanulate. Involucral bracts 28–29; outer bracts linear ovate, acute, 5 mm long, 1–1.5 mm wide; inner bracts linear, 5–6 mm long, 0.9 mm wide. *Florets* 48–54, pistillate more numerous than the functionally staminate. *Pistillate florets* ca. 35; corollas 2–2.5 mm long; achenes oblong, 1–3 mm long, 0.3–1.2 mm wide, pubescent with long, apically acute, duplex hairs. *Functionally staminate florets* ca. 13; corollas 3.5–4 mm long; style branches acute or rounded, 0–0.4 mm long; anthers 1.5–1.7 mm long with tails equaling antheropodium; ovaries sterile.

*Distribution.* *Chionolaena lychnophorioides* is restricted to the state of Minas Gerais in southeastern Brazil. It occurs in the planalto, which has a temperate climate and well-marked dry season. This species grows on stony and rocky mountain slopes, between 1,350 and 1,450 m. Flowering collections were made in April, May, and December.

*Additional specimens examined.* BRAZIL. MINAS GERAIS: Itacolumy Ouro Preto, 7 July 1884, *Glaziou 14960a* (MO, US); Itacolumy (E of Ouro Preto), 8 Apr. 1925, *Chase 9389* (GH, MO); Itacolumy, Feb. 1892, *Ule 2601* (HBG); Itacolumy, Ouro Preto "campestre da serra," 28 Dec. 1950, *A. Macedo 2801* (NY, RB, US); Pico Itambe, depressao, terreno (valo) no alto Serra, 5 May 1942, *M. Magalhaes 1696* (COL); Serra de Ibitipoca, Pico do Piao, 1,350 1,450 m, formações de arenito de Serie Lauras, 14 May 1970, *Sucre & Krieger 6836* (RB).

*Chionolaena lychnophorioides* is distinguished by its usually solitary capitula with numerous florets and its linear leaves. It is related to *C. arbuscula*, from which it is readily distinguished by its broadly linear leaves with slightly revolute margins and capitula with pistillate florets outnumbering the functionally staminate florets.

**13. Chionolaena mexicana** Freire, sp. nov. TYPE: Mexico. Hidalgo: Sierra de Pachuca, 10,000 ft., 20 Feb. 1899, *Pringle 7700* (holotype, K). Figure 17.

*Frutex* erectus dichotome ramosus, usque ad ca. 0.3 m altus. Caules ascendente-erecti, tomentosi, foliati, vetustiores glabri nudi, cicatricibus foliorum notati. *Folia* alterna, suberecto-patentia, inferiora deflexa, obovata, obtusa, 15–25 mm longa, 3–7 mm lata, apice mucronata, margine revoluta, supra tomentosa, subtus dense et persistenter incana. *Corymbi* terminales. *Capitula* heterogama. Involucrum campanulatum. Bracteae involucri 34 36, exteriores ovatae, interiores lineares, lamina alba. Flores 25–26, albidi in apicibus rosei. *Flores radii* 14–15, feminei, fertiles. Corollae filiforme-bilabiatae ca. 3.8 mm longae. Stilus bifidus. Achenia oblonga, ca. 1 mm longa, ca. 0.3 mm lata, minute puberula. *Flores disci* ca. 11, hermaphroditi, steriles et masculae fungentes. Corollae tubulosae, 5-lobatae, ca. 4 mm longae. Stylus bifidus, ramis apice truncatis et dorso pubescentibus. Antherae ca. 1.8 mm longae, caudae antherarum ca. 0.3 mm longae. Achenia sterilia, anguste oblonga. Pappus albus, uniserialis, setis scabris corolla parum longioribus, barbellatis, basi in annulo concretae formantes, florum tubulosarum apice incrassatis.

Erect, dichotomously branched, rigid shrub, 30 cm high. *Leaves* narrowly obovate, slightly attenuate at the base, obtuse, 1.5–2.5 cm long, 3–7 mm wide with slightly revolute margins, tomentose adaxially, densely whitish lanate abaxially. *Capitula* heterogamous, 10–18, arranged in corymbs sessile and terminal on the upper branches. *Involucre* obdeltate. Involucral bracts 34–36; outer bracts ovate, slightly acuminate, 2.2–2.5 mm long, 1 mm wide; inner bracts linear, obtuse, 5–6.5 mm long, 0.5 mm wide, dark above the stereome. *Florets* 25–26, pistillate slightly more numerous than the functionally staminate. *Pistillate florets* 14–15; corollas 3.8 mm long; achenes oblong, 1 mm long, 0.3 mm wide, pubescent with short, apically obtuse, duplex hairs. *Functionally staminate florets* ca. 11; corollas 4 mm long; style branches truncate, 0.4 mm long; anthers 1.8 mm long with tails slightly shorter than antheropodium; ovary sterile, flattened, 0.7 mm long, 0.2 mm wide, pubescence as in pistillate florets.

Style of functionally staminate floret. Below: Mexican and Central American (Costa Rica) distribution. A–N, *Gonzalo Flores M. PV78120* (UC).

*Distribution.* Known only from the type collection, the state of Hidalgo, Sierra de Pachuca at 2,700 m. A flowering collection was made in February.

This species is readily distinguished from all other species of *Chionolaena* by its obovate leaves, corymbosely arranged heterogamous capitula, and achenes with obtuse short hairs. Its closest relative appears to be *C. concinna*, the only other Mexican species with obovate leaves, capitula arranged in corymbs, and achenes with obtuse short hairs. *Chionolaena mexicana* differs from *C. concinna* by its erect, rigid habit, and capitulescence terminal at maturity. In addition, the leaves of *C. concinna* are narrowed into a petiolariform base. In *C. mexicana*, the leaves are basally attenuate.

**14. Chionolaena phylicoides** (Gardner) Baker in Martius, Fl. Bras. 6: 131. 1882. *Leucopholis phylicoides* Gardner, London J. Bot. 2: 11. 1843. TYPE: Brazil. Rio de Janeiro: Organ Mountains, 1836–1841, *Gardner 5772* (lectotype, selected here, GH, photograph at LP; isolectotypes, G—3 sheets, NY, S). Figure 18.

Erect, rigid shrub, moderately branched with stems densely leafy, 15–45 cm high. *Leaves* oblong, acute, 5–10 mm long, 1–2 mm wide, glabrous and bright adaxially, densely woolly and completely concealed by the revolute margins abaxially. *Capitula* homogamous, unisexual, arranged in dense umbels sessile and terminal on the upper branches. *Involucre* narrowly oblong. Involucral bracts 20–30; outer bracts linear ovate, acuminate, 4–5 mm long, 1 mm wide; inner bracts linear, obtuse, 4–5 mm long, 0.7–0.8 mm wide. *Florets* 7–12, all hermaphroditic functionally staminate florets with ovary not developed, functionally pistillate florets without anthers. *Functionally pistillate florets* ca. 10; corollas 3  3.8 mm long.; style branches truncate, 0.4–1 mm long; anthers 0; achenes oblong, 0.8–0.9 mm long, 0.2–0.5 mm wide, pubescent with long, duplex hairs obtuse at the tip. *Functionally staminate florets* 7–12; corollas 2–3.5 mm long; style branches truncate, 0–0.5 mm long; anthers 5, 1.2–1.8 mm long with tails equaling antheropodium; ovaries sterile, flattened, 0.5 0.8 mm long, 0.15–0.40 mm wide, pubescence as in pistillate florets.

*Distribution.* Restricted to the states of Minas Gerais and Rio de Janeiro in southeastern Brazil where a slightly marked dry season occurs. This species grows commonly in rocky places on hillsides beween 1,950 and 2,850 m. Flowering collections were made between June and November.

*Additional specimens examined.* BRAZIL. MINAS GERAIS: 3 Nov. 1887, *Glaziou 16157* (G, NY); Serra do Caparaó, Pico do Calçado, 2,850 m, 25 Sep. 1941, *Brade 17012* (NY); Pico do Cristal, 2,600 m, 24 Oct. 1941, *Brade 17004* (NY). are completely concealed by the revolute margins. *Chionolaena phylicoides* is, however, distinguished by its homogamous capitula and reflexed leaves.

**15. Chionolaena sartorii** Klatt, Leopoldina 23: 89. 1887. *Gnaphalium sartorii* Sch.-Bip. ex Klatt, Leopoldina 23: 89. 1887, prosyn. sub. *C. sartorii*, nomen nudum. *Gnaphalium sartorii* (Klatt) F. J. Espinosa-Garcia, Bol. Soc. Bot. México 45: 21. 1984. TYPE: Mexico. Sempoaltepec, June 1942, *Liebman 308* (holotype, C; isotype (fragment), GH). Figure 19.

Caespitose subshrub with weakly woody stems, 8–10 cm high. *Leaves* narrowly linear, acute, 1–2 cm long, 1 mm wide with slightly revolute margins, tomentose adaxially, densely whitish lanate abaxially. *Capitula* heterogamous, 3–4, arranged in corymbs sessile and terminal on the upper branches. *Involucre* obdeltate. Involucral bracts 20–25; outer bracts narrowly ovate, acuminate, 3 mm long, 1–1.2 mm wide; inner bracts linear, subacute, 5.5–6 mm long, 0.5 mm wide. *Florets* ca. 20–21, pistillate more numerous than functionally staminate. *Pistillate florets* 14–15; corollas 4 mm long; achenes oblong 0.8 mm long, 0.3 mm wide, pubescent with short, apically obtuse, duplex hairs. *Functionally staminate florets* ca. 6; corollas 4 mm long; style branches rounded, 0.2 mm long; anthers 1.8 mm long with tails equaling or slightly exceeding antheropodium; ovaries sterile, 0.8 mm long, 0.3 mm wide, pubescence as in pistillate florets.

*Distribution.* Known only from the type locality in Sempoaltepec, Mexico, at about 3,300 m. The flowering collection was made in June.

*Chionolaena sartorii* is recognized by its caespitose habit, linear leaves, acute inner bracts, and few, corymbosely arranged capitula.

**16. Chionolaena seemannii** (Sch.-Bip. in Seemann) Freire, comb. nov. *Gnaphalium seemannii* Sch.-Bip. in Seemann, Bot. Voy. "Herald" 7–8: 309. 1856. TYPE: Mexico. Sierra Madre, NW Mexico, *Seemann 1994* (holotype, K). Figure 20.

*Chionolaena corymbosa* Hemsley, Diagn. Pl. Nov. 2: 32. 1879. Nomen superfluum. TYPE: Mexico. Sierra Madre, NW Mexico, *Seemann 1994*.

Woody, rigid shrub with ascendent, erect and densely leafy branches, 15–20 cm high. Stems subdichotomously branched. *Leaves* linear elliptic, acute, 3.5–4.5 cm long, 4–5 mm wide with slightly revolute margins, glabrous adaxially, densely whitish lanate abaxially. *Capitula* heterogamous, up to 10, arranged in primary terminal, sessile corymbs becoming lateral later in development. *Involucre* broadly campanulate. Involucral bracts ca. 38, dark toward middle; outer bracts ovate, obtuse, 4 mm long, 2 mm wide; inner bracts 6 mm long, 0.5 mm wide. *Florets* ca. 84, pistillate much more numerous than the functionally staminate. *Pistillate* florets ca. 70; corollas 3.5 mm long; achenes elliptic, 0.7 mm long, 0.3 mm wide, pubescent with short, apically obtuse, duplex hairs. *Functionally staminate florets* ca. 14; corollas 3.5–3.8 mm long; style branches truncate, 0.4 mm long; anthers 2 mm long with tails slightly exceeding antheropodium; ovary sterile, oblong, flattened, 0.5 mm long, 0.2 mm wide, pubescence as in pistillate florets.

*Distribution.* Known only from the type locality, Sierra Madre, Mexico. No flowering data are available.

*Chionolaena seemannii* is recognized by its corymbosely arranged, broadly campanulate capitula, long linear leaves, and subdichotomously branched stems.

**17. Chionolaena wittigiana** Baker in Martius, Fl. Bras. 6: 129. 1882. TYPE: Brazil. Minas Gerais: in cacumine Serra de Itatiaia, *Glaziou 6590* (lectotype, selected here, K; isolectotype, C). Figure 21.

Woody shrub with ascendent, erect, and densely leafy stems, 15–30 cm high. *Leaves* linear or linear elliptic, stiff, 2–2.5 cm long, 1.5–3 mm wide with slightly revolute margins, adaxially arachnoid pubescent, densely lanate and whitish abaxially. *Capitula* heterogamous, numerous, arranged in dense corymbs, sessile and terminal on the upper branches. *Involucre* obdeltate. Involucral bracts 20–24; outer bracts linear ovate, acuminate, 4–5 mm long, 1 mm wide; inner bracts 5–6 mm long, 0.5–0.8 mm wide. *Florets* 12–24, functionally staminate florets more numerous than pistillate florets. *Pistillate florets* 8–9; corollas 1.8–3 mm long; achenes oblong elliptic, 0.5–0.8 mm long, 0.3–0.4 mm wide, pubescent with long, apically acute, duplex hairs. *Functionally staminate florets* 12–15; corollas 1.5–2.2 mm long; style branches truncate, 0.25–0.30 mm long; anthers 1–1.8 mm long with tails equaling antheropodium; ovaries sterile, flattened or contracted toward middle, 0.4–0.6 mm long, 0.3 mm wide, pubescence as in pistillate florets.

*Distribution.* Restricted to the state of Minas Gerais in southeastern Brazil. This species is found on stony and rocky mountain slopes between 2,400 and 2,600 m. Flowering collections were made in October and November.

*Chionolaena wittigiana* is recognized by its linear, somewhat stiff leaves and the heterogamous capitula arranged in compact corymbs.

*Additional specimens examined.* BRAZIL. MINAS GERAIS: Itatiaia, 9 July 1872, *Glaziou 5896* (paratype of *Chionolaena glomerata*) (P); Serra do Itatiaia, ca. 2,400 m, "in rupibus," 19 Oct. 1903, *Dusén 2132* (S); Itatiaia, Agulhas Negras, 2,600 m, 22–28 Jan. 1938, *Markgraf & Brade 5704* (herb. No. 39366, NY); Agulhas Negras, Serra do Itatiaia, 30 Dec. 1895, *Ule 3733* (HBG).

## DUBIOUS SPECIES

*Chionolaena longifolia* Baker in Martius, Fl. Bras. 6(3): 131. 1882.

I have not found specimens of *C. longifolia* in any herbaria where I have studied. Baker (1882: 131) cited only one collection of *C. longifolia* (*Sellow 2114*). The type was probably destroyed. There is a photograph distributed by the Field Museum of Natural History (No. 15146) as the type for *C. longifolia*. The photograph agrees with Baker's description; however, the label on the photo reads: "*Sello 853*" instead of *Sello 2114*. It therefore must be excluded from the original material.

# A REVISION OF *MALVAVISCUS* (MALVACEAE)[1]

*Billie L. Turner*[2] *and*
*Meghan G. Mendenhall*[3]

## ABSTRACT

Comprehensive reevaluation of herbarium material of the genus *Malvaviscus* yields two widespread species, *M. arboreus* of North America and *M. concinnus* of South America, two localized species, *M. achanioides* of Mexico and *M. williamsii* of Peru and Colombia, and a widespread cultivar of unknown origin, *M. penduliflorus*.

In spite of recent attempts to delimit and classify its many specific and subspecific taxa, *Malvaviscus* (Malvaceae) remains enigmatic. The genus is highly variable morphologically and given to populational forms. Furthermore, these forms intergrade producing an array of character combinations. An extreme taxonomic treatment of the genus would recognize a horde of intergrading forms. Indeed, this extreme infrageneric variation has led to the proposal of over 50 specific names within *Malvaviscus*, though Schery (1942) recognized only three in his monograph of the genus.

Because of the common intergradation and recombination of character states, few characters within *Malvaviscus* have proven useful for specific recognition. Modern interpretations of the genus have generally recognized about a dozen overlapping taxa. However, we believe that the overwhelming majority of the species proposed under *Malvaviscus* represent only two biologically significant taxa, *M. arboreus* in North America and *M. concinnus* in South America.

## HISTORY OF THE GENUS

The genus *Malvaviscus* was established almost 200 years prior to its monograph by Schery (1942). Among the first generic names to include *Malvaviscus* were *Alcea*, *Althaea*, and *Malva*. Linnaeus did not recognize the genus and placed its species in *Hibiscus* in 1753. In 1759, Fabricius distinguished *Malvaviscus* based on a single species, i.e., *Hibiscus malvaviscus* L. (A discussion of the typification of *Malvaviscus* can be found in Taxon 17: 87, 1968.) In 1788, Swartz proposed to rename the genus as *Achania*. In 1824, A. P. de Candolle divided *Malvaviscus* into two sections: *Achania* and *Anotea*. *Anotea* was raised to generic rank by Kunth in 1846, and *Achania* is now recognized as synonymous with *Malvaviscus*.

Generic treatments have not been in agreement. Schery's monograph (1942) included a complex of 11 varieties of *M. arboreus* as well as two additional species that have since been transferred to *Pavonia*. Other treatments, which have recognized up to a dozen species, occur in floras throughout the range of *Malvaviscus* (Robyns, 1966; Standley, 1923; Standley & Steyermark, 1949). However, the only significant treatment of the genus since Schery has been the exemplary work of Fryxell (1988) in his monograph of the Malvaceae of Mexico. In his discussion of the taxonomic problems within *Malvaviscus*, Fryxell acknowledged the difficulty of clearly delimiting species: "There is a certain sameness of morphology that runs through the genus, and clear-cut differentiating characters are lacking." Fryxell recognized six species of *Malvaviscus* in Mexico, three of which are maintained here.

## CHROMOSOME NUMBERS

The first report of a chromosome count for *Malvaviscus* was presented by Skovsted in 1935 (Table 1). He reported a count of $2n$ = ca. 84 for an unidentified cultivated species in Kew Gardens, presumably obtained originally "from gardens on the Gold Coast." We take the species to be *M. penduliflorus* of the present treatment since Skovsted noted:

> Morphologically, the type under observation is distinctly different from the wild growing *M. arboreus* Cav. Its

[1] We are grateful for the encouragement and helpful comments of our esteemed colleague, Paul Fryxell, throughout the course of this study. Our investigation is based upon the examination of approximately 3,200 specimens on deposit at the following institutions: BRG (3), F (701), herb. Fryxell (2), GH (431), HUA (7), LL (200), MG (6), MO (783), NY (492), RB (6), SP (9), TEX (170), US (381). Nancy Webber provided the illustration.

[3] Department of Botany, University of Texas, Austin, Texas 78713, U.S.A.

TABLE 1. Chromosome numbers in *Malvaviscus*.

| Taxon | 2*n* number | Voucher/reference |
|---|---|---|
| *M. arboreus* var. *arboreus* reported as var. *mexicanus* | ca. 56 | Mexico. Veracruz: *Fryxell & Bates 940*; Bates (1976) |
| *M. arboreus* var. *arboreus* reported as var. *mexicanus* | ca. 56 | Mexico. Veracruz: *Fryxell et al. 1676*; Bates (1976) |
| *M. arboreus* var. *arboreus* reported as *M. penduliflorus* | ca. 28 | Mexico. Jalisco: *Fryxell, Bates & Blanchard 1575*; Bates (1976) |
| *M. arboreus* var. *drummondii* | ca. 28 | U.S.A. Texas: Travis Co., *Mendenhall 485*; reported here |
| *M. penduliflorus* reported as *M.* sp. | ca. 84 | Kew Gardens, where cultivated; Skovsted (1935) |
| *M. penduliflorus* | 86 | India. Karnataka: where cultivated; Krishnappa & Munirajappa (1982) |

cytological behaviour indicates that it is probably a hybrid although its origin appears unknown. It is commonly cultivated in Trinidad where it is vegetatively reproduced as it is apparently completely sterile.

Krishnappa & Munirajappa (1982), however, reported *M. penduliflorus* to have a count of $2n = 86$, presumably a miscount of $2n = 84$, or possibly an aneuploid clonal derivative of what would seem to be its original number, $2n = 84$, since other taxa in *Malvaviscus* appear to have an ancestral base number of $x = 14$, if not $x = 7$. Bates (1976) listed a count of $2n =$ ca. 28 for *M. penduliflorus*, but we believe the voucher concerned is more likely a morphological variant of the widespread, highly variable *M. arboreus* var. *arboreus*, as conceived of here.

Our report of $2n =$ ca. 14 pairs for *M. arboreus* var. *drummondii* is to some extent biased because of the report of $2n = 28$ by previous workers. In truth, the count would have been any number between 12 and 15 pairs, the chromosomes being very small and not forming neat bivalents.

In summary, only two taxa of *Malvaviscus* have been counted with reasonable certainty to date: *M. arboreus* var. *arboreus* with $2n =$ ca. 28 and ca. 56, and the cultivated *M. penduliflorus* with counts of $2n =$ ca. 84 and 86 (Table 1). The base number of the genus appears to be $x = 14$, if not 7. The latter base would agree with that found in the large, closely related genus *Pavonia*, where some 35 or more species have been counted, all on a base of $x = 7$, ranging from $n = 14$ to $n = 56$ (although some authors have reported occasional counts of both $n = 13$ for a species that otherwise has been counted as $n = 14$ (e.g., *Pavonia zeylanica* (L.) Cav. with $2n = 52$ (Krishnappa & Munirajappa, 1980) vs. $2n = 56$ (Dasgupta & Bhatt, 1976, 1981, 1982)).

## SPECIES CONCEPT

In this treatment, species concepts in *Malvaviscus* are largely those of the senior author, the junior author being new at the herbarium bench. Because fieldwork on the genus was limited, species concepts are based on morphogeographical considerations and our experience with species recognition in other groups (e.g., Asteraceae, Fabaceae), both in the field and as hypothesized by herbarium evaluations. We believe our specific delimitations in *Malvaviscus* are populational in nature and are comparable to what most workers refer to as good species. We do not claim this to be true for *M. penduliflorus*, for we suspect that the plants referable to this species are relatively uniform, mostly sterile cultivars, developed very early on by accidental or synthetic means. We have recognized *M. penduliflorus* as a "synthetic species," not occurring naturally in the wild except as it has persisted or escaped cultivation by vegetative means, although it is possible that occasional hybrids between *M. penduliflorus* and *M. arboreus* might occur, as noted under the discussion that follows each.

Our species concepts are similar to those of previous revisional workers on *Malvaviscus*, namely Schery (1942) and Fryxell (1988). In spite of the plethora of pressed specimens available for study, extraordinary variation, and widespread distribution of *Malvaviscus*, Schery recognized a single species with eleven varieties while Fryxell recognized six species in Mexico, which suggests that he would likely have recognized less than ten taxa for the remainder of its distribution. In short, our recognition of five species for *Malvaviscus* (including *M. penduliflorus*) is conservative, standing between the evaluations rendered by Schery and Fryxell. Except for *M. penduliflorus*, we believe

the taxa that we have recognized are comparable in nature and constitute populational or biological units that can be verified by future field workers.

## Taxonomic Treatment

**Malvaviscus** Fabr., Enum. 155. 1759. TYPE: *Hibiscus malvaviscus* L. [= *Malvaviscus arboreus* Cav.]. See Dandy (1966) for typification of *Malvaviscus*.

*Achania* Sw., Prodr. 102. 1788. TYPE: *Achania pilosa* Sw.

Erect or clambering (vinelike) shrubs or small trees, pubescent or glabrous. Leaves petiolate, the blades linear-lanceolate to broadly ovate-cordate, unlobed to 3–5-lobed, serrate to subentire; stipules subulate, deciduous. Flowers solitary or several in the leaf axils or sometimes in apical cymes; bractlets of the involucel linear to obovate (rarely broadly ovate), usually (5–)8–9; calyx campanulate or tubular, 5-lobed; petals 5, red (rarely white), asymmetrically obovate-cuneate, auriculate toward the base, forming a tubular corolla; androecium usually exserted, the staminal column with 5 apical teeth, the filaments short and ± retrorse; styles 10 with capitate stigmas. Fruit a fleshy schizocarp, oblate, red (rarely white), with 5 carpels, each 1-seeded. Base chromosome number, $x = 14$.

*Diagnosis and relationships.* *Malvaviscus* is a member of the tribe Malvavisceae C. Presl, Reliq. Haenk. 2: 135, 1835 (as "Malvaviscaceae") by virtue of its five uniovulate carpels, schizocarpic fruit, ten free styles, and apically 5-toothed staminal column. Distinguishing generic characters of *Malvaviscus* are its auriculate petal and red or rarely white baccate fruit. The petal auricle is the basal lobe that gives each petal its characteristic mitten shape. Apical lobes are called simply lobes. The genera thought to be closest to *Malvaviscus* are *Pavonia*, *Lopimia*, and *Anotea*. The largest of these, *Pavonia*, has dry fruits. *Lopimia* and *Anotea* are small genera that have blue-black fruits (dry in *Lopimia*) and lack the auriculate petal.

Although *Malvaviscus* can be found in gardens throughout the tropical and subtropical world, it is native to the Western Hemisphere. Its range extends from Peru and northern Brazil to the southern United States and the West Indies. Although individuals and populations are highly variable, especially in Mexico and Central America, we recognize two major taxa, *M. arboreus* in the north and *M. concinnus* in the south. A third, relatively localized species of northwesternmost South America, *M. williamsii*, is recognized but clearly belongs to the *M. concinnus* complex. Were the characters that mark it not so easily identified, and if it had not already been treated at the specific level, we would probably have recognized this as an intergrading variety of the latter. Finally, for practicality, we maintain two species that would otherwise be absorbed by *M. arboreus*. These are *M. penduliflorus*, a distinctive hybrid cultivar, and *M. achanioides*, an intermediate form between *M. arboreus* and *M. concinnus*.

## Key to Species of *Malvaviscus*

1a. Leaves mostly 15–35 cm long, the blades usually strongly cordate; vestiture of peduncles mostly pilose; corollas mostly 40–70 mm long; calyces mostly 18–30 mm long; fruits mostly 15–30 mm across; South America, Panama, Costa Rica, and Gulf slopes of Honduras and Mexico (Chiapas, Tabasco, Veracruz).
  2a. Calyces mostly 18–20 mm long; vestiture of peduncles and petioles densely pilose with hairs 1–3 mm long; Honduras and Mexico ..... 3. *M. achanioides*
  2b. Calyces mostly 20–30 mm long; vestiture of velutinous hairs mostly 0.2–1.5 mm long; South America, Panama, and Costa Rica.
    3a. Involucellar bracts broadly elliptical-ovate, widest at or near the middle, the margins strongly imbricate; Peru and Colombia ..... 5. *M. williamsii*
    3b. Involucellar bracts filiform to linear lanceolate, broadest at or near the base; South America, Panama, and Costa Rica ..... 4. *M. concinnus*

1b. Leaves mostly 5–20 cm long, if longer the blades ovate to elliptical, abruptly to not at all cordate; vestiture various but not usually densely pilose with hairs 1–3 mm long; corollas mostly 15–70 mm long; calyces mostly 8–18(–20) mm long; fruits, when present, mostly 8–14 mm across; North America and West Indies or else cultivated.
  4a. Cultivated, mostly sterile, rarely producing fruits; flowers pendulous, the corollas mostly 42–70 mm long; leaves ovate and subglabrous; widespread in gardens, and often escaping or persisting following cultivation ..... 2. *M. penduliflorus*
  4b. Wild and cultivated, usually fertile and producing red or white fruits; flowers usually erect, the corollas mostly 15–50 mm long; leaves variable in shape and vestiture; throughout southern and central Mexico, southeastern United States, West Indies, and rarely coastal areas of northern South America, occasionally cultivated and persisting elsewhere.
    5a. Leaves rather uniformly 3-lobed and mostly obtuse at the apex, strongly cordate; stems and petioles diffusely pubescent with overlapping stellate hairs that form a velvety vestiture only rarely exceeding 0.25 mm high;

mostly United States, just barely extending into Mexico along the Gulf coastal regions of Tamaulipas ..... 1b. *M. arboreus* var. *drummondii*

5b. Leaves various, but the blades usually acute at the apices, truncate or cordate; stem and petioles variously pubescent to glabrous, but the vestiture usually not as described above, if evenly velvety-pubescent then some or most of the hairs exceeding 0.25 mm; widespread throughout tropical and subtropical habitats of Mexico, Central America, and West Indies, rarely elsewhere in cultivation ..... 1a. *M. arboreus* var. *arboreus*

**1. Malvaviscus arboreus** Cav., Diss. 3: 131. t. 48. 1787.

Prodr. 385. 1796, nom. superfl. *Malvaviscus malvaviscus* (L.) Millsp., Publ. Field Columbian Mus., Bot. Ser. 2: 73. 1900. TYPE: "Hibiscus malvaviscus" (holotype, LINN-875.22).

*Achania mollis* Aiton, Hort Kew. 2: 459. 1789. *Malvaviscus mollis* (Aiton) DC., Prodr. 1: 445. 1824. TYPE: Mexico (holotype, BM not seen, without additional information according to Fryxell, 1988).

*Achania pilosa* Sw., Prodr. 102. 1788. *Malvaviscus pilosus* (Sw.) DC., Prodr. 1: 445. 1824. *Hibiscus pilosus* (Sw.) Fawcett & Rendle, Fl. Jamaica 5: 137. 1926. TYPE: Jamaica. *Swartz s.n.* (holotype, S not seen, according to Fryxell, 1988).

*Pavonia spiralis* Cav., Icon. 5: 20. t. 434. 1799. *Malvaviscus ciliatus* DC., Prodr. 1: 445. 1824, nom. superfl. *Achania ciliata* Sprengel, Syst. Veg. 3: 100. 1826, nom. superfl. TYPE: Panama. Taboga Island, *Née s.n.* (holotype, MA not seen).

*Malvaviscus cordifolius* Moench, Meth. Suppl. 208. 1802. TYPE: no longer extant, according to Stafleu & Cowan (1981).

*Malvaviscus acapulcensis* Kunth, Nov. Gen. Sp. 5: 288 [folio ed. p. 224]. 1822. TYPE: Mexico. Guerrero: near Acapulco, *Humboldt & Bonpland*, 1803 (holotype, P-HBK not seen, according to Fryxell, 1988).

*Malvaviscus grandiflorus* Kunth, Nov. Gen. Sp. 5: 286 [folio ed. p. 223]. 1822. TYPE: Mexico. Guanajuato: prope Guanajuato, *Humboldt & Bonpland*, 1803 (holotype, P-HBK not seen; fragment holotype, F).

*Malvaviscus pentacarpus* DC., Prodr. 1: 445. 1824. TYPE: Icones Florae Mexicanae no. 124 (Torner Collection acc. no. 631.1093, Hunt Institute). (Cf. photo F-30507 of G copy (not the type), according to Fryxell, 1988.)

*Malvaviscus arboreus* var. *cubensis* Schldl., Linnaea 11: 360. 1837. *Malvaviscus arboreus* subsp. *cubensis* (Schldl.) Hadač, Folia Geobot. Phytotax. Praha 5: 432. 1970. TYPE: Cuba. *Poeppig s.n.* ex herb. Kunze (holotype, LZ destroyed; isotype, W? not seen, according to Fryxell, 1988).

*Pavonia urticaefolia* C. Presl, Reliq. Haenk. 2: 128. 1835. *Malvaviscus urticifolius* (C. Presl) Fryxell, Syst. Bot. 12: 279. 1987. TYPE: Mexico. "In terris occidentalibus" (probably in the state of Guerrero or Mexico during Haenke's trip from Acapulco to Mexico City and return during Nov.–Dec. 1791), *Haenke s.n.* (lectotype, designated by Fryxell (1988), PR-197902A not seen; isolectotype, PR-197902B not seen).

*Malvaviscus sepium* Schldl., Linnaea 11: 361. 1837. *Malvaviscus arboreus* var. *sepium* (Schldl.) Schery, Ann. Missouri Bot. Gard. 29: 226. 1942. TYPE: Mexico. Veracruz: near Xalapa, June 1829, *Schiede 480* (holotype, B destroyed; photoholotype, F, NY).

*Malvaviscus arboreus* var. *mexicanus* Schldl., Linnaea 11: 359. 1837. TYPE: Mexico. Veracruz: near Veracruz, *Schiede s.n.* (lectotype, designated by Fryxell (1988), HAL not seen).

*Malvaviscus brevipes* Benth., Bot. Voy. Sulphur 68. 1844. TYPE: Costa Rica. Nicoya, *Barclay s.n.* (holotype, BM not seen, according to Fryxell, 1988).

*Malvaviscus sagraeanus* A. Rich., Hist. Phys. Cuba, Pl. Vasc. 131. t. 14. 1845 [1841]. *Malvaviscus arboreus* var. *sagraeanus* (A. Rich.) E. G. Baker, J. Bot. 37: 345. 1899. TYPE: Cuba, *de la Sagra s.n.* (holotype, P? not seen; isotype, K not seen, according to Fryxell, 1988).

*Malvaviscus pulvinatus* A. Rich., Hist. Phys. Cuba, Pl. Vasc. 133. 1845 [1841]. TYPE: Cuba, *de la Sagra s.n.* (specimen unknown, according to Fryxell, 1988).

*Malvaviscus arboreus* var. *parviflorus* Griseb., Fl. Brit. W. I. 83. 1859. TYPE: Jamaica. Without locality, without date, *Wullschlaegel 768* (holotype, GOET not seen, according to Fryxell, 1988).

*Malvaviscus palmanus* Pittier & J. D. Smith, Bot. Gaz. (Crawfordsville) 23: 238. 1897. *Malvaviscus arboreus* var. *palmanus* (Pittier & J. D. Smith) Schery, Ann. Missouri Bot. Gard. 29: 222. 1942. TYPE: Costa Rica. San José: forests of La Palma, 5,100 ft., July 1895, *Tonduz 9712* (holotype, CR not seen; isotype, US; photoisotype, MO).

*Malvaviscus arboreus* var. *sloanei* E. G. Baker, J. Bot. 37: 345. 1899. TYPE: Jamaica. Sloane's Herb. vol. iv. F. 45 (holotype, BM not seen, according to Fryxell, 1988).

*Malvaviscus brevibracteatus* E. G. Baker, J. Bot. 37: 347. 1899. TYPE: Belize. Stann Creek, 27 Dec. 1899, *J. Robertson 34, 35* (syntypes, BM not seen, according to Fryxell, 1988).

*Malvaviscus lanceolatus* Rose, Contr. U.S. Natl. Herb. 5: 175. 1899. TYPE: Mexico. Chiapas: near Cicharras, 12–15 Feb. 1896, *Nelson 3807* (holotype, US; isotypes, GH—2 sheets).

*Malvaviscus arboreus* var. *grisebachii* E. G. Baker, J. Bot. 37: 345. 1899. TYPE: Jamaica. (Based on *M. arboreus* var. α Grisebach, which apparently applies to a vestiture form of *M. arboreus* var. *arboreus*.) Grisebach cited no specimen; neither did Baker. Any lectotype, if designation is needed, would presumably reside at BM or K.

*Malvaviscus polakowskii* E. G. Baker, J. Bot. 37: 346. 1899. TYPE: Costa Rica. Without specific locality,

without date, *Polakowsky 197* (holotype, BM not seen).

*Malvaviscus jordan-mottii* Millsp., Publ. Field Columbian Mus., Bot. Ser. 2: 73. 1900. TYPE: Cayman Islands. Cayman Brac, above Spot Bay, 8 Feb. 1899, *Millspaugh 1166* (holotype, F).

*Malvaviscus rivularis* Brandegee, Zoe 5: 211. 1905. TYPE: Mexico. Sinaloa: near Culiacán, banks of the Cofradia River, *Brandegee*, 1904 (holotype, UC not seen; isotype, US).

*Malvaviscus conzattii* Greenman, Field Mus. Nat. Hist. Bot. Ser. 2: 333. 1912. TYPE: Mexico. Oaxaca: San Pablo, Huitzo, 1,600 m, 25 Aug. 1907, *Conzatti 1981* (holotype, F; isotype, K not seen).

*Malvaviscus oaxacanus* Standley, Contr. U.S. Natl. Herb. 23: 775. 1923. TYPE: Mexico. Oaxaca: N of Tuxtepec, 9 Apr. 1894, *Nelson 348* (holotype, US).

*Malvaviscus hintonii* Bullock, Kew Bull. 1937: 291. 1937. *Malvaviscus arboreus* var. *hintonii* (Bullock) Schery, Ann. Missouri Bot. Gard. 29: 217. 1942. TYPE: Mexico. Mexico State: Distr. Temascaltepec, Tejupilco, 15 May 1933, *Hinton 3928* (holotype, K not seen; isotypes, A, NY).

*Malvaviscus arboreus* var. *brihondus* Schery, Ann. Missouri Bot. Gard. 29: 213. 1942. TYPE: Belize. Honey Camp, Sep. 1929, *Lundell 480* (holotype, MO; isotypes, F, US).

*Malvaviscus arboreus* var. *lobatus* Robyns, Ann. Missouri Bot. Gard. 52: 572. 1966. TYPE: Panama. Chiriquí: Fred Collins' Finca at edge of coffee plantation, 6,000 ft., 2 Aug. 1960, *J. Ebinger 692* (holotype, MO; isotype, F).

Erect or clambering shrubs 1–10 m high. Stems variously stellate-pubescent to glabrate, rarely glabrous. Leaves mostly 5–25 cm long, 3–12 cm wide, petioles mostly 1–12 cm long, the blades variously ovate to cordate, less often elliptical, mostly unlobed, but occasionally with shallow subterminal lobes, variously irregularly serrate, or rarely entire, pubescent with mostly stellate hairs, often densely so, but sometimes glabrous or nearly so. Calyces mostly 8–15(–18) mm long, variously pubescent, the hairs simple or stellate, rarely glabrous, the subtending bracts mostly 5–8(–11), linear to linear-oblanceolate. Corollas red, rarely white, mostly (15–)20–42(–50) mm long, the petals mostly imbricate at anthesis, not normally flaring. Staminal column usually exserted for ca. ¼ of its length, rarely included. Fruit usually bright red but sometimes white, 8–14(–16) mm across. Chromosome number, $2n$ = ca. 14 and 28 pairs.

We interpret this widespread, highly variable species as having a single populationally meaningful variety, variety *drummondii*, as noted below. We include in variety *arboreus* most other material previously placed in *M. arboreus* from North America north of Panama, and that from the West Indies. This includes *Malvaviscus arboreus* var. *mexicanus*, recognized by Fryxell (1988), and other taxa accepted by him as distinct, as noted in the synonymy above. *Malvaviscus arboreus* var. *arboreus* is perhaps the most variable species that the senior author has had the displeasure to work with. Detailed mapping of character states in Mexico and other regions reveals a hodge-podge of variation that must relate to localized genetic partitioning, as well as environmental influences. Thus, while any given population is relatively uniform with respect to, say, vestiture or leaf shape, closely contiguous as well as distant populations may show markedly different vestiture types and leaf shapes. The same may be said with respect to corolla and calyx size, and their vestiture.

A similar type of variation to that mentioned above is found throughout the West Indies and in Central America; all of this must be evident from the considerable synonymy and varietal names that have been proposed for *M. arboreus*.

We also believe that at least some of the variation found in *M. arboreus* must have arisen relatively recently by local hybridization with *M. penduliflorus*, a cultivar which, for convenience and because of its wide introduction in gardens throughout the world, we have treated as a species. Evidence for this is mostly speculative (based largely on herbarium collections from areas where *M. arboreus* grows with or near *M. penduliflorus*) for, as noted by Fryxell (1988), *M. penduliflorus* appears to be largely sterile (at least it does not readily set fruit). Nevertheless, occasional plants do develop fruits; indeed, in parts of southern Mexico and Central America, fruiting specimens assignable to that species seem to occur. The latter plants might be viewed as ancestral fruiting stocks of *M. arboreus* (we have treated these as such), from which the remarkably uniform *M. penduliflorus* developed. This is discussed in more detail under the latter.

*Distribution (Figs. 1, 2).* Mexico, West Indies, and throughout most of Central America (occasionally cultivated elsewhere, as indicated below), 0–2,000 m; flowering all seasons.

*Diagnosis and relationships.* We include *M. hintonii* in synonymy under *M. arboreus* var. *arboreus*, although Fryxell (1988) maintained the species (as *M. urticifolius*), while Schery reduced it to varietal rank under *M. arboreus*. The name is applied to specimens with white corollas, which otherwise appear to have the characters of *M. arboreus*. Indeed, it might reside within our concept of *M. penduliflorus*, except for its shorter corollas and pilose vestiture along the upper stems. One of the syntypes of *M. hintonii* (*Hinton 7912*, NY, US) has a notation by the collector that "the

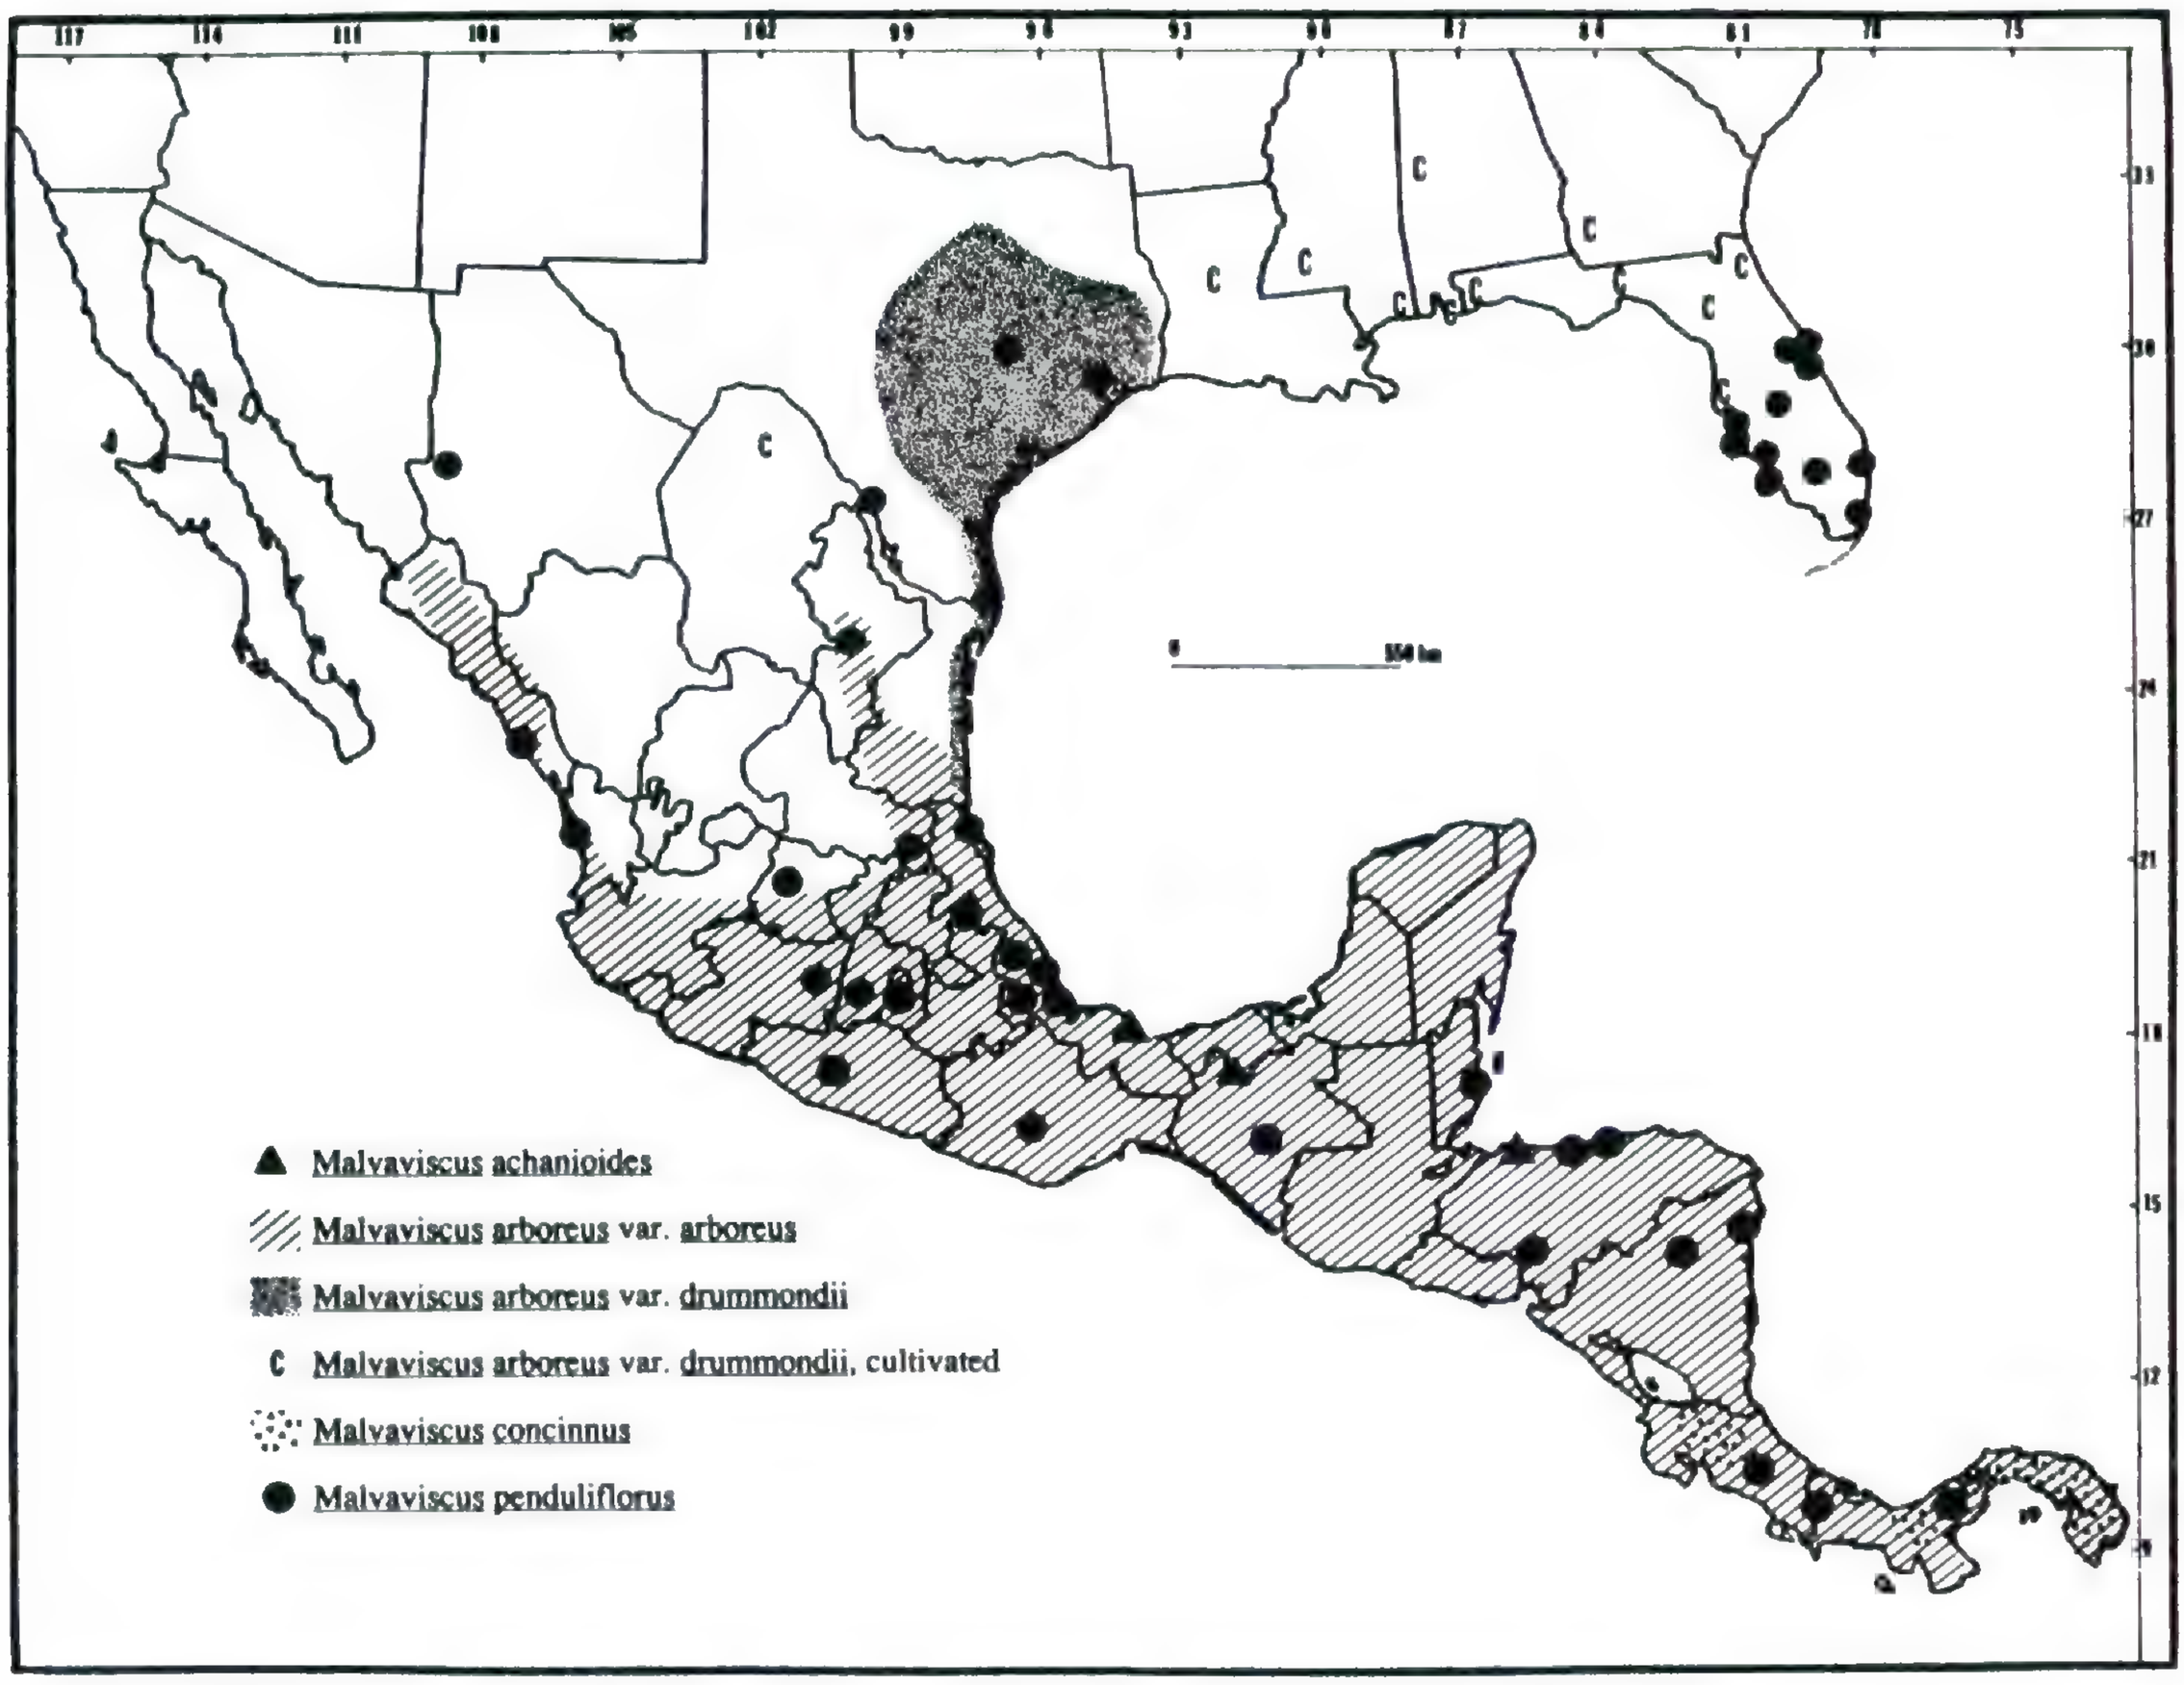

FIGURE 1. Natural distribution of *Malvaviscus* in North and Central America. Isolated collections of *Malvaviscus arboreus* var. *drummondii*, which are marked with "C," are known to be cultivated, thought to have persisted after cultivation, or thought to have escaped from cultivation.

fruit is very rare," suggesting that this might be a color form of *M. penduliflorus*, or perhaps a hybrid segregate between the latter and *M. arboreus*. For additional discussion of this problem see *M. penduliflorus*.

*Malvaviscus conzattii*, because of its relatively large corollas and lanceolate leaves, was relegated to synonymy under *M. penduliflorus* by Schery (1942). Corolla size would position it in our concept of the latter, but its leaf blade shape (having cordate bases) suggests that it belongs to the *M. arboreus* complex, although it is possible that the type concerned is of hybrid origin, as noted above.

*Malvaviscus oaxacanus* and *M. lanceolatus* were both retained by Fryxell (1988), but we believe these to be localized populational "calyx-forms" or "leaf-forms" of *M. arboreus* var. *arboreus*. *Malvaviscus oaxacanus* possesses a rather dense, short, furfuraceous vestiture on the calyces, otherwise it is very similar to *M. arboreus*. *Malvaviscus lanceolatus* has lanceolate-elliptic, nearly glabrous leaves (similar to those of *M. penduliflorus*) and nearly glabrous involucels, otherwise it is very similar to typical *M. arboreus*. Schery (1942) also included both of these names in synonymy under *M. arboreus*.

In an initial "run-through" of the entire *M. arboreus* complex, we thought it possible to recognize *M. lanceolatus* as distinct, but restricted the name to those individuals and/or populations with strictly ovate-elliptic, nearly glabrous leaves and glabrous or nearly glabrous calyces. So construed, the "species" would have comprised (along with the type) the following specimens: MEXICO. CHIAPAS: Mpio. Unión Juárez, between Unión Juárez and Santo Domingo, 1,060 m, 6 Sep. 1980, *Fryxell 3203* (MO, NY). OAXACA. ca. 8.4 mi. S of Putla de Guerrero, ca. 1,000 m, 16 Jan. 1979, *Croat 45810* (MO); Putla, Vicente, ca. 1,200 m, *MacDougall*, 1970 (NY); Juquila, Lachao, Santa Rosa, ca. 1,200 m, *MacDougall*, 1971 (NY); Yaveo, Arroyo San Pedro, 440 m, 23 Mar. 1938, *Mexia 9204* (GH, MO, NY, US); S slope of Sierra S of Lachao, 1,700 m, 5 Dec. 1962, *Moran 10114* (US). Fryxell (1988), however, cited specimens from Nayarit, Jalisco, Morelos, and Puebla that we intended to include within our concept of *M. arboreus* var. *arboreus*, most of these having ovate

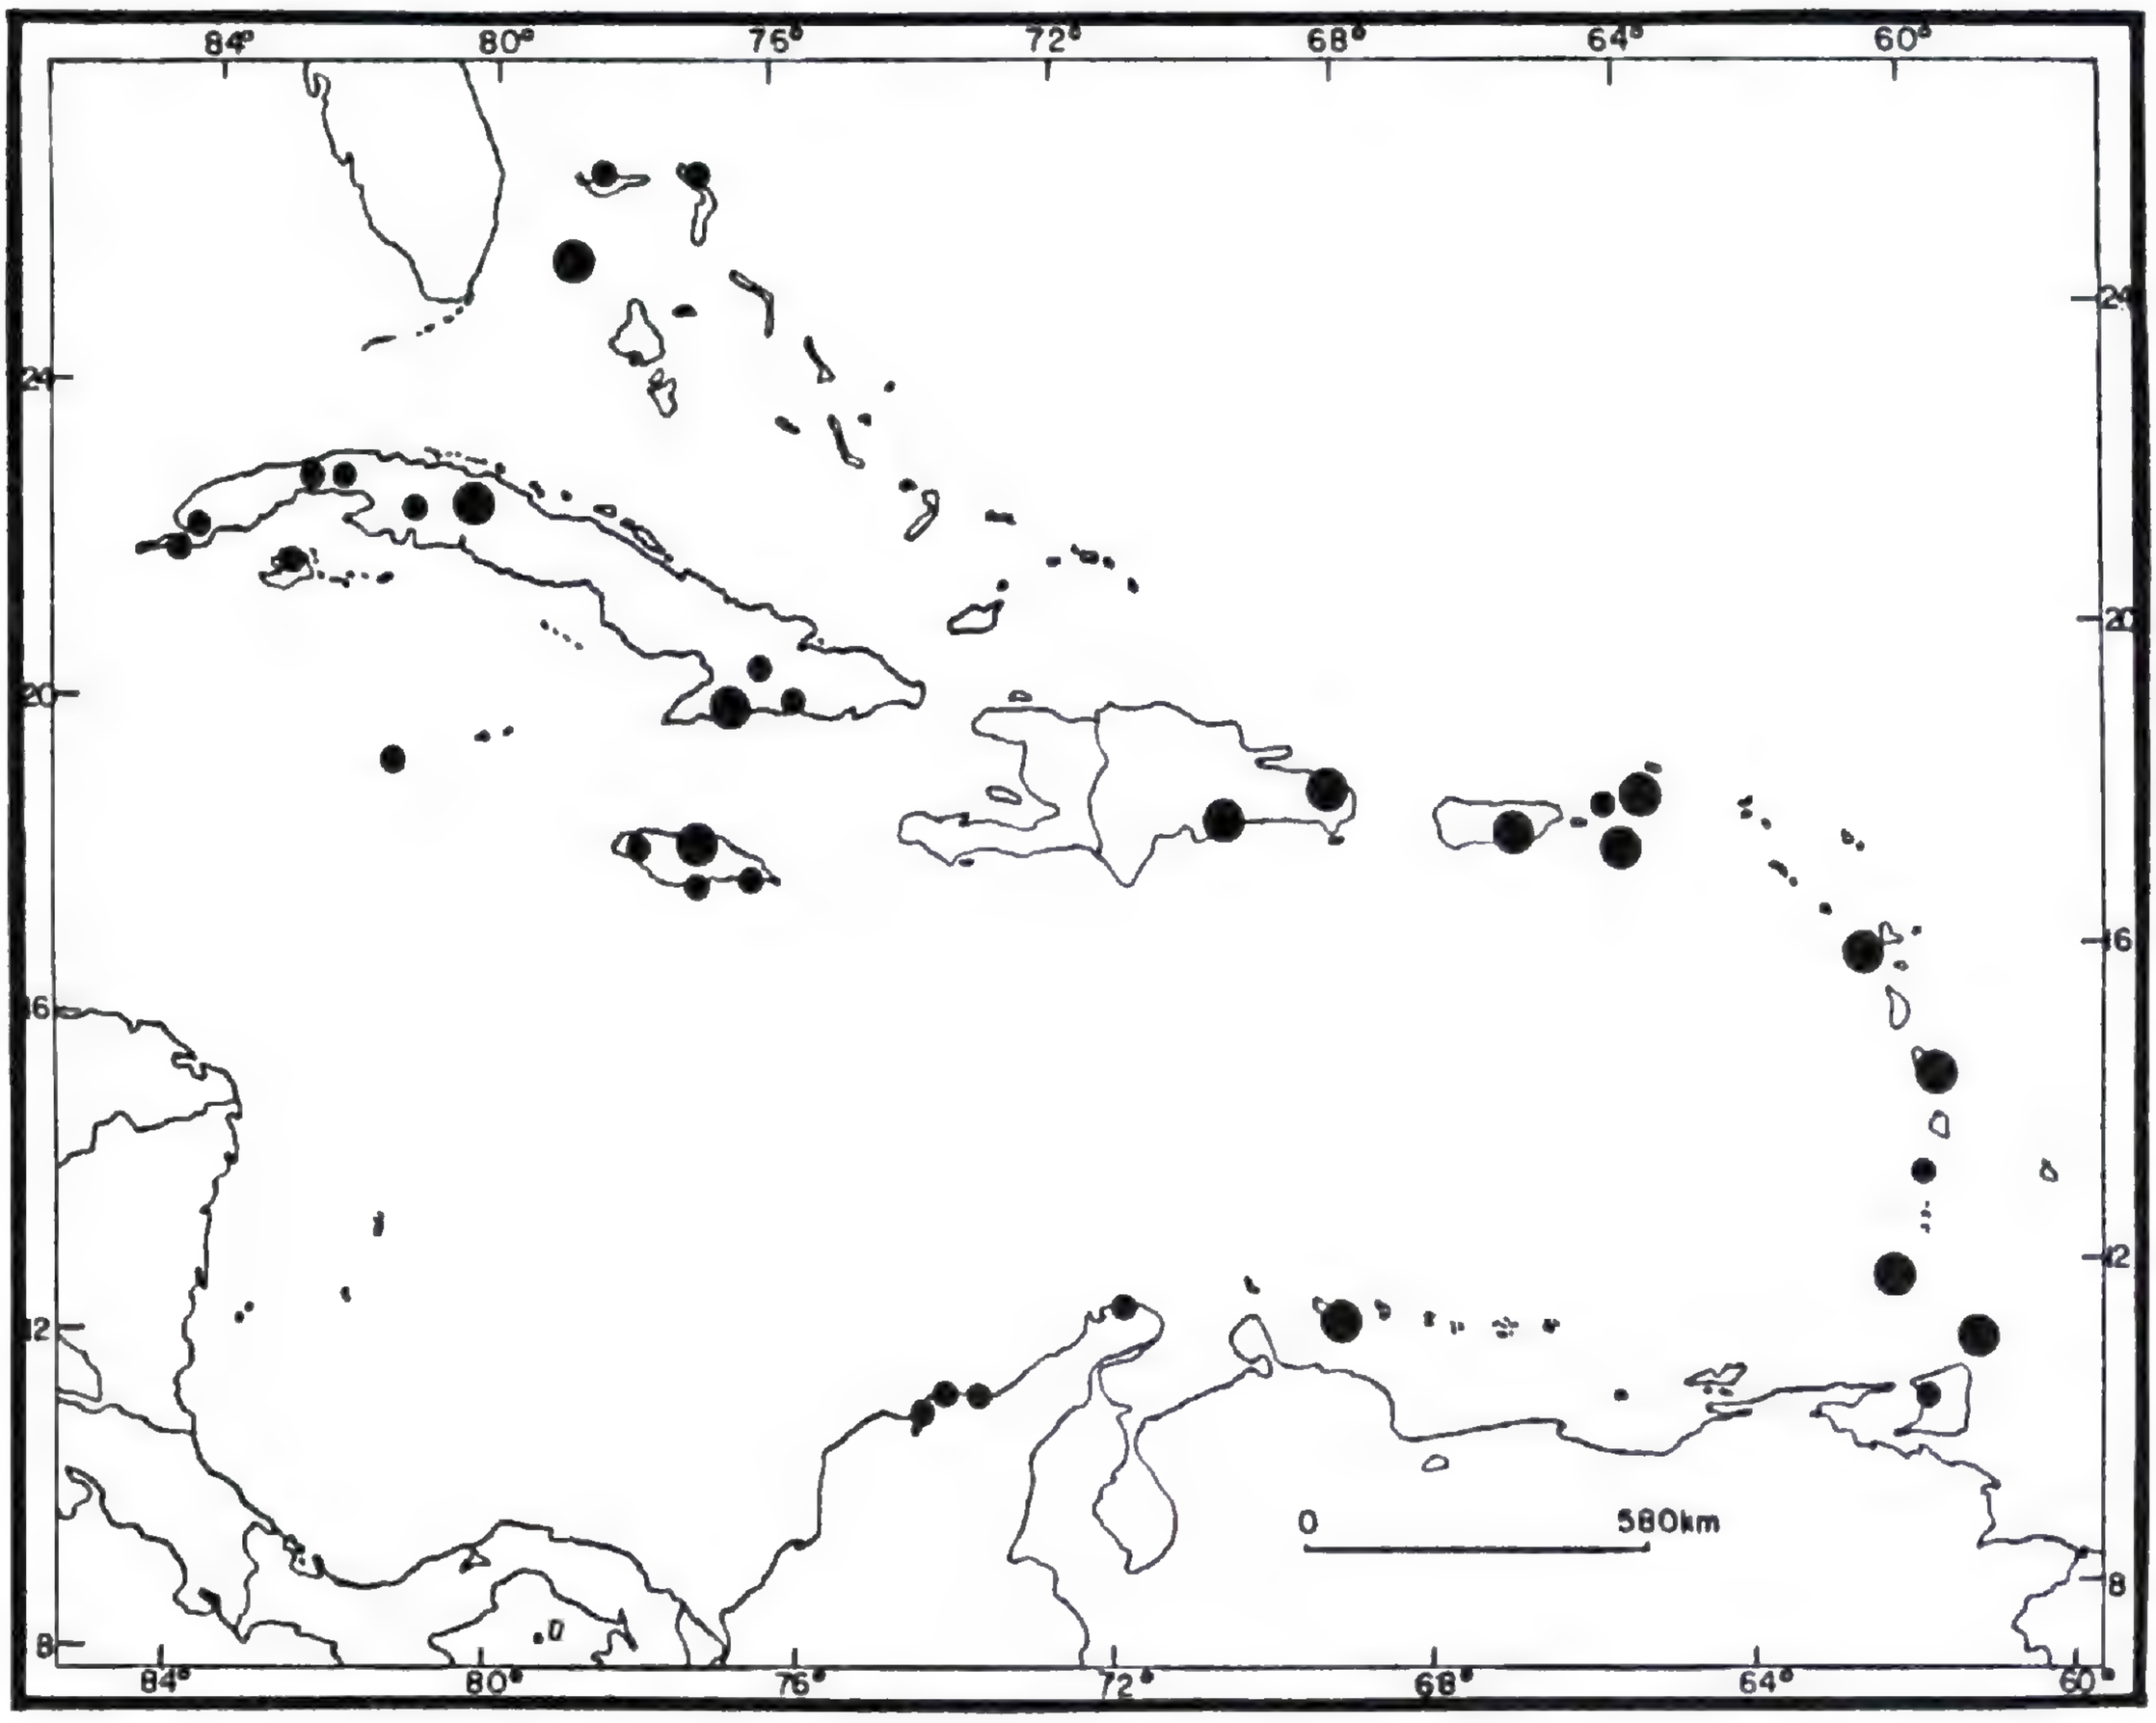

FIGURE 2. Collections of *Malvaviscus arboreus* var. *arboreus* (small closed circles); and *M. penduliflorus* (large closed circles) from the West Indies.

leaf blades and a vestiture reminiscent of the latter. Indeed, all of *M. lanceolatus*, sensu Fryxell, can be submerged within *M. arboreus* without creating much of a morphological ripple, for even as we intended to circumscribe *M. lanceolatus*, the taxon would have differed from *M. arboreus* by a combination of weakly differentiating characters, mainly leaf shape (lanceolate-elliptic), essentially glabrous stems and foliage, relatively large glabrous calyces, and longer corollas (mostly 40–50 mm). The same can be said with respect to the "cultivar," *M. penduliflorus*, for it appears to be a largely sterile derivative from the *M. arboreus* complex centering about *M. lanceolatus* (sensu Fryxell). Indeed, all of the characters that purportedly distinguish *M. penduliflorus* and *M. lanceolatus* from *M. arboreus* crop up in one or more combinations throughout the range of *M. arboreus*, as treated here. For example, *M. palmanus* has been applied to populations from Central America having ovate-elliptic blades and other characters resembling those of *M. lanceolatus*.

In eastern Panama and parts of Costa Rica, *M. arboreus* shows variation in the direction of *M. concinnus*, especially in the size of calyx and fruit and in leaf shape and vestiture, and occasional specimens from this region have been somewhat arbitrarily positioned in one or the other species. A case might be made for the treatment of the mostly South American *M. concinnus* as a broad regional variety of *M. arboreus*, such as was done by Schery (1942) under the name *Malvaviscus arboreus* var. *longifolius*. Strangely, Robyns (1966), in his treatment of *Malvaviscus* for Panama, mentioned none of this variation, relegating all of the Panamanian material that he examined to *M. arboreus* var. *mexicanus*, including the cultivated *M. penduliflorus*. Nevertheless, he described a new variety, *M. arboreus* var. *lobatus*, which is no more than a form of his *M. arboreus* var. *mexicanus* with apically lobed petals.

*Representative specimens examined.* UNITED STATES. FLORIDA: Monroe Co., Big Pine Key, hammock borders, 26 July 1981, *Brumbach 9708* (GH, MO, cultivated?). HAWAII: Maui, Kohala, persistent along roadside, 8 Aug. 1926, *Degener 9840* (NY, cultivated?). LOUISIANA. Orleans Parish, New Orleans, 1 Nov. 1971, *Ewan 23082* (NY, cultivated). NORTH CAROLINA: New

Hanover Co., Wilmington, along railroad cut, 3 Sep. 1970, *Leonard 3714* (GH, NY). MEXICO. CAMPECHE: Tuxpeña, 22 Nov. 1931, *Lundell 970* (A, F, MO, NY, US). CHIAPAS: Nuevo Amatenango, 1,300 m, 17 July 1941, *Matuda 4724* (A, LL, MO, NY). COLIMA: without locality, 1–31 Dec. 1890, *Palmer 963* (GH, NY, US). DISTRITO FEDERAL: Tlalpam, July 1905, *Rose 8497* (GH, NY, US). DURANGO: 10 mi. N of Tamazula, deep canyon bottom, 1,500 ft., 19 Dec. 1939, *Gentry 5258* (GH, MO, NY). GUANAJUATO: San Miguel Allende, 9 Aug. 1947, *Kenoyer 1912* (A). GUERRERO: Mina, Manchon, ravine, 27 Sep. 1936, *Hinton 9597* (A, F, MO, US). **1b. Malvaviscus arboreus** var. **drummondii** (Torrey & A. Gray) Schery, Ann. Missouri Bot. Gard. 29: 215. 1942. *Malvaviscus drummondii* Torrey & A. Gray, Fl. N. Amer. 1: 230. 1838. *Pavonia drummondii* (Torrey & A. Gray) Torrey & A. Gray, Fl. N. Amer. 1: 682. 1840. *Hibiscus drummondii* (Torrey & A. Gray) M. J. Young, Familiar Lessons in Botany with Flora of Texas 186. 1873. TYPE: United States. Texas: Austin Co., San Felipe de Tejas, *T. Drummond*, 1835 (Texas Drummond Coll. III, no. 1) (lectotype, selected here, NY [Torrey herbarium]; isolectotype, GH; probable isolectotype, NY).

Selection of a NY specimen from the Torrey collection as lectotype was necessitated by the absence of material at GH that might have been examined by either Gray or Torrey; the isotypes cited above were accessioned by GH well after *M. drummondii* was published.

It is unclear whether Young was describing *Hibiscus* as a new species, as a new combination after Torrey & A. Gray, or as a previously treated taxon. It is unlikely that Young intended to present a new species. Elsewhere in the flora Young's new species bear the notation "n. sp." The specimen described was certainly of Torrey & Gray's previously described *Malvaviscus drummondii* (red flowers, red fruit), and the identical specific epithet suggests Young was transferring the species to *Hibiscus*. However, Young did not cite Torrey & Gray as basionym authors and did not specifically state that *Hibiscus drummondii* was a new combination. Young did have at least indirect access to the *Flora of North America*; Torrey & Gray were cited elsewhere in the flora. However, many species that Torrey & Gray had named did not include an author citation. It seems possible that Young was simply unable to associate an author with what she thought was a legitimate name, *Hibiscus drummondii*.

*Malvaviscus arboreus* var. *drummondii* closely resembles variety *arboreus*, but the former plants are erect suffruticose, clone-forming, herbs or shrublets 0.5–1.5 m high; blades having mostly obtuse or rounded apices and abruptly cordate bases, the vestiture of petioles and peduncles densely and uniformly stellate-pubescent, the hairs

scarcely exceeding 0.25 mm. Chromosome number, $2n$ = ca. 14 pairs.

*Distribution (Fig. 1).* Sparsely occurring in northeastern Mexico and southern Texas along the Gulf Coast, but more widespread (albeit patchy) and numerous throughout central and eastern Texas, especially in rich soils along streams in shaded areas, cultivated or escaped from cultivation eastward to Florida; flowering all seasons, depending upon time, severity, and duration of frost conditions.

*Diagnosis and relationships.* According to Schery (1942), the variety *drummondii* "is one of the most distinct varieties of *M. arboreus*," which is an overstatement if one considers that he included within his concept of *M. arboreus* several taxa that others, including the present workers, would treat as distinct species. Actually, variety *drummondii* is a weakly differentiated, relatively uniform, populational complex of *M. arboreus*, which is largely restricted to central Texas. Southward along the Gulf coastal region of northeastern Mexico it appears to grade into variety *arboreus*, especially in the vicinity of Tampico, Mexico. Southward from Tampico variety *arboreus* becomes increasingly shrubby or clambering, the leaves less uniformly lobed, with mostly acute apices and a vestiture on the petioles and stems that is sparsely distributed, usually in lines, or sometimes glabrate or nearly so. Fryxell (1988) did not account for *M. arboreus* var. *drummondii* in his treatment of Mexico; the several specimens from Mexico that we cite here as belonging to variety *drummondii* are superficially similar to variety *arboreus* and, as indicated, the two taxa appear to intergrade in northeastern Mexico.

It is questionable whether variety *drummondii* is truly native to the states east of Texas, although it is certainly native to Texas, as attested to by the numerous and remarkably uniform populations that grow in central Texas. The taxon apparently was, early on, taken into cultivation in the more coastal southeastern United States. Collections in this area have been relatively isolated and are represented in Figure 1 as cultivated, whether known to be cultivated, thought to be persisting after cultivation, or thought to be escaped.

*Representative specimens examined.* UNITED STATES. ALABAMA: Tuscaloosa Co., University of Alabama campus, near Smith Woods, 25 July 1965, *Dermus 444* (GH, cultivated?). FLORIDA: Columbia Co., ca. 3 mi. **2. Malvaviscus penduliflorus** DC., Prodr. 1: 445. 1824. *Malvaviscus arboreus* var. *penduliflorus* (DC.) Schery, Ann. Missouri Bot. Gard. 29: 233. 1942. *Malvaviscus arboreus* subsp. *penduliflorus* (DC.) Hadač, Folia Geobot. Phytotax. 5: 432. 1970. TYPE: Mexico. Without locality, date, or collector, Icones Florae Mexicanae no. 100 (Torner Coll. acc. no. 6331.1712, Hunt Institute, according to Fryxell, 1988).

*Malvaviscus penduliflorus*, except for its large corollas (mostly 5–6 cm long) and somewhat larger calyces (mostly 15–20 mm long), falls well within the descriptive parameters of *M. arboreus* var. *arboreus*. Chromosome number, $2n$ = ca. 84, 86.

*Distribution (Figs. 1–3).* *Malvaviscus penduliflorus* is a widespread cultivar of unknown origin. It is widely planted in gardens throughout the New World and escapes cultivation, to judge from information on herbarium labels. In addition, it is believed to hybridize occasionally with locally native taxa, mostly *M. arboreus*; flowering all seasons.

*Diagnosis and relationships.* *Malvaviscus penduliflorus* is remarkably uniform throughout its artificial range and is distinguished from *M. arboreus* var. *arboreus* by its larger corollas (mostly 50–60 mm long vs. 20–50 mm) and somewhat larger calyces (mostly 15–20 mm long vs. 10–15 mm). In addition, the leaves are nearly always ovate and subglabrous, and the flowers tend to be single and axillary with a pendulous nature. Its original habitat (or the area from which the "cultivar" might have arisen) is unknown, but it was first described by de Candolle from drawings made for the *Icones Florae Mexicanae* (cf. Fryxell, 1988), perhaps from garden material. As noted by Fryxell (1988), the species only rarely sets fruit, and this is verified by our own observations. Nevertheless, the area of origin of this species is probably south-central Mexico, for numerous collections from this region might reside within the descriptive parameters of *M. penduliflorus* except that the corollas tend to be shorter.

It is likely that *M. urticifolius* (= *M. hintonii*) is a white-flowered corolla form of *M. penduliflorus* with somewhat shorter petals, for as noted by Fryxell (1988), *M. hintonii* appears to be largely sterile and appears to occur in cultivation. We have, nevertheless, placed *M. hintonii* within the synonymy of *M. arboreus* var. *arboreus* because its leaf shape and vestiture more closely resemble that of *M. arboreus*. Certainly, it is not typical of material we include under *M. penduliflorus*. The corolla of *M. penduliflorus* is nearly always crimson or red; occasional specimens will have corollas that are pale pink (e.g., *Hu 12353A*, from Hong Kong, US), or "pure white" (*Plowman 11215*, Peru, F). It should also be noted that while the androecium is normally included within, or barely exceeding the corolla, as noted by Fryxell (1988), it is not uncommon to find the androecium extending beyond the corolla for 1–3 cm (e.g., *Cowan 4923*, TEX; *Hinton 13529*, LL; *Taylor 36*, TEX); at least this is true for our concept of this widespread, cultivated taxon.

We accept the likelihood that *M. hintonii* is a synonym of the earlier *M. urticifolius* (as treated by Fryxell, 1988), the latter having been first collected by Haenke, probably on his trip from Acapulco to Mexico City and return during the year 1791.

As noted under *M. arboreus* var. *arboreus*, it is likely that occasional hybridization between *M. arboreus* and *M. penduliflorus* occurs, at least to judge from seemingly intermediate specimens, most of these occurring in regions where both are known to occur near each other.

This is all discussed here to emphasize that the probable region of origin of the morphologically uniform cultivar *M. penduliflorus* is south-central Mexico, perhaps from the region south of Mexico City.

*Representative specimens examined.* UNITED STATES. **3. Malvaviscus achanioides** (Turczaninow) Fryxell, Syst. Bot. 4: 253. 1979. *Abelmoschus achanioides* Turczaninow, Bull. Soc. Imp. Nat. Moscou 31: 196. 1858. *Hibiscus achanioides* (Turczaninow) Hemsl., Biol. Centr. Amer., Bot. 1: 121. 1879. TYPE: Mexico. Tabasco: "in sylvis Teapae," 2,000 ft., *Linden 838* [*938*] (holotype, not located; photoisotype, F).

*Malvaviscus cutteri* Standley, Publ. Field Columbian Mus., Bot. Ser. 4: 315. 1929. TYPE: Honduras. Atlantida: Lancetilla Valley near Tela, Dec. 1927–Mar. 1928, *Standley 54127* (holotype, F; isotypes, A, US).

Shrub or small tree 1–4 m high. Stem densely pilose, the hairs 1–2 mm long. Leaves mostly 15–35 cm long, 5–20 cm wide, scarcely reduced upward; petioles 3–15 cm long, pilose like the stem; blades broadly ovate to cordate, rarely weakly lobed, pubescent on both surfaces, especially along the major veins, the margins irregularly serrate, undulate, to nearly entire. Flowers mostly 1–7 in short terminal subfasciculate clusters, or rarely 20–30 in an abbreviated panicle, the peduncles mostly 0.5–3.0 cm long. Calyces mostly 16–22 mm long, pilose, yellowish, the subtending bracts 8–11 and

about ½ as long at the calyx. Corollas 4–5 cm long, red, not flaring, petal apices occasionally lobate. Fruit ca. 15 mm across, fleshy, and red.

*Distribution (Fig. 1).* Eastern Honduras to Mexico, along the lower montane slopes and adjacent flood plains of the Gulf coastal regions, mostly evergreen rainforests, 100–1,000 m; flowering October to January.

*Diagnosis and relationships.* The large leaves, which are scarcely reduced upward along the stem, pilose vestiture, and large calyces distinguish this species from the more typical elements of *M. arboreus*. In vegetative characters, and because of its large yellowish calyces, it approaches *M. concinnus* of South America, but in most other traits it is like *M. arboreus*.

Specimens from Honduras, which have been called *M. cutteri*, have somewhat larger, thinner, more cordate, leaves than specimens from Mexico; otherwise these are quite similar. Occasional specimens from the more montane Pacific slopes of western Chiapas (e.g., *Matuda 5357*, Boquerón, ca. Motozintla, 2,540 m, LL), and perhaps some of those examined by Fryxell (1988) but not examined by us, resemble *M. achanioides* in vestiture and leaf shape, but in other characters they more nearly approach *M. arboreus* (e.g., the corollas are quite short, ca. 30 mm long, and tend to flare) and we have placed such collections in the latter, believing the pubescence and larger leaves to be convergent characters in this area.

An alternative treatment might include all of *M. achanioides* within an expanded *M. arboreus*, but that would also collapse the more artificially maintained *M. penduliflorus*. In short, we have maintained a nomenclature that is both traditional and pragmatic, though imperfect if one considers the character variations found in the occasional populations, which tend to blur the specific lines proposed.

Finally, except for its somewhat smaller calyces and less flaring, somewhat shorter corollas, *M. achanioides* is similar to the more southern *M. concinnus*, and some future workers might opt to treat the former as part of the latter complex.

*Additional specimens examined.* MEXICO. CHIAPAS: Mpio. Ixtacomitán, stream above Ixtacomitán, 455 m, *Breedlove 56796* (LL, NY). TABASCO: Mpio. Teapa, Cerro del Cocona, 3 km from Teapa, 26 Oct. 1980, *Cowan 3318* (F, MO, NY, TEX); Grutas del Cocona, ca. Teapa, 18 Nov. 1979, *Ramos 2696* (NY). VERACRUZ: 5 km E of Tebanca (5 km E of E side of Lago Catemaco), 830 m, 15 Jan. 1981, *Nee 19971* (F). GUATEMALA. *Martínez et al. 23588* (MO). HONDURAS. ATLANTIDA: Lancetilla Valley near Tela, 6 Dec.–20 Mar. 1928, *Standley 52756* (A, F, US).

4. **Malvaviscus concinnus** Kunth, Nov. Gen. & Sp. 5: 286. 1822. *Achania concinna* (Kunth) Sprengel, Syst. Veg. ed. 16, 3: 100. 1826. TYPE: Ecuador. Loja: "Crescit prope Loxam Peruvianorum," *Humboldt*, 1802 (holotype, P-HBK not seen; photoisotype (from Berlin), F, GH).

*Malvaviscus balbisii* DC., Prodr. 1: 445. 1824. TYPE: Brazil (according to Index Kewensis). Without locality, without collector (holotype, G-DC, microfiche (single leaf only)).

*Malvaviscus cordatus* Balbis ex DC., Prodr. 1: 445. 1824. nomen nudum (merely listed by de Candolle as synonymous with *M. balbisii* DC.).

*Malvaviscus populifolius* C. Presl, Reliq. Haenk. 2: 135. 1853. TYPE: "In terris occidentalibus Mexici," without date, *Haenke s.n.* (holotype, PR not seen; photoholotype TEX, from negative in possession of Fryxell, who graciously loaned the same).

Fryxell did not account for this name in his Mexican treatment but noted that the type material does "not conform to anything I have seen from Mexico" (pers. comm.). We agree with this observation and believe that the type concerned, on morphological grounds, is best placed with *M. concinnus*, thinking that Haenke probably collected the material in Central or South America, but subsequently mislabeled as from Mexico, as also suggested by Fryxell (pers. comm.).

*Malvaviscus elegans* Linden & Planchon, Pl. Columb. 1863. TYPE: Venezuela. Trujillo: La Pena, 1,675 m, ca. 1846, *Schlim 751* (holotype, BR not seen; photoisotype, F).

This tome (*Plantae Columbianae*) was not effectively published until ca. 1875, according to Sprague (1927). The name, however, was only questionably published at that time, there being only five copies produced for distribution and these without knowledge of the authors concerned. Guerke (1892) took up the name, and one might give the latter date as the point of effective publication.

*Malvaviscus funckeanus* Linden & Planchon, Pl. Columb. 1863. TYPE: Venezuela. Distrito Federal: Caracas, La Cumbre, without date, *Funck 372* (holotype, BM not seen).

See discussion after *M. elegans*, above. Guerke (1892) took up this name for his *Flora Brasiliensis* treatment.

*Malvaviscus speciosus* Linden & Planchon, Pl. Columb. 1863. TYPE: Venezuela. Mérida: forests, 1,950 m, Aug. 1842, *Linden 354* (holotype, BM not seen; photoisotype, F).

See discussion after *M. elegans*, above.

*Malvaviscus spathulatus* Garcke in Otto & Dietr., Allg. Gartenzeitung 21: 321. 1853. TYPE: Costa Rica. *Oersted 407* (holotype, B destroyed?; photoholotype, F-9429; isotype, C not seen; photoisotype, F-21598).

*Malvaviscus longifolius* Garcke in Otto & Dietr., Allg. Gartenz. 22: 321. 1854. TYPE: cultivated in Erfurt, Germany, from seed collected in northern Peru,

*Warszewicz s.n.* (holotype, B destroyed?; photoholotype, F-9427).

*Malvaviscus cuspidatus* Turcz., Bjull. Moskovsk. Obšč. Isp. Prir., Otd. Biol. 31: 190. 1858. SYNTYPES: Venezuela. Caracas: La Cumbre, *Funck 350* (specimen not located); Caracas, La Cumbre, *Funck* [*Galeotti*] *372* (syntypes, G not seen, P not seen; photosyntype, F-23715, according to Fryxell, 1988).

*Malvaviscus oligotrichus* Turcz., Bjull. Moskovsk. Obšč. Isp. Prir., Otd. Biol. 31: 190. 1858. *Malvaviscus glabrescens* Planchon & Linden ex Triana & Planchon, Ann. Sci. Nat. (Paris) 17: 168. 1862, nom. superfl. TYPE: Colombia. Norte de Santander: Ocaña, 1850, *L. Schlim 105* (isotype, G not seen; photoisotype, F).

*Malvaviscus leucocarpus* Planchon & Linden ex Triana & Planchon, Ann. Sci. Nat. (Paris) 17: 169. 1862. TYPE: Colombia. Sativa, Cordillera Oriental, *Triana 5278/3* (lectotype, P not seen; isolectotype, COL not seen, according to Fryxell).

See: Bol. Soc. Argent. Bot. 8: 101. 1960.

*Malvaviscus velutinus* Planchon & Linden ex Triana & Planchon, Ann. Sci. Nat. (Paris) 17: 168. 1862. TYPE: Colombia. Tolima: Maraquita, "Entre la Mesa et El Espinal, bassin du Magdalena," 400–1,200 m, Jan. 1854, *Triana 3132* (holotype, P not seen; isotypes, NY not seen, US not seen; according to Fryxell, pers. comm.).

*Malvaviscus guerkeanus* Hieron., Bot. Jahrb. Syst. 21: 320. 1895. TYPE: Colombia. Low wet areas along Río Magdalena, Mar. 1868, *A. Stuebel 106b* (lectotype, B destroyed?; isolectotypes, F, GH).

*Malvaviscus maynensis* Huber, Bol. Mus. Paraense Hist. Nat. 4: 583. 1906. TYPE: Peru. "Cerro de Canchahuaya," Quebrada de Cerrado, 27 Oct. 1898, *J. Huber 1383* (holotype, MG; photoholotype, F; isotype, R).

*Malvaviscus integrifolius* Ulbr., Verh. Bot. Vereins Prov. Brandenburg (1908) 88. 1909. TYPE: Brazil. Amazonia: "bei Humaytha am oberen Juruá," 22 Apr. 1901, *E. Ule 5444* (holotype, B destroyed?; fragment holotype, R; photoholotype, F, GH; photoisotype, US).

*Malvaviscus ulei* Ulbr., Notizbl. Königl. Bot. Gart. Berlin 6: 328. 1915. TYPE: Brazil. Amazonia: "Alto Acre bei Seringal Auristella," June 1911, *Ule 9591* (holotype, B destroyed?; photoholotype, GH).

Shrubs, small trees, or clambering vines, mostly 1–8 m high. Leaves broadly ovate to cordate, densely pubescent to subglabrous, the vestiture uniformly short and variously spaced to long and closely packed so as to appear velutinous. Flowers single and axillary, or in terminal aggregations, the peduncles 1–10 cm long. Calyces mostly broadly campanulate at maturity, 18–40 mm long, 10–30 mm wide, variously pubescent, as noted in the discussion below, the subtending bracteoles mostly 10–20, filiform to linear-lanceolate (1–3 mm wide), if the latter, nearly always broadest at or near the base. Corollas pale pink to dark red, usually broadly flaring at anthesis, mostly 40–70 mm long, rarely less, broadly to sometimes narrowly oblanceolate, usually at least a few petals with some degree of apical lobing, rarely not. Style and staminal column mostly protruding from the corolla for 10–40 mm. Fruits large and fleshy, red or white, mostly 15–30 mm wide at maturity, the seeds large, ovoid, up to 10 mm long and 4 mm wide.

*Distribution (Figs. 1, 3).* Northwestern South America along the upper tributaries of the Amazon River in Peru, Ecuador, Colombia, Venezuela, Brazil, Panama, and Costa Rica, from 100 to 2,000 m, often in lower montane cloud forests; flowering all seasons.

*Diagnosis and relationships. Malvaviscus concinnus* is an extremely variable species throughout its range, often over very short distances, the variation being much like that found in *M. arboreus* in North America. Thus, collections from San Martín, Peru, may possess a minutely stellate-pubescent vestiture (0.2 mm high or less) upon the calyces and associated bracts (*Klug 3919*, F, GH, MO, NY, US), or the vestiture may be quite pronounced or hirsute-stellate (0.5–1.5 mm high) on these same organs (*Schunke-Vigo 7767*, MO, US), and intermediates between these extremes may also occur (*Schunke-Vigo 6898*, MO, US). The corolla length and degree of apical flaring are quite variable: among the specimens just cited, and others from San Martín, the length varies from ca. 42 mm (*Schunke-Vigo 6898*, MO, US) and not so widely flaring (4 cm across), to ca. 65 mm (*Allard 22074*, US) and markedly flaring (to 9 cm across).

Variation from population to population is especially apparent along the upper, more western, tributaries of the Amazon River basin from Venezuela, Colombia, Ecuador, and Peru eastward to 70°W longitude. Thus, the names *M. elegans*, *M. oligotrichus*, *M. longifolius*, and *M. maynensis* have been applied to forms with broadly lanceolate leaves; *M. velutinus* to forms with a vestiture of densely packed, long-stellate hairs; *M. integrifolius* and *M. ulei* to forms with nearly entire leaves, the latter having somewhat shorter petioles and longer calyces; and *M. speciosus* with trilobed, cordate leaves. In all of the aforementioned type material, as well as among the representative specimens cited, there is considerable variation in leaf shape, corolla size, vestiture, and fruit dimensions, so much so that one is forced to the conclusion that there exists in South America a single widespread, highly variable species, *M. concinnus*, and a more localized, more readily recognized, relatively uniform species, *M. williamsii*. The latter might have been treated, with equal validity, as a variety of *M. concinnus*. But *M. williamsii* is much

better delimited than variety *drummondii*, the only infraspecific taxon maintained under *M. arboreus*, and it is certainly better delimited than *M. achanioides*.

Some comments on the large white fruits occasionally found in *M. concinnus* seem in order. Such fruits in North America are mostly confined to Panama and Costa Rica, where they are usually associated with plants having large cordate leaves; however, similar fruits also occur on elliptical-leaved specimens from Costa Rica that have been called *M. palmanus* (e.g., *Burger 5425*, F, NY; *Burger 5492*, F, NY; *Burger 7228*, F, GH), but which we include in *M. arboreus*. White fruits, though smaller than those found in Central America, occasionally occur on Mexican plants referable to typical *M. arboreus*. Thus, fruit color (the basis for the name *M. leucocarpus*), like leaf shape and vestiture, is variable and cannot be used alone for delimitation.

*Representative specimens examined.* PANAMA. COCLE: El Cope, E of sawmill above El Cope, 2,300 ft., 27 July 1978, *Hammel 4096* (MO). DARIEN: lower slopes of Alturas de Nique along Río Coasi, 26 Dec. 1980, *Hartman 12258* (MO). PANAMA: N of El Llano, 500–800 m, 25 July 1972, *Gentry 5573* (F, MO). VERAGUAS: near Sante Fé, road at base of Cerro Tute, 3,000 ft., 18 Sep. 1979, *Antonio 1899*, 1901 (MO). COSTA RICA. ALEJUELA: between Cañas and Upala, 4 km NNE of Bijagua, ca. 400 m, 24 June 1976, *Croat 36309* (MO); San Carlos, márgen del Río Peñas Blancas, 29 June 1985, *Haber 1756* (MO). HEREDIA: Finca La Selva, OTS Field Station along the Río Puerto Viejo, just E of the junction with the Río Savapiquí, ca. 100 m, 29 Nov. 1982, *McDowell 995* (LL, TEX), 3 Dec. 1982, *McDowell 1028* (MO); Tirimbina, 700 ft., 1 June 1971, *Proctor 32220* (LL). COLOMBIA. AMAZONAS: east bank of Amazon River ca. 3 mi. N of Leticia, 27 Jan. 1969, *Croat 7566* (MO). ANTIOQUIA: Cordillera Central Boquerón, ca. 16 km NW of Medellín on road to Turbo, 6°20′N, 75°40′W, 2,500–2,600 m, 10 Jan. 1986, *Stein 3160* (MO). ATLANTICO: region de Barranquilla, llanada de Juanmina, 10 m, 15 Jan. 1961, *Dugand 5499* (NY). BOLIVAR: near Cartagena, La Popa, 50–175 m, 2 Nov. 1926, *Killip 14052* (A, GH, NY). BOYACA: Valle de la Uvita, near Uvita, 2,490–2,560 m, 16 Sep. 1938, *Cuatrecasas 1850* (F, US). CESAR: La Jagua, Magdalena Valley, 5 Sep. 1924, *Allen 565* (F, MO). CUNDINAMARCA: Mpio. La Mesa, carretera de La Mesa a Anapoima, 1,300 m, 14 May 1952, *Fernández 1336* (NY, US). GUAJIRA: N slopes of Cerro del Espejo Serranía de Perija, Venezuela border, 10°28′N, 72°50′W, 2,550 m, 28 Apr. 1987, *Gentry 57192* (MO). HUILA: 1 km S of Villavieja, E of Río Magdalena, 400 m, 21 July 1950, *Smith 1241* (GH, US). MAGDALENA: Las Nubes, Sierra del Libaus, 4,500–6,000 ft., 15 Dec. 1898–23 Jan. 1899, *Smith 734* (several individuals and specific localities under this number) (A, F, GH, MO, NY). META: Río Guejar, S of El Mico Airstrip, 400 m, 7 Nov. 1949, *Philipson 1372* (F, US). PUTUMAYO: Umbria, 0°54′N, 76°10′W, 325 m, Oct.–Nov. 1930, *Klug 1712* (A, F, MO). SANTANDER: vicinity of Las Vegas, 2,600–3,000 m, 21–23 Dec. 1926, *Killip 16087* (A, GH, MO, NY, US). SUR DE SANTANDER: vicinity of Barranca Berjema, Magdalena Valley between Sogamoso and Colorado rivers, 100–500 m, 20 Jan. 1935, *Haught 1532* (F). TOLIMA: Armero, Valle del Río Magdalena, 400 m, 6 Oct. 1940, *Cuatrecasas 10496* (F, MO, NY, US). VENEZUELA. ARAGUA: subida de Las Vueltas, Parque Nacional, 1,300 m, Aug. 1947, *Pittier 15.519* (US). CERRO EL AVILA: Quebrada Quintero, 1,600 m, *Manara*, 1976 (NY). DISTRITO FEDERAL: Camino de ronda Las Flores a Papelón (Guayabal), 23 Aug. 1939, *Delgado 271* (F, US); near Caracas, between Cotiza and Los Venados, Oct. 1924, *Albert 76* (US); vicinity of Caracas, Chacaito Gorge, 800–1,000 m, 24 Aug. 1923, *Pittier 1116* (A, GH, NY, US). LARA: hacia la Estación Experimental del Ministerio de Agricultura y Cría en Sanare, 1,500 m, Aug. 1959, *Aristeguieta 3943* (F). MERIDA: Río Gonza, La Isla Jaji, 1 Nov. 1968, *López-Palacios 1918* (NY). MIRANDA: E of Quebrada Serraduro, E of Hacienda Garate, 16 km NE of Caucaguito, 30 km NE of Petare, between Petare and Guarenas, 1,200–1,500 m, 6 Oct. 1963, *Steyermark 91616* (GH). PORTUGUESA: Pozo Blanco, estación lluviosa, 2 Oct. 1979, *Ortega 804* (MO). TACHIRA: Quebrada Agua Azul, S of El Reposo, 14 km SE of Delicias, 7°31′N, 72°24′W, 2,150–2,300 m, 22–23 July 1979, *Steyermark 11874* (MO). ECUADOR. CHIMBORAZO: Sibambe, Hacienda "La Carmela," 100–1,600 m, 16 Aug. 1943, *Solís 5349* (F). ESMERALDAS: between Tonchigue and Galera, Esmeraldas–Muisne Road, 23 Nov. 1980, *Harling 16693* (F). GUAYAS: 12 km W of Guayaquil, Hacienda Barcelona Trasil, 4 Apr. 1962, *Gilmartin 667* (US). MANABI: above Noboa, 200 m, 19 July 1942, *Haught 3413* (GH, NY, US). MORONA–SANTIAGO: Parroquia Cumanda, Río Pastaza, ca. 4 km W of Mera, 23 Aug. 1968, *Lugo 355* (F, NY). NAPO: Río Gueppi (tributary of Río Putumayo), below Peruvian border post of Puerto Peru, 200 m, 15 May 1978, *Gentry 21871* (F, MO). EL ORO: Sitio denominado pénjamo, 100 ft., 23 Nov.–16 Dec. 1978, *Escobar 824* (HUA, TEX); between Santa Rosa and La Chorita, 0–100 m, 27 Aug. 1923, *Hitchcock 21141* (NY, US). PASTAZA: Puyo–Tena road, 4.5 km from Puyo, ca. 900 m, 8 July 1980, *Sobel 2452* (NY). SANTIAGO–ZAMORA: E slope of the cordillera, valley of the Ríos Negro and Chupianza on the trail from Sevilla de Oro to Méndez, 1 Nov. 1944, *Camp E-829* (US). PERU. AYACUCHO: Estrella, between Huanta and Río Apurimac, 500 m, 8 and 14 May 1929, *Killip 23065* (F, NY, US). HUANUCO: Leoncio Prado, La Divisora, Cordillera Azul near border with Ucayali, 1,620–1,760 m, 75°48′W, 9°05′S, 10 Aug. 1980, *Gentry 29567* (F, MO); Pachitea, Honoria, Bosque Nacional de Iparia, a lo largo del Río Pachitea cerca del campamento Miel de Abeja, 300–400 m, 5 May 1967, *Schunke-Vigo 925* (F, NY, US). JUNIN: Schunke Hacienda, above San Ramón, 1,400–1,700 m, 8–12 June 1929, *Killip 24714* (F, NY, US). LORETO: along Río Amazonas, S of Iquitos, 18 Aug. 1972, *Croat 19309* (F, GH, MO, NY); Maynas, Moena Cano between Iquitos and Río Itaya, 7 Jan. 1976, *Gentry 15654* (F, MO, NY); Balsapuerto, 220 m, Apr. 1933, *Klug 3015* (A, F, GH, MO, NY, US); Coronel Portillo, Bosque Nacional de Iparia, a lo largo del Río Ucayali cerca del pueblo de Iparia, 18 Aug. 1968, *Schunke-Vigo 2617* (F, GH, MO). MADRE DE DIOS: Tambopata, Tambopata Nature Reserve, ca. 30 air km SSW Puerto Maldonado at effluence Río La Torre/Río Tambopata (SE bank), 12°49′S, 69°17′W, 260 m, 17 May 1980, *Barbour 5332* (F, MO,

NY). SAN MARTIN: Juan Jui Alto Río Huallaga, 400 m, Oct. 1934, *Klug 3919* (F, GH, MO, NY, US); near Boquerón, Boquerón Pass, 92 km from Tingo María on highway to Pucallpa, 400 m, 16 Dec. 1949–5 Jan. 1950, *Allard 22074* (US); Mariscal Caceres, Uchiza, E of Puente del Río Uchiza, 400 m, 25 July 1974, *Schunke-Vigo 7767* (MO, US); Marsical Caceres, Tocache Nuevo, Puerto Pizana, Río Huallaga, 350 m, 4 June 1974, *Schunke-Vigo 6898* (MO, US). TUMBES: Zarumilla, Bosque Nacional de Tumbes, cerca de Campo Verde, 600–800 m, 17 Dec. 1967, *Simpson 380* (F, NY). UCAYALI: Bosque von Humboldt, entrance to Carretera Marginal, km 88 of Pucallpa–Tingo María Road, 75°02′W, 08°45′S, 220 m, 14 June 1987, *Gentry 58344* (F, MO). BRAZIL. AMAZONAS: Manariao, basin of Rio Juruá, 27 May 1933, *Krukoff 4589* (A, F, MO, NY, US); basin of Rio Juruá, near mouth of Rio Embira (tributary of Rio Tarauaca), 7°30′S, 70°15′W, 1 July 1933, *Krukoff 5150* (A, F, MO, NY, US).

**5. Malvaviscus williamsii** Ulbr., Notizbl. Bot. Gart. Berlin-Dahlem 11: 545. 1932. *Malvaviscus arboreus* var. *williamsii* (Ulbr.) Schery, Ann. Missouri Bot. Gard. 29: 226. 1942. TYPE: Peru. Loreto: Lower Río Nanay, forest between Río Nanay and Río Napo, 6 June 1929, *L. Williams 706* (holotype, B destroyed?; isotype, F not located). Ulbrich cited only two specimens, one at B the other at F, neither of which we could locate. From the description and location there is little doubt as to the identity of the material concerned. In lieu of extant types we have proposed the following: NEOTYPE: Peru. Loreto: Maynas, "trail between Río Amazonas above Indiana and Mazan (Río Napo) between Mazan and halfway," mature upland rainforest over clay, 100–130 m, 5 July 1971, *Sidney McDaniel 15218* (neotype, MO; isoneotype, F). Figure 4.

Erect or clambering (lianalike) shrub to 7 m high, stems densely and evenly pubescent with short hairs (the felt ca. 0.2 mm high). Leaves mostly 10–30 cm long, 6–22 cm wide; petioles 3–16 cm long, pubescent like the stems; blades mostly cordate, rarely subcordate, the margins irregularly dentate to nearly entire. Flowers mostly axillary and single along the upper stems, erect or occasionally pendulous; corollas pink to bright carmine, 48–70 mm long, at least some of them lobed, the apical portion usually flaring at anthesis and the staminal column usually exserted for 10–30 mm. Calyces 18–30 mm long in fruit, usually densely pubescent with long, stellate, yellowish hairs, the associated bracts 5 or 10, 10–18 mm long, 4–8 mm wide, broadly elliptical-ovate, widest at or near the middle, sparsely stellate pubescent, the margins mostly strongly imbricate. Fruits red (white), 8 mm high, 15–30 mm diam., fleshy at maturity.

*Distribution (Fig. 3).* Northwestern South America, along the Pacific Coast tributaries of western Colombia, and also in a restricted area on the eastern slopes of the Andes, along the Napo River in Peru; flowering all seasons.

*Diagnosis and relationships. Malvaviscus williamsii*, because of the very broad imbricate bracts (Fig. 4), is readily distinguished from the seemingly sympatric *M. concinnus*. The former, however, occurs mostly along the Pacific Coast tributaries, although the type is from the eastern slopes of the Andes, mainly along the Napo River in Peru (Fig. 3). Material from the latter region is essentially indistinguishable from that of the Pacific coastal region. Populations of *M. concinnus* are not known to occur with or especially close to *M. williamsii*, nor does the principal character (bract shape), which distinguishes between the two, irreverentially crop up hither and yon, as occurs with most other "diagnostic" characters in the genus *Malvaviscus*. Most specimens of *M. concinnus* have linear or linear-lanceolate bracts (mostly 1–3 mm wide), which are broadest at or near the base; occasional specimens, however, have somewhat broader bracts (3–5 mm) and may be said to approach the character state found at the type locality of *M. williamsii*. Because of this, some workers might prefer to accord the taxon only varietal rank, as was done by Schery (1942). But among the species of *Malvaviscus*, it is as distinct and probably more so than *M. achanioides* and *M. penduliflorus*, which are retained. In short, our specific assessments are consistent with our evaluation and treatment of the *M. arboreus* complex of North America.

*Additional specimens examined.* COLOMBIA. ANTIOQUIA: Mpio. de Turbo, carretera Tapon del Darien, 10–20 m, *Brand & Narváez 620* (MO, HUA); Mpio. Chigorodo, ca. 15 km W of Chigorodo, ca. 100 m, 14 Mar. 1962, *Feddema 1893* (NY); Mpio. Chigorodo, Vereda Malagon, ca. 20 m, 11 Feb. 1986, *Renteria 4505* (MO); Mpio. Uraba, ca. al Río Chado, 70–90 m, Feb. 1950, *Uribe 2024* (US—2 sheets). CHOCO: Mpio. de Río Sucio, orillas del Río Truando, entre la confluencia de los Ríos Chintado y Salado, *Romero-Castaneda 6121* (MO); orillas del Río Truando, 24 Oct. 1956, *Romero-Castaneda 4674* (MO); near Madurex Logging Camp above Teresita, below rapids on Río Truando, 7–8 Feb. 1967, *Duke 9992* (MO); area of Baudo on Río Baudo, ca. 5 m, 3 Feb. 1967, *Fuchs et al. 21725* (MO, US); area of Baudo, 11 Feb.–29 Mar. 1967, *Fuchs & Zanella 22225* (US—2 sheets); 8–10 km E of Tutunendo, 150

FIGURE 4. *Malvaviscus williamsii* (*Feddema 1893*, US).

m, 14 June 1982, *Gentry & Brand 36872* (MO); between Bolívar and Quibdo, 290 m, 8 Nov. 1983, *Juncosa 1338* (MO). PERU. LORETO: Gamitanacocha, Río Mazan, 100–125 m, 20 Feb. 1935, *Schunke-Vigo 293* (A, F, NY, US); Maynas, Río Momon hacia arriba caserios de San Francisco, 130 m, 8 Mar. 1978, *Díaz & Jaramillo 129* (F, MO). NARIÑO: between Tumaco and El Diviso, along Río Mojada, 150 m, 8 Jan. 1956, *Vogel 32* (US).

## EXCLUDED NAMES

*Malvaviscus palmatus* Ulbr., Verh. Bot. Vereins Prov. Brandenburg 1908: 89. 1909. TYPE: Brazil. Minas Gerais: "am oberen [Rio] Juruá," 25 Apr. 1901, *E. Ule 5443* (holotype, B destroyed?; isotype, MG).

Schery (1942), not having examined type material, accepted this species in *Malvaviscus* with reservation, noting, "from description only, it is difficult to say with surety that this species may not belong in the genus *Pavonia*; yet Ulbrich's description of the fruit and his excellent illustration of the type specimen indicate that this plant probably is a *Malvaviscus*. On the other hand, the original description does not state that the petals are auriculate, from which the inference is that the plant may be *Pavonia*." Examination of the type shows the fruit, which was described by Ulbrich as "niger baccatus," to be rather rigidly, or not clearly, bacculate, having five well-defined fused carpels each with a small, smooth, rounded ridge extending down its length, the whole appearing brownish red. In short, the fruit is *not* clearly black and fleshy as described, although this might have been so in living material; there is no indication that Ulbrich observed fresh fruits, and our observations leave the matter moot. Regardless, dissection of the corolla did not reveal any clearly defined auricles on the petals, and because of this and the seeming absence of stellate pubescence and the markedly palmately lobed leaves, we here transfer the species to *Pavonia*.

**Pavonia palmata** (Ulbr.) B. Turner & M. Mendenhall, comb. nov. *Malvaviscus palmatus* Ulbr., Verh. Bot. Vereins Prov. Brandenburg 1908: 89. 1909. TYPE: Brazil. Minas Gerais: "am oberen [Rio] Juruá," 25 Apr. 1901, *E. Ule 5443* (holotype, B destroyed?; isotype, MG).

# THE RISE AND FALL OF *PSEUDOLUDOVIA ANDREANA* (CYCLANTHACEAE)[1]

*Roger Eriksson*[2]

ABSTRACT

*Pseudoludovia andreana*, described in a monotypic genus, is based on a mixed collection. The element here selected as lectotype is conspecific with *Sphaeradenia laucheana*. *P. andreana* is reduced to a synonym of *S. laucheana*, and *Pseudoludovia* is placed into synonymy under *Sphaeradenia*. *Sphaeradenia laucheana* is neotypified.

In the most recent monograph of the Cyclanthaceae, Harling (1958) recognized 11 genera. Since then, two additional genera have been described, *Chorigyne* (Eriksson, 1989) and *Dianthoveus* (Hammel & Wilder, 1989). The existence of the monotypic genus *Pseudoludovia* Harling has been questioned lately, however, and the genus has not been accounted for in recent investigations of the Cyclanthaceae (Wilder, 1978, 1981; Eriksson, 1989; Hammel & Wilder, 1989).

An André collection (no. 2298) from rather high altitudes in central Colombia, with a fertile specimen deposited at K and a sterile duplicate at NY (Harling, 1958), gave rise to *Pseudoludovia andreana* Harling. A sterile specimen from southern Colombia was also cited in the original description. The genus combined characteristics of both *Ludovia* and *Sphaeradenia*. The leaves of these collections are entire, the habit is climbing as in *Ludovia*, and the young infructescence has united pistillate flowers with one apical placenta, concrescent styles, well-developed tepals, and asymmetrical staminate flowers as in *Sphaeradenia*. Superficially, the vegetative and fruiting parts of the material in K seem to be connected (Fig. 1).

In 1974 in southern Colombia, Wilder and Hernandez collected live, sterile material of a species with entire leaves, which resembled those described for *Pseudoludovia andreana* (Wilder, 1978). In cultivation, part of this material developed inflorescences that clearly showed it to belong to the genus *Ludovia*. At that time Wilder (1978) questioned the existence of *Pseudoludovia*, due to the similarity of the leaves. Furthermore, he suggested that if *Pseudoludovia andreana* was based on a mixed collection, the infructescence should be selected as type material. Consequently, he described his material as the new species *Ludovia bierhorstii* G. Wilder. Later he had the characteristics of the type of *P. andreana* in K described to him, which supported his earlier view (Wilder, 1981).

During a visit to the herbarium at Kew, I examined the type of *Pseudoludovia andreana* and concluded that this taxon is based on a mixed collection. This conclusion is based on the following: (1) The leaf is very similar to those of the later described *Ludovia bierhorstii*. (2) The young fruiting spadix has the same morphology as those of *Sphaeradenia laucheana* (Mast.) Harling. (3) The infructescence is not connected to the vegetative parts, but has been mounted to simulate connection. The fractures of the pieces do not match, and the epidermal cells differ somewhat between them. (4) The part interpreted by Harling as the lower part of the peduncle (Fig. 1, below arrow) is most certainly a stem fragment, which would be consistent with a lianalike habit. This being a peduncle, the plant would have a terminal inflorescence. This condition is unknown in the *Sphaeradenia* group, to which *Sphaeradenia* and *Ludovia* belong and to which *Pseudoludovia* was assigned. (5) No further fertile material of *Pseudoludovia* has ever been found, although it has been looked for. All fertile collections with leaves like those described for *P. andreana* have turned out to be *L. bierhorstii*. Furthermore, *S. laucheana* has recently been collected in the vicinity of the type locality of *P. andreana*. (6) A line on the label of *André 2298* reads "fol. . . . ad apic. bifid." [leaves . . . towards apex bifid], which is not the case with the leaf on the sheet. However, the statement would fit a *Sphaeradenia* species.

I think it is most probable that the mixture has been made after the material had been sent from

[1] I thank Lennart Andersson for reading the manuscript and suggesting improvements, and Gunnar Harling and George Wilder for sharing their points of view on the subject.

[2] Department of Systematic Botany, University of Göteborg, Carl Skottsbergs Gata 22, S-413 19 Göteborg, Sweden

South America, since *L. bierhorstii* is known only from the lowlands of southern Colombia and northern Ecuador and not from the area stated on the label.

According to the *International Code of Botanical Nomenclature* (ICBN) articles 7.4 and 9.2 (Greuter et al., 1988), one of the elements of this mixed collection must be selected as lectotype. Harling's description is based on both elements and gives no indication to which the name should be attached. Wilder has typified the taxon to which the leaf belongs with other material (Wilder, 1978), and his name *Ludovia bierhorstii* has been accepted and used. Designating the leaf as type would reduce this name to a synonym. I therefore select the infructescence of *André 2298* (K) as lectotype for *Pseudoludovia andreana*. This is in accordance with ICBN recommendation 7B.5 (Greuter et al., 1988). Accordingly, the specimen labeled as *André 2298* at NY, consisting of only vegetative parts, should not be regarded as a duplicate of the type collection.

*Pseudoludovia andreana*, typified with the infructescence of *André 2298* (K), clearly belongs to the earlier described genus *Sphaeradenia* (Harling, 1954). The well-developed adaxial perianth lobes of the staminate flowers, the slightly elongate anthers without secretion globule, the free and cuspidate tepals that are rather thick at base and have an apical glandule, and the stigmas that are lanceolate seen from above and do not surpass the tepals in height fall well within the variation range of, and show that it is conspecific with, *Sphaeradenia laucheana*. The latter name is earlier and has priority (ICBN 57.1, Greuter et al., 1988). Consequently I reduce *P. andreana* to a synonym of *S. laucheana*, leaving the genus *Pseudoludovia* to fall into synonymy under *Sphaeradenia*.

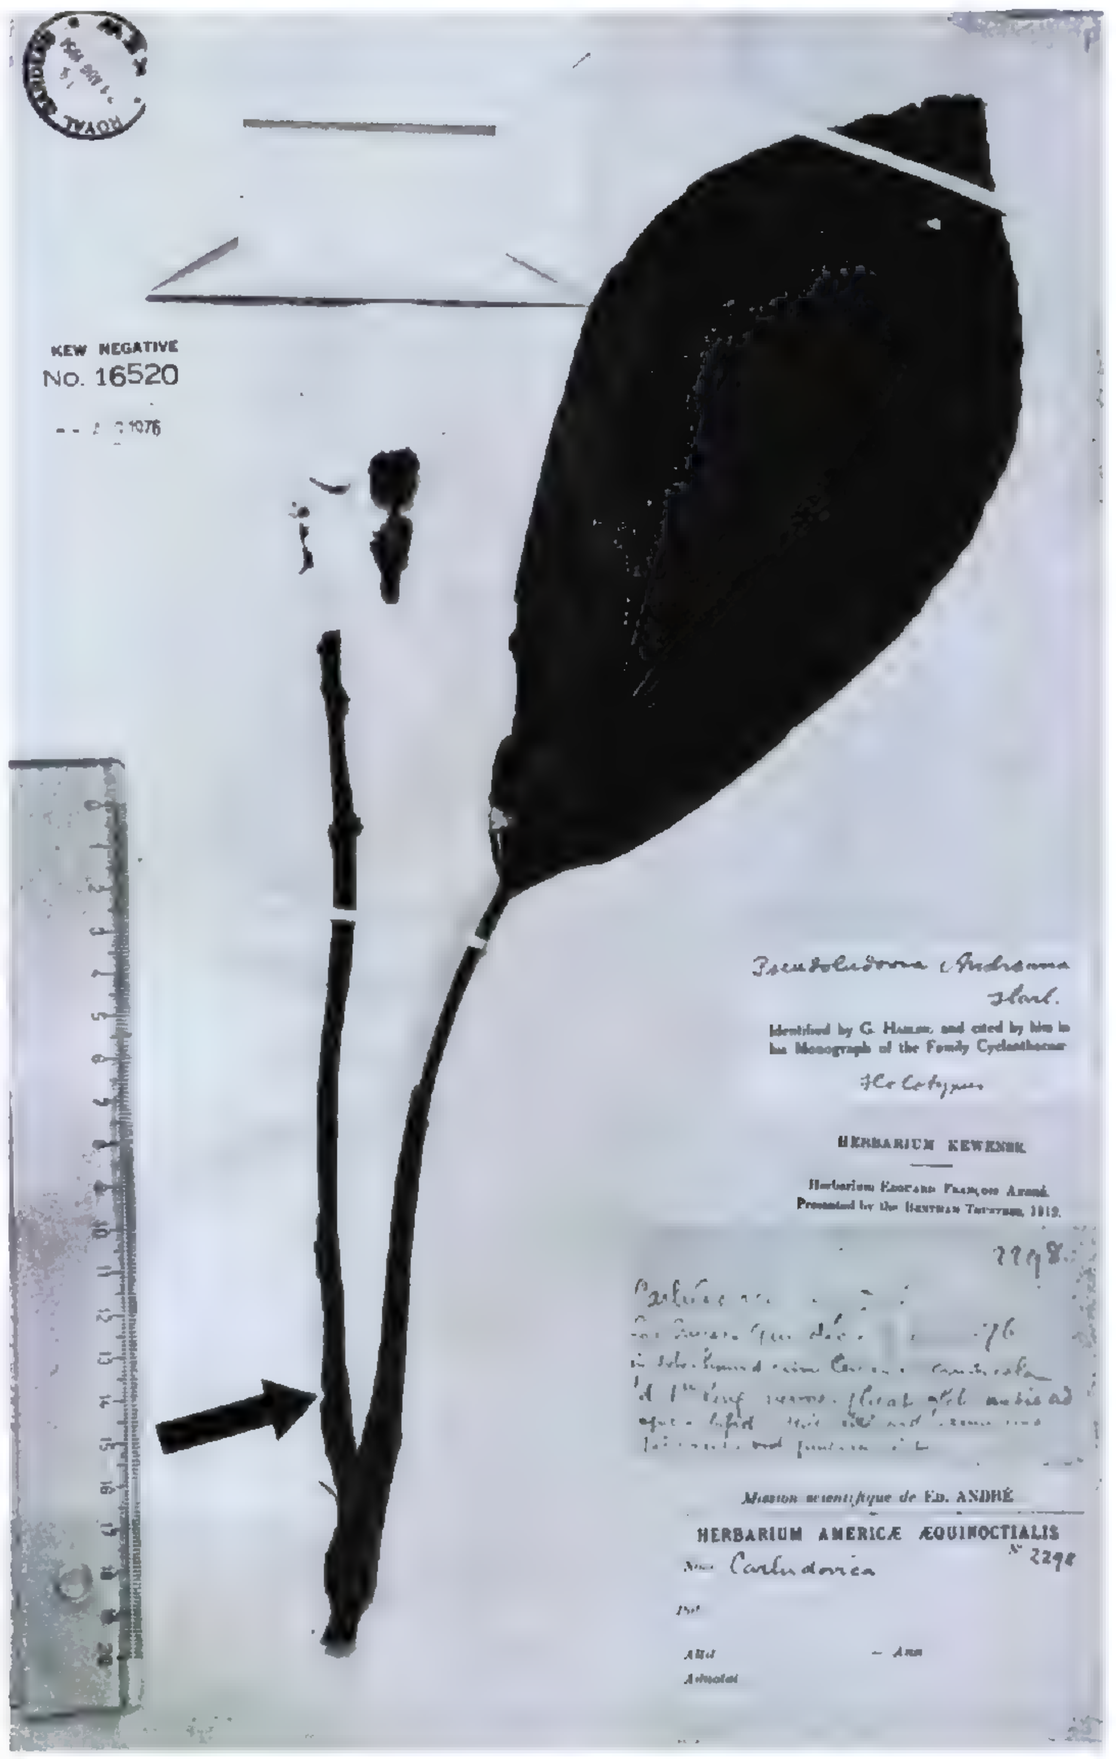

FIGURE 1. The mixed type specimen of *Pseudoludovia andreana* in K. The arrow indicates where the different parts have been mounted together.

**Sphaeradenia laucheana** (Mast.) Harling, Acta Horti Berg. 17: 3. 1954. *Salmia laucheana* Hort. Sander. ex Mast., Gard. Chron., ser. 3, 13: 442. 1893. *Carludovica laucheana* (Mast.) Hook. fil., Curtis's Bot. Mag., ser. 3, vol. 55, tab. 7683. 1899. TYPE: *27 May 1897, Hort. Kew s.n.* (neotype, selected here, K).

*Pseudoludovia andreana* Harling, Acta Horti Berg. 18: 340. 1958. TYPE: Colombia. Tolima, Quindío or Risaralda: Las Cruces, Quindío, 9 Mar. 1876, *André 2298* (infructescence) (lectotype, selected here, K).

*Sphaeradenia laucheana* (Mast.) Harling was imported from Antioquia, Colombia, by Sander & Co. of St. Albans (Hooker, 1899) and was presented at the Ghent exhibition in Belgium in 1893. It did not receive any prize, however, as did the cyclanth *Ludovia lancifolia* Brongn. *Gardeners' Chronicle* reported on the exhibition and included an unsigned description of this plant under the name *Salmia laucheana* Hort. Sander (Masters, 1893). This description must be ascribed to M. T. Masters, the editor of the magazine (Stafleu & Cowan, 1981). The beginning of Masters's description reads "Salmia laucheana, Hort. Sander— A cyclanth of the genus Carludovica . . ." According to ICBN 34.2 (Greuter et al., 1988), the assignment to *Carludovica* does not invalidate the name *Salmia laucheana*.

A clone of this plant was received by Kew in 1895; it flowered for the first time in May 1897, when a specimen was pressed. Hooker (1899) redescribed this cultivated material as *Carludovica laucheana* and provided an excellent illustration. He also cited *Salmia laucheana* from *Gardeners' Chronicle*.

Harling (1954) transferred *C. laucheana* to the new genus *Sphaeradenia*. As basionym he cited the name from Hooker's description, regarding *Salmia laucheana* as a "nomen seminudum" (Harling, 1958). However, the description in *Gardeners' Chronicle* is rather exhaustive with respect to vegetative structures, and the name is thus validly published. Harling's incorrect reference to the author of the basionym does not invalidate the combination made by him; it should be regarded as a bibliographic error (ICBN 33.2, Greuter et al., 1988).

There is no original material of *S. laucheana*, and, accordingly, a neotype must be selected. Harling accredited Hooker with the basionym, and therefore he incorrectly regarded the pressed specimen, *Hort. Kew s.n., 27 May 1897* (K), as the holotype. However, because this specimen was prepared from a clone of the original material, I select it as neotype for *Sphaeradenia laucheana*.

# CHROMOSOME CYTOLOGY IN TROPICAL AFRICAN *GLADIOLUS* (IRIDACEAE)[1]

*Peter Goldblatt,*[2] *Masahiro Takei,*[3] *and Z. A. Razzaq*[4]

## Abstract

Original chromosome counts for 16 species of tropical African *Gladiolus*, 5 southern African, and 3 Eurasian species, 17 of these not before examined, confirm that $x = 15$ is probably the ancestral basic number for the genus. Until now, $x = 15$ has been the only recorded base number in *Gladiolus*, but several tropical African species have been found to depart from this pattern, the only known examples of dysploidy in the genus. In subgenus *Gladiolus*, *G. atropurpureus* has $x = 12$ ($2n = 24 + 0$–$5$B, 36); *G. serapiflorus*, *G. gregarius*, and *G. pseudospicatus* have $x = 11$ ($2n = 22$); *G. unguiculatus* has $x = 13$ ($2n = 26 + 0$–$2$B, also possibly $2n = 24$); and *G. actinomorphanthus* has $2n = 28$. Because on morphological grounds most of these species do not seem to be immediately related, we suggest that dysploid reduction in tropical African *Gladiolus* may have occurred in four separate lineages. Results confirm polyploidy in *G. dalenii*, $2n = 60$ and 90, and the three Eurasian species examined. The first count for the Malawian *G. bellus*, $2n = 60$, indicates polyploidy in only one more tropical African species of *Gladiolus*. Counts of $2n = 39$ in two populations of *G. decoratus* suggest triploidy based on $x = 13$, making this one more possible example of dysploidy for the genus. Although the chromosomes of *Gladiolus* are relatively small, some karyotypic details provide additional data relating to species relationships. Measurements of total chromosome length show that irrespective of base number, most of the diploid species have a comparable amount of chromosome material. Two species, *G. melleri* ($2n = 30$) and *G. decoratus* ($2n = 39$), however, have significantly higher amounts of chromosome material, ca. 33–40% above expected levels, a condition possibly related to their characteristic rapid growth and flowering early in the growing season.

Ever since the first chromosome counts (Vilmorin & Simonet, 1927; Ernst-Schwarzenbach, 1931; Bamford, 1935) were made in *Gladiolus*, the largest and most taxonomically complex genus of Iridaceae subfamily Ixioideae (Goldblatt, 1991), $x = 15$ has been considered the probable ancestral base number for the genus (Goldblatt, 1971). Except for the occasional occurrence of B chromosomes, the several Eurasian, southern African, and Madagascan species counted all have diploid numbers based on $x = 15$ and the only significant cytological variation reported in *Gladiolus* has been polyploidy. Eurasian species are consistently polyploid (van Raamsdonk & de Vries, 1989) while most southern African and all Madagascan species examined are diploid. Until now, only two endemic tropical African species have been studied cytologically (Table 1) and these have corresponded to the Afro-Madagascan pattern in being diploid, $2n = 30$. A third, *G. dalenii*, which also occurs in Arabia, South Africa, and Madagascar, is polyploid in Africa, $2n = 45$, 60, 75, and 90. Counts here for 16 tropical species of *Gladiolus*, 12 never before counted, at least for tropical Africa, and an additional five southern African species, confirm that while $x = 15$ is the probable ancestral base number, important variation occurs in some tropical species. Descending dysploidy, probably in four separate lineages, has led to the establishment of secondary base numbers, $x = 14$, 13, 12, and 11. Polyploidy is confirmed in *G. dalenii* in tropical Africa (the species is diploid in Madagascar). One more tropical species, *G. bellus*, appears to be polyploid. *Gladiolus*, a genus of some 215–220 species, remains poorly sampled cytologically, and in view of the variation recorded here, needs to be investigated in more detail.

## Materials and Methods

Seeds or corms of wild collected species (Table 1) were sprouted in the greenhouse, and emergent leaf and root tips were harvested for analysis of mitosis in one of two ways. For rapid determination

TABLE 1. Chromosome numbers in sub-Saharan African and Madagascan *Gladiolus*. For comparative purposes, some Eurasian species were also examined, but past counts for the area are not reviewed. Original counts are indicated in bold type and provided with collection data; previously published counts are referenced, and nomenclature adjusted to reflect current taxonomy (Lewis et al., 1972; Goldblatt, 1989). Unless otherwise indicated, voucher specimens are housed at MO.

[1] Counts of $2n = 66$ for *G. watsonius* (as *Homoglossum*) by Sharma & Talukdar (1960) are almost certainly based on misidentified plants.

of chromosome number, root tips were pretreated in saturated aqueous m-bromonaphthalene for 4 hours at room temperature, then fixed in 3:1 absolute ethanol-glacial acetic acid for 5 minutes. After hydrolysis in 10% HCl at 60°C for 6 minutes, tips were squashed in FLP orcein (Jackson, 1973). For more critical analysis, leaf and root tips were pretreated in 0.002 M aqueous 8-hydroxyquinoline for 4–5 hours at room temperature, then fixed in modified Carnoy's solution (absolute ethanol-glacial acetic acid-chloroform 6:3:1) at 8°C for about 24 hours. Both root and leaf tips were stained in Feulgen reagent and squashed in 1% aceto-orcein. Photographed preparations were all made using the latter technique.

## OBSERVATIONS

Chromosomes of *Gladiolus* are relatively small, 0.7–2.9 μm (Figs. 1–21), and diploid numbers are based on $x = 15$ in the majority of species examined (Table 1). Several tropical African species differ in base number. The common tropical African species *G. gregarius* has $2n = 22$, based on counts from four populations as far apart as Central African Republic, southern Zaire, and Tanzania; closely related *G. pseudospicatus*, centered in southern Zaire and most common on soils with high concentrations of heavy metals, also has $2n = 22$ (Figs. 1, 2). *Gladiolus serapiflorus* has $2n = 22$, based on several counts from a single population from Zaire (Fig. 3). The widespread *G. atropurpureus* appears to have $x = 12$: two populations from Zaire have $2n = 24$, sometimes with B chromosomes ranging in number from 1 to 5 (Figs. 4, 5); and three individuals in a population from Malawi are triploid, $2n = 36$ (Fig. 6).

The widespread and common *Gladiolus unguiculatus* has proven cytologically puzzling. While most plants sampled from two populations in southwestern Zaire have $2n = 26$ (or $2n = 26 + 2B$), some individuals have $2n = 24$ (Figs. 7–9). The Zairean endemic, *G. actinomorphanthus*, has $2n = 28$ (Fig. 10) in two populations examined.

Karyotypes of most species comprise metacentric to submetacentric chromosomes (symmetrical

in arm ratio) of fairly uniform size. All chromosomes have a large heterochromatic segment that stains darkly at early prophase. In *Gladiolus gregarius*, *G. pseudospicatus*, and *G. decoratus*, each with the longer chromosomes 2.1–2.7 μm long, thus exceeding the average, the size range is continuous. However, bimodal karyotypes with one or two conspicuously longer chromosome pairs 2.4–2.9 μm long, characterize *G. atropurpureus*, *G. serapiflorus*, and the $2n = 26$ cytotypes of *G. unguiculatus* (Figs. 3–5). The Mediterranean *Gladiolus byzantinus*, $2n = 90$, included in this study for comparative purposes, also has a bimodal karyotype (Fig. 21), but only one pair of longer chromosomes despite its hexaploid karyotype.

Total chromosome length, a comparative measure of genome size, is similar in most of the diploid species (Table 2), irrespective of base number, and most species have between 31.4 and 39.5 μm of chromosome material. This supports our view that dysploidy alone has been responsible for changes in base from $x = 15$ to 11. Two species, *G. melleri* and *G. decoratus*, have significantly higher amounts of chromosome material, 33–40% above expected levels. We suggest that this may be related to their comparatively rapid growth patterns early in the growing season. Both complete their flowering by the end of December, or earlier, and within the first few weeks of the rainy season. Other species with similar growth patterns such as *G. unguiculatus* and *G. atropurpureus* do not have comparably enlarged genomes (Table 2).

There is usually one pair of satellites per chromosome complement in diploid species ($2n = 22$–30). In *G. atropurpureus*, however, there are consistently two pairs of satellites (satellite number in the presumed triploid plants is uncertain). In the population of *G. decoratus* that we examined, also presumably triploid, the karyotype includes three satellite chromosomes.

Polyploidy is reconfirmed for tropical African *Gladiolus dalenii* and for the Eurasian *G. byzantinus*. An Ethiopian population of *G. dalenii* has $2n = 90$, and one from Zimbabwe has $2n = 60$. The Malawian endemic *G. bellus*, not before counted, has $2n = 60$ (Fig. 20) and must be assumed to be a tetraploid species. Counts of $2n = 39$ in *G. decoratus* (Fig. 19), obtained from corms of three individuals of one population from southern Malawi, and from one corm of a second population, suggest triploidy and a base number of $x = 13$ for the species. This awaits confirmation when more material becomes available. Counts for both Asian species examined, *G. kotschyanus* and *G. atroviolaceus*, $2n = 60$, are consistent with polyploidy in other Eurasian species of *Gladiolus*, but the only other count for the latter, $2n = 45$ (van Raamsdonk & de Vries, 1989), is puzzling.

TABLE 2. Total length (μm) of metaphase chromosome complement of selected species of *Gladiolus*, mostly from tropical Africa. Bimodal karyotypes are indicated by X. Figures in parentheses for *G. unguiculatus* refer to voucher numbers in Table 1.

| Taxon | Diploid number $2n$ | Size range μm | Total chromosome length μm | Length of basic set μm | Bimodality |

B chromosomes, reported in *Gladiolus* previously only in the Madagascan *G. decaryi* (Goldblatt, 1989), seem common in *G. atropurpureus* and *G. unguiculatus*. Additional *G. decaryi*, examined here, lacked B chromosomes. As is usual with B chromosomes, they are small, ca. 0.8 μm long, often vary in number within individuals, and can be recognized at prophase by their precocious and uniformly dark staining (Figs. 5, 9). Whether the variation in chromosome number in *G. unguiculatus*, either $2n = 24$ or 26, is also due to the presence of a type of B or supernumerary chromosome has not been established. In plants with $2n = 26$, the number is consistent in several individuals examined, and no precocious staining was noted except when the number exceeded 26, when typical B chromosomes could be identified. We suspect that plants with $2n = 24$ may be hybrids, perhaps with *G. serapiflorus*, $2n = 22$, which grows at the same site. Study material was collected in fruit, and counts were obtained from germinating seeds. This makes it impossible to confirm hybridity in the vouchers, at least until seedlings flower in 3–4 years. Provisionally we assume that *G. unguiculatus*, at least in southern Zaire, is dysploid, normally with $2n = 26$.

We are uncertain whether the additional chromosome in one plant of a Zimbabwean population of *G. crassifolius* is a B chromosome or not, but other individuals examined have a normal complement of $2n = 30$.

## DISCUSSION

Including the original counts in this paper, and after bringing the taxonomy up to date, some 75 species of *Gladiolus* are known cytologically (Table 1). Although this seems substantial, it is less than 35% of the estimated 220 species in the genus (Goldblatt, in prep.). The first chromosome counts made in *Gladiolus* (Vilmorin & Simonet, 1927; Ernst-Schwarzenbach, 1931; Bamford, 1935) established $x = 15$ as the likely ancestral base number for the genus. Although most Cape and eastern southern African species counted were diploid, $2n = 30$, these early studies also suggested that polyploidy was common in *Gladiolus*. Studies by Lewis et al. (1972) and Geerinck (1972) indicate that the several tropical and eastern southern African polyploid species recognized in these early cytological studies are conspecific (Table 1), and the earliest name for the species has been shown to be *G. dalenii* (Hilliard & Burtt, 1979). It is now evident that polyploidy is uncommon in *Gladiolus* outside Eurasia, where species are tetraploid to dodecaploid, except for a puzzling count of $2n = 45$ in *G. atroviolaceus* (van Raamsdonk & de Vries, 1989). Outside Eurasia *Gladiolus* is pre-

dominantly diploid, and dysploidy is more frequent than polyploidy.

The ancestral basic chromosome number in *Gladiolus* is probably $x = 15$, as assumed in the past (Goldblatt, 1971). The species in which dysploidy occurs all seem specialized, although in different ways. Thus none seems a suitable candidate for an ancestral position in the genus in which several broad foliage leaves, branched stems, broadly winged seeds, and a base number of $x = 15$ appear symplesiomorphic (Goldblatt, 1991; in prep.). The species in which dysploidy occurs are all small-flowered and small in stature, both features probably plesiomorphic in *Gladiolus*. Except for *G. actinomorphanthus*, they also all have clawed tepals grooved toward the base and united for a short distance, a probable synapomorphy uniting about half the species of the genus in subgenus *Gladiolus*.

No other characters unite all the dysploid species, and we conclude that except for *G. atropurpureus* and *G. serapiflorus*, which appear closely related, descending dysploidy has occurred independently in four lineages. This conclusion is partly supported by the karyotypes. Those of *G. atropurpureus* and *G. serapiflorus* are bimodal with a single comparatively long chromosome pair. Morphologically, *G. atropurpureus* and *G. serapiflorus* seem united in their very short foliage leaves, often reduced to sheaths with vestigial blades, and coarsely fibrous corm tunics.

*Gladiolus gregarius* and *G. pseudospicatus* have three synapomorphies, two unique in the genus, long imbricate bracts and a short style with short branches, and a third, unbranched stems. *Gladiolus unguiculatus* also has unbranched stems but is remarkable in having flowering and vegetative cycles at different seasons. Lastly, *G. actinomorphanthus*, which seems primitive in having actinomorphic flowers, belongs to an alliance of species adapted to unusual soil conditions that have terete 4-grooved leaves and seeds in which the wings are reduced to vestigial ridges.

Polyploidy has evidently played a minor role in the evolution of *Gladiolus*, except in Eurasia and North Africa where a single polyploid event in the founding population, ancestral to all the species in the region, could account for the pattern here. Polyploidy elsewhere has been sporadic. Except for reports of triploidy in *G. scullyi* and *G. orchidiflorus* (Table 1) that need additional study, only one species in the Cape region, tentatively assigned to *G. leptosiphon*, is polyploid. Excluding *G. dalenii* and *G. bellus*, only two tropical and eastern southern African species have been reported as polyploid, *G. papilio* and *G. saundersii*, and both the latter counts are for so-called hybrids (Bamford, 1935). At least wild *G. saundersii* appears to be diploid. The significance of polyploidy in *G. dalenii* is difficult to gauge. It is one of the most successful species of the genus, and certainly the one with the widest geographical distribution (Goldblatt, 1989; in prep.). It extends from the eastern Cape, South Africa, to Senegal in West Africa and from Madagascar to Ethiopia and Yemen. Perhaps polyploidy has played a role in enabling the species to thrive under the wide range of conditions that occur across its range. The role of humans in its dispersal may also be important. The species is cultivated in West Africa, and as an important medicinal plant it may have been spread over long distances by human agency.

The presumed ancestral basic chromosome number in *Gladiolus*, $x = 15$, is shared in subfamily Ixioideae only with the mono- or ditypic *Radinosiphon* (Goldblatt, 1971), and the two genera are evidently palaeotetraploid. This base number is apomorphic in Ixioideae, and it is the only synapomorphy uniting *Gladiolus* and *Radinosiphon*. Most other genera of Ixioideae have lower base numbers (Goldblatt, 1971), $x = 11$ and 10 being most frequent. Other high base numbers in Ixioideae are $x = 16$ in *Tritoniopsis*, 13 or 14 in *Romulea*, and 13 in *Geissorhiza* and *Hesperantha*, the two genera possibly the most closely related to *Gladiolus* after *Radinosiphon*.

# IMPACT OF THE EOCENE ON THE EVOLUTION OF *PINUS* L.[1]

*Constance I. Millar*[2]

## Abstract

*Pinus* evolved in middle latitudes of the Northern Hemisphere in the middle Mesozoic. By the late Cretaceous pines had spread east and west throughout Laurasia, attaining high diversity in eastern Asia, the eastern United States, and western Europe, but having little representation at high northern latitudes. Changing climates in the early Tertiary established warm and humid tropical/subtropical conditions in a broad zone to 70°N throughout middle latitudes. Pines and their relatives disappeared from many middle-latitude areas during this time and were replaced by diverse angiosperm taxa of the boreotropical flora, which were adapted to the equable, tropical climate. The effect of this climate change and spread of boreotropical flora was to displace pines from their former habitats. A hypothesis is defended that pines shifted, during the three warm periods of the Eocene, into three major refugial areas in the Northern Hemisphere: high latitudes, low latitudes, and upland regions of middle latitudes, especially in western North America. Some of these refugial areas (e.g., Mexico/Central America) underwent active volcanism and mountain-building in the Eocene and became secondary centers of pine diversity. Many phylogenetic patterns within *Pinus* can be traced to this fragmentation, isolation, and evolution in Eocene refugia. Subsections *Oocarpae* and *Sabinianae* appear to have originated from refugia in Mexico and Central America. Older subsections such as *Sylvestres*, *Ponderosae*, *Contortae*, and *Strobi* were distributed over several *refugia*; subsections *Leiophyllae*, *Australes*, and *Cembroides* evolved in southern refugia in North America; and *Canarienses* evolved in southern refugia along the Tethys seaway in Eurasia. Following the cooling and drying of the climate at the end of the Eocene, many angiosperm taxa of the boreotropical flora became extinct and pines recolonized middle latitudes, a zone they have occupied to the present. Migration out of refugia provided additional opportunities for hybridization and introgression, as formerly isolated lineages expanded and met.

The past two decades have seen an explosion of information on the paleohistory of the Earth. Evidence on plate tectonics has clarified the position of continents in different ages, continental geomorphology, and the dynamics of inland seaways and changing coastlines. Physical and biological evidence has been used to infer paleoclimates with finer resolution in time and space. New fossil discoveries have added to the record of past vegetation, and new diagnostics for identifying taxa have led to systematic revisions of many fossil floras. The widespread use of radioisotope dating has added precision to determining the ages of fossil floras.

This information, together with phylogenetic analyses of extant taxa, has contributed new insights and a revised understanding of evolution for many plant groups. In pines (family Pinaceae, genus *Pinus* L.), major syntheses have focused on two time periods in the history of the genus. Studies on the Mesozoic history of the pine family, and especially *Pinus*, have significantly changed our understanding of the origin of the genus (Miller, 1976, 1977, 1982, 1988; Robison, 1977; Blackwell, 1984; Stockey & Ueda, 1986; Stockey & Nishida, 1986). Similarly, studies on the Quaternary history of pines have led to new interpretations about the impact of recent paleohistoric events on the genetic structure and evolutionary relationships of extant species (Critchfield, 1984, 1985).

The broad-scale events that influenced the evolution of the genus between its origins in Mesozoic (Table 1) and its present diversity remain obscure. How did important secondary centers of pine diversity in Mexico, western North America, and eastern Asia originate? How do these areas relate to the primary centers of origin for the genus? What events triggered the diversifications of taxa within the genus, and how have historical events influenced current and fossil distribution? Although there have been important contributions to understanding regional biogeography and evolution of pines in the Tertiary (Eguiluz Piedra, 1985, 1988; Axelrod, 1986; Lauria, 1991), the impact of Pa-

[1] I especially thank B. B. Kinloch for valuable discussion and review of the manuscript. I also thank D. Axelrod, L. Loveless, C. Miller, S. Strauss, E. Zavarin, and an anonymous reviewer for critical comments on the manuscript. I dedicate this paper to the late W. B. Critchfield (1923–1989), whose studies on the impacts of the Pleistocene on conifers demonstrated that genetic structure of extant species cannot be understood without looking to the past.

TABLE 1. Approximate ages and durations of geological eras from the Mesozoic to present.

| Era | Period | Epoch | Duration (millions of years) | Millions of years ago |
|---|---|---|---|---|
| Cenozoic | Quaternary | Holocene | Approximately the last 10,000 years | |
| | | Pleistocene | 2.4 | 2.5 |
| | Tertiary | | | |
| | Neogene | Pliocene | 4.5 | 7 |
| | | Miocene | 19 | 26 |
| | Paleogene | Oligocene | 12 | 34[1] |
| | | Eocene | 16 | 54 |
| | | Paleocene | 11 | 65 |
| Mesozoic | Cretaceous | | 71 | 136 |
| | Jurassic | | 54 | 190 |
| | Triassic | | 35 | 225 |

[1] The Oligocene–Eocene boundary is accepted to be 34 Ma, coinciding with the terminal Eocene event. Authors publishing before the middle 1970s and some current ones accept the boundary as 38 Ma.

leogene (Paleocene through Oligocene) events, especially the Eocene, on the evolution of the genus as a whole has not been analyzed. In this paper, I attempt to synthesize recent information on plate tectonics, climate, fossils, and biogeography of pines and other dominant plant groups as they affected pine evolution. From this synthesis, I argue that the Eocene was one of the most important phases in pine evolution.

## SYSTEMATICS AND CURRENT BIOGEOGRAPHY OF *PINUS*

The genus *Pinus* is one of the most widely distributed genera of trees in the Northern Hemisphere. Pines occur predominantly at middle latitudes (30°–55°N), but important centers of pine species also exist at high (> 55°N) and low latitudes (< 30°N) (Figs. 1, 2; Critchfield & Little, 1966). Pines are abundantly represented in North America, Central America, Europe, and Asia, with some taxa extending into northern Africa. Within their range, pines occur in diverse habitats, extend from sea level to 3,700 m, and dominate natural vegetation in many regions. They are absent from hot, wet, tropical environments, where they are poor competitors with other taxa (Mirov, 1967; Bond, 1989). At tropical latitudes, pines occur only in uplands or semi-arid regions.

*Pinus* contains more species than any other genus of conifers, although *Podocarpus* may rival it. Pines have been recognized since Classical times, and more than 40 classification systems have been proposed (Critchfield & Little, 1966; Mirov, 1967; Little & Critchfield, 1969; Price, 1989; Millar & Kinloch, 1991). The most widely accepted is the system of Little & Critchfield (1969), which built upon and modified the classification of Shaw (1914, 1924). Little & Critchfield (1969) divided *Pinus* into 3 subgenera, 5 sections, 15 subsections, and 94 species (Fig. 3). They updated the classification by incorporating new types of information based on genetic data, especially from contemporary studies on hybridization and biochemical variation. Thus, their classification implicitly suggests phylogenetic relationships and common origins of species and groups of species. Since the time of Little and Critchfield's classification, several new species have been described, especially from species-rich and as yet still incompletely known regions such as Mexico. In this paper, I accept Little and Critchfield's authority for species, and cite authors of taxonomic names only for those taxa outside of their system. I also accept most aspects of their

classification as the best presently available hypothesis of phylogenetic relationships among the groups of extant taxa.

## Mesozoic Biogeography

### ORIGIN OF PINES

The prevailing hypothesis until the mid-1970s on the origin of the genus relied on the contemporary interpretation of Mesozoic fossil flora and the prevailing theories of the origin of cool temperate vegetation (Chaney, 1940; Mirov, 1967; Mirov & Hasbrouck, 1976). Fossil pines had been described from Triassic, Jurassic, and abundant Cretaceous locales, with pines especially abundant and diverse at high northern paleolatitudes. Mirov's widely cited interpretation dated the genus to the late Paleozoic or earliest Mesozoic, with its origin centered in a far-northern circumpolar continent known as Beringia. According to Mirov, the subsequent evolution of pines unfolded in a steady and progressive migration southward during the Mesozoic and Tertiary, culminating in a final southward thrust toward the equator during the Pleistocene.

This interpretation was cast into doubt by systematic revisions of Mesozoic coniferous fossils. Alvin, Creber, Miller, Stockey, and others compared internal anatomy of fossil and extant pinaceous cones and found four diagnostic traits that characterize *Pinus* (summarized in Miller, 1976). When previously described fossils were reanalyzed, many that were originally ascribed to *Pinus* were reclassified in the extinct pinaceous genera *Pityostrobus* and *Pseudoaraucaria*. This applied to all the known pinaceous remains from the Triassic and Jurassic, and many from the Cretaceous. In particular, all of the high-latitude macrofossils, primarily in the collections of Heer, 1868–1883, originally treated as *Pinus* were reclassified, in some cases, even as angiosperms.

The revisions, combined with new fossil discoveries in the last two decades, result in a Cretaceous fossil record of about 25 species of pines from eight Northern Hemisphere regions (Table 2; Fig. 4). About half are known from petrified cones whose internal anatomy has been confirmed as *Pinus*. Others are needle, wood, or pollen fossils, generally accepted to be *Pinus*. Of special note is the distribution of these fossil pines. Although a geographic bias may be expected due to proximity of fossil locations to active paleobotanists, fossil pines occur at middle and a few high latitudes, widely spread east and west, with apparent centers in the northeastern United States, Japan, and western Europe. The earliest known pine, *P. belgica*, from the early Cretaceous (about 130 Ma) was found in Belgium. Pollen of an early Cretaceous pine was also found in amber deposits from Alaska (Langenheim et al., 1960). All other pine fossils are known from middle to late Cretaceous deposits.

The taxonomic diversity of fossil pines in the Cretaceous record is broad; two major subgenera and five subsections are represented. The origin of the genus is thought to be early-middle Mesozoic, although probably not the Paleozoic as suggested by Mirov (Miller, 1976; Eguiluz Piedra, 1985; Axelrod, 1986; Millar & Kinloch, 1991). A major change from Mirov's thinking concerns the location of the center of origin of the genus and the paths of subsequent radiation. At the beginning of the Mesozoic, there was one land mass, Pangaea (Smith et al., 1981). By the early Jurassic, a northern supercontinent, Laurasia, separated and began to drift from a southern continent, Gondwanaland. Although there may have been more land above sea in northern latitudes than at present (Wolfe, 1985) little evidence exists for a circumpolar continent, Beringia, that would have supported the origin of pines (Hickey et al., 1983; Eguiluz Piedra, 1985; Wolfe, 1985).

Most importantly, no fossil evidence exists for a high-latitude Mesozoic center of origin for pines. Mesozoic pine fossils occur between 31°N and 50°N latitude, with only two records from higher latitudes (Table 2). Similarly, fossils of six species of *Pseudoaraucaria* and over 20 species of *Pityostrobus*, genera considered most closely related to *Pinus* and most likely to have been the ancestral gene pool to *Pinus*, also occurred exclusively at middle latitudes, concentrated in eastern North America and western Europe (Miller, 1976, 1988). Hence, a circumpolar origin for *Pinus* is unsupported, and pine origins in middle latitudes are more likely. The regions of the northeastern United States and western Europe, which would have been contiguous in the early and middle Mesozoic (Smith et al., 1981), are the current candidates for the center of origin of the genus (Miller, 1976; Eguiluz Piedra, 1985; Axelrod, 1986; Millar & Kinloch, 1991). Alternatively, the diversity of Cretaceous pines and *Pityostrobus* in Japan suggests that pines might have evolved in eastern Asia.

### DISTRIBUTION OF PINES AND CLIMATE OF THE LATE CRETACEOUS

To understand the impact of the early Tertiary on pines, it is important to stress the Late Cretaceous distribution of pines and the prevailing cli-

mate at the end of the Mesozoic. By the Late Cretaceous, pines had reached eastern and western edges of Laurasia and occurred at middle latitudes in many locations between these extremes (Table 2; Fig. 4). The widespread distribution of pines in Laurasia by this time indicates that wherever within middle latitudes they originated, their main route of migration was east and west, and not predominately southward, as Mirov suggested. Migration from eastern North America to western Europe was not impeded until late in the Mesozic, by which time Laurasia had begun to split into North America and Europe. Laurasia severed first in the south and last in the north. High-latitude connections in the North Atlantic became increasingly reduced toward the end of the Mesozoic, and low seas may have covered the land (Ziegler et al., 1983; Tiffney, 1985a; Parrish, 1987). This region would have provided only minor corridors for pine migration. Evidence also exists for land connections at high latitudes in the Bering Sea region between Siberia and Alaska being used as corridors for temperate-adapted flora.

Within the new continents, continuing east–west migration in the late Cretaceous must have been hindered by seaways that extended the full north–south length of the continents (Kurten, 1966; Tiffney, 1985a). These seaways divided the continents into separate phytogeographic provinces, creating greater floristic affinities between eastern North America and western Europe, and western North America and eastern Asia, than between the east-west parts of each continent (Wolfe, 1975; Tiffney, 1985a).

The Late Cretaceous was a time of climatic quiescence and equability (Parrish, 1987; Upchurch & Wolfe, 1987; McGowran, 1990). Sea levels were high, and tectonic activity low, creating stable global climates. Although the breakup of Pangaea had commenced, paleocontinents were still relatively undispersed, resulting in average temperatures in the middle and high latitudes about 10°-20°C warmer than the present (Savin, 1977; Shackleton & Boersma, 1981; Parrish, 1987; Upchurch & Wolfe, 1987). Evidence on rainfall in the Cretaceous inferred from foliar physiognomy of angiosperms indicates that rainfall patterns were zonal. The Northern Hemisphere had a humid region around the paleoequator, a dry zone at low-middle latitudes, and a zone of higher rainfall above 45°N (Parrish, 1987). In general, however, latitudinal gradients were shallower, and changes in temperature with latitude were about ½–⅓ of present gradients (Parrish, 1987; Upchurch & Wolfe, 1987). Temperature and rainfall appear to have

been stable annually, with little seasonality at latitudes below 45°N (Upchurch & Wolfe, 1987). At higher latitudes, day lengths and precipitation apparently varied seasonally. The major cordillera of the Northern Hemisphere were not developed, or existed only at low elevations. Volcanic activity was minor, so there were few orographic effects on climate and little regional diversity in climate.

## Early Tertiary Biogeography

### CHANGING CLIMATES

Major changes in climate and vegetation characterized the early Tertiary (Wolfe, 1990). Although these events have long been discussed by paleobotanists interested in angiosperm evolution (Wolfe, 1975; Tiffney, 1985a, b; Friis et al., 1987), their impact on conifer evolution has not been analyzed. In general, average temperatures rose and rainfall increased in the early Tertiary. The trends toward increasing temperature and humidity started in the early Paleocene and continued into the Eocene, reaching maxima in the early Eocene, about 52 Ma. By this time, average temperatures had increased 5°–7°C above the Late Cretaceous (Savin, 1977), and tropical/subtropical conditions apparently extended at many middle and high latitudes to 70°–80°N (Wolfe, 1985; McGowran, 1990). High temperatures and humidity, however, did not persist stably throughout the Eocene. Although the late Paleocene/early Eocene (54–52 Ma) was the warmest and wettest period, there were at least two other warm periods, from about 46 to 42 Ma, and about 36 to 34 Ma, separated by cooler intervals that were approximately equal in duration to the warm periods (Fig. 6; Wolfe, 1978, 1985; McGowran, 1990). Average annual temperatures may have fluctuated as much as 7°–10°C between warm and cool periods of the Eocene (Wolfe, 1978). Several causes for these climatic developments have been suggested, including major tectonic events, changes in sea level, and submarine volcanism resulting in accumulation of atmospheric carbon dioxide and greenhouse heating (Wolfe, 1978; Parrish, 1987; McGowran, 1990; Kerr, 1991). Alternatively, large amounts of carbon dioxide may have been produced as a result of ocean-atmosphere interactions following a major extraterrestrial impact at the Cretaceous/Tertiary boundary (O'Keefe & Ahrens, 1989), which led to greenhouse warming (Wolfe, 1990).

Although latitudinal gradation was not great, the pattern in the Eocene differed from both the Cretaceous and the later Tertiary and Quaternary: in general, many low-latitude locations were relatively warm and seasonally dry, middle latitudes were warm and wet, and high latitudes were cool and dry (Parrish, 1987; Wolfe, 1978). Truly arid zones apparently did not exist; there is no evidence for Paleogene arid deserts or tundra (Axelrod, 1979).

Although these general trends in temperature and humidity existed throughout a broad latitudinal zone worldwide, there was geographic heterogeneity in the intensity of conditions. The warm humid zone was widest in North America and western Europe, and narrower in central and eastern Asia (Chaney, 1940; Parrish, 1987; Hsu, 1983). In general, continental elevations were low throughout the Paleogene, and upland areas apparently existed primarily in one middle-latitude region of western North America and in Antarctica (Axelrod, 1966; Wolfe, 1985, 1987; Wolfe & Wehr, 1987; Wing, 1987). In the upland area of western North America, the climate was anomalously temperate compared to other middle-latitude areas. Volcanism and mountain-building in this area during the Eocene also created heterogeneity in local climates and habitats.

### THE ANGIOSPERM BOREOTROPICAL FLORA

The changes in climate during the early Tertiary drastically affected global floristics (Friis et al., 1987; Wolfe, 1975, 1978, 1985). Diverse tropical and subtropical angiosperm floras appeared with increasing geographic representation during the Paleocene and the warm intervals of the Eocene throughout broad zones at middle latitudes in both Northern and Southern Hemispheres. Originally identified from the London Clay formations of England (Reid & Chandler, 1933), similar angiosperm floras have been described from many deposits elsewhere, including western and eastern North America (from the Pacific Coast to Nebraska and Texas; Vermont, Alabama), western and eastern Europe (including England, France, Belgium, Germany, Bulgaria, Ukraine, and Russia), northern Egypt, China, and Japan (Mai, 1970; Graham, 1972; Wolfe, 1975, 1985; Tiffney, 1985a, b). Subtropical assemblages occurred north as far as 70° in Alaska, and at other high-latitude locations in Canada, Greenland, and Siberia (Wolfe, 1977, 1985). In North America, the average zone extended from 30°N to 50°N (Wolfe, 1985). The origin and major radiation of many angiosperm taxa is documented in these diverse floras.

Plant communities in these Paleogene floras were adapted to warm, humid, and equable conditions. These taxa were similar to those found in modern rainforest vegetation of Malaysia and other extant tropical rainforest regions and show comparable adaptations. Common genera include *Engelhard-*

*tia*, *Ficus*, *Pterocarya*, *Nypa*, *Platycarya*, *Wetherellia*, *Alangium*, and *Nyssa*. A few gymnosperms such as *Glyptostrobus*, *Taxodium*, and occasionally *Sequoia* occurred in these floras, but they, too, were apparently adapted to warm, humid conditions.

Recognizing their northern locations and their adaptations to warm, humid conditions, Wolfe (1975, 1977) referred to these widespread angiosperm assemblages as the "boreotropical flora." While this assemblage in no way suggests an organic, indivisible unit, it does imply that similarly adapted individual taxa migrated east and west rapidly and unimpeded, at middle latitudes throughout North America and Eurasia in the early Tertiary. The boreotropical flora reached its greatest development in the warm periods of the Eocene. During cool intervals, its latitudinal extent shrank.

## EOCENE PINES

The early Tertiary radiation of many angiosperm lineages and the migration of angiosperm boreotropical taxa east and west at middle latitudes has many parallels with the late Mesozoic radiation and migration patterns of pines. Boreotropical floras occur in the same locations worldwide during the early Tertiary as pines did in the late Mesozoic. With very few exceptions, pines are not found in boreotropical fossil floras. This prompts the question, where did the pines go?

The Tertiary record of pines begins in the Eocene; no pines are known from the Paleocene. Pines of the earliest Eocene occur primarily in high (65°–80°N) and low (2°N) latitude deposits in North America and Eurasia (Table 3; Fig. 5). High-latitude locations include central Alaska (Wahrhaftig et al., 1969; Dickinson et al., 1987; Fredericksen et al., 1988), Ellsmere Island, Greenland, Iceland, and Spitsbergen (Manum, 1962; Schweitzer, 1974). Low-latitude pines occurred in Borneo (Muller, 1966) and from one low-middle latitude location of the late early Eocene, near San Diego, California (Axelrod, 1986). Pines in these deposits were associated with other pinaceous conifers and with cool temperate angiosperms such as *Betula*, *Alnus*, and *Ulmus*. Ages of these fossils correspond to the first warm humid period of the Eocene (Fig. 6).

Fossil pines from the middle Eocene continue to be represented at high and low latitudes, but appeared for the first time in the Tertiary in middle-high latitude locations in North America and Eurasia. Most of the known fossils from the cool period of the earlier middle Eocene are in western North America, from British Columbia (Miller, 1973; Stockey, 1983, 1984), Washington (Wolfe & Wehr, 1987), Idaho (Axelrod, 1986), and Colorado (Wodehouse, 1933; MacGinite, 1953) (Table 3; Fig. 5). Western North America in general contains some of the richest plant-bearing deposits from the Eocene in the world, and dozens of fossil floras have been described. Only a few of these contain pines and other temperate taxa, and these are all concentrated in northern Idaho, central Wyoming, north to central Idaho, and British Columbia. This is the region that has been identified as an upland area with average elevations of 1,200–1,500 m (Axelrod, 1965; Axelrod & Raven, 1985; Wolfe, 1987). Pine deposits in some of these areas are associated with active volcanos and high elevations (e.g., Bull Run, Thunder Mountain, Axelrod, 1965, 1986; Creede, 2,500 m, Wolfe & Schorn, 1989).

The warm humid period of the middle Eocene is represented by few pine fossils (Table 3). Pine was present at high latitudes in the Mackenzie Delta of Alaska (80°N, Norris, 1982), at low-middle latitudes in Borneo (2°N, Muller, 1966) and southern Alabama (36°N, Gray, 1960), and also at a few middle latitudes in Nevada (50°N, Axelrod, 1966, 1968), within the upland plateau of western North America.

Pine fossils from the subsequent cool period of the later Eocene occurred at middle latitudes in Washington (Miller, 1974), Nevada (Axelrod, 1966, 1968), Colorado (Leopold & MacGinite, 1972; Axelrod, 1986), New Mexico (Leopold & MacGinite, 1972), and Japan (Huzioka & Takahashi, 1970; Tanai, 1970, interpreted by Wolfe, 1985 to be early-late Eocene), Fushun, China (Hsu, 1983), as well as a continuing presence in Borneo (Muller, 1966) and at high latitudes (Norris, 1982) (Table 3).

The latest Eocene marks the final widespread period of tropical conditions at middle latitudes in the Paleogene (Fig. 6). Pine fossils from the late Eocene occur primarily at high latitudes in western Siberia (Dorofeev, 1963), Alaska (Norris, 1982), British Columbia (Hopkins et al., 1972), at low latitudes in Borneo (Muller, 1966), and along the Tethys seaway in southeastern Europe (Chiguriaeva, 1952). Pines from the southeast coast of China, in the provinces of Jiang-su, Zhejian, and Fujian (Hsu, 1983), may also be from this period (Table 3).

## THE TERMINAL EOCENE EVENT AND PINE EXPANSIONS

The end of the Eocene was marked by the most profound climatic event of the Tertiary (Burchardt, 1978; Wolfe, 1978; Parrish, 1987; McGowran,

1990). The fluctuations from warm to cool periods during the Eocene were minor compared to the drop in regional temperatures at the end of the Eocene. Average annual temperatures dropped approximately 10°–13°C, in some areas over only one million years (Fig. 6). The decline in average temperatures was accompanied by a large decrease in rainfall and increase in seasonality. Whereas in the Eocene the mean annual range of temperatures (seasonality) is estimated as only 3°–5°C, in the early Oligocene it is estimated as 25°C—about twice the range of the present (Wolfe, 1971). In many parts of the world, complex continental climate patterns developed, possibly for the first time, and continental ice sheets first occurred in the Oligocene (McGowran, 1990). Extensive volcanism and mountain-building in the Rocky Mountains, Himalayas, and Mexican ranges created local climatic diversity. Major tectonic events have been associated with the climatic cooling at the end of the Eocene with two schools of thought on their effect. One line of evidence suggests that changing positions of the Earth's continents and oceans had direct effects on the Earth's climate, leading to major cooling (Barron, 1985; McGowran, 1990). Another possibility is that the formation of giant uplifted plateaus in southern Asia and the American West led to accelerated chemical weathering, a decline in atmospheric carbon dioxide, and a "greenhouse cooling" effect (Ruddiman & Kutzback, 1989, 1991).

This terminal Eocene event (Wolfe, 1978) was marked by widespread extirpation of boreotropical angiosperm taxa from many middle latitudes worldwide, leaving only remnants in a few areas where the climate presumably remained mild. The extinctions of boreotropical floras were mirrored by great expansion of pines and other cool-adapted taxa into many middle-latitude locations. Many of the same fossil-bearing sites that contained boreotropical taxa in their late Eocene horizons were dominated by cool-temperate conifer taxa in early Oligocene horizons. In some localities, this change occurred in only one million years (Axelrod, 1965).

The existing record suggests that pines made their first Tertiary appearance at many middle-latitude locations during the Oligocene (Table 4; Fig. 7), recolonizing areas where they had occurred

in the Mesozoic. Pines are known from Oligocene deposits that range in North America from the Gulf of Alaska (Wolfe, 1972), British Columbia (Banks et al., 1981), Washington (Underwood & Miller, 1980), Montana (Miller, 1969; Leopold & MacGinite, 1972), Idaho (Axelrod, 1986), Oregon (Wolfe, 1981), Colorado (Leopold & MacGinite, 1972; Schorn & Wolfe, 1989), to a single specimen from Chiapas, Mexico (Langenheim et al., 1967) (Table 4). In Asia, Oligocene deposits are in eastern and western Transcaucasia (Palibin, 1935; Czeczott, 1954), and in northwest China, in the Quidam Basin, and in the Jinguan Basin of western Gansu (Sung, 1958; Hsu, 1983). In Japan, pine was present as a minor component of a few floras (Tanai, 1972). Pine was abundant in the Oligocene strata of Borneo (Muller, 1966). Although some of the pine-bearing deposits were associated with areas of volcanism and mountain-building, others were in lowland and coastal areas where boreotropical flora had flourished in previous epochs.

The climatic deterioration of the early Oligocene was followed by an ameliorating and warming trend during the late Oligocene and into the Miocene. Rainfall, however, stayed moderately low and climatic conditions remained temperate at middle latitudes. The record indicates that pines rose in abundance throughout middle latitudes in North America (Axelrod, 1986), Europe (van der Burgh, 1973; Klaus, 1989), and Asia (Hsu, 1983) in the Miocene; the direct ancestors of many modern pine species can be traced to Miocene pines. The warm conditions of the Miocene supported expanded pine forests at high latitudes, such as Banks Island (78°–80°N, Hills et al., 1974), MacKenzie Delta (72°–85°N, Ritchie, 1984), and Wrangell Mountains, Alaska (68°N, Wolfe, 1969) (Table 5). Pine fossils in low-latitude deposits, such as Veracruz, Mexico (17°N, Graham, 1976) indicate the continued presence of pines in mountainous low latitudes, despite the fact that lowlands in these latitudes were dominated by boreotropical flora.

## Impact of Early Tertiary Climate on Pine Evolution

### Eocene pine refugia

The preceding overview of biogeography provides evidence for the hypothesis that pine distributions shifted latitudinally and that pines expanded and contracted in elevational extent several times from the late Mesozoic to the middle Tertiary. In general, the hypothesis states that pine populations (1) occurred throughout middle latitudes in the Mesozoic, (2) were fragmented and displaced to high and low latitudes and to middle-latitude uplands in the Eocene, and then (3) reappeared widely throughout middle latitudes in the Oligocene and Miocene, where they remained for the rest of the Tertiary.

The Mesozoic origin and spread of pines east and west throughout Laurasia apparently occurred under a warm temperate climate that was equable and had little latitudinal gradation. Early migration and radiation of pines was favored in the Mesozoic not only by climatic conditions, but by the absence at high–middle latitudes of competing angiosperm taxa. Although angiosperms apparently originated about the same time as the pines in the Early Cretaceous (Taylor & Hickey, 1990), their rise to dominance in middle latitudes did not occur until the late Cretaceous (Wolfe & Upchurch, 1986).

The shift in global climates toward warm humid conditions of middle latitudes in the early Tertiary appears to have favored the migration and radiation of angiosperms at the expense of pines. Although pines have broad tolerance of climatic and edaphic conditions, they do not survive or grow well in hot and humid climates (Mirov, 1967). More importantly, in these conditions they are poor competitors with angiosperms in seedling establishment, height growth, and reproduction. Conifers dominate in areas where angiosperm competition is reduced, for example, by fire, cold, or nutrient shortages (Bond, 1989).

Such a situation apparently initiated widespread extirpations of pines over the lowlands at middle latitudes. The remaining areas of suitable pine habitat acted as refugia for pines during the warm, humid periods of the Paleogene.

In general, the fossil evidence indicates three important refugial zones. The circumpolar high-latitude zone originally thought by Mirov to be the cradle of *Pinus* emerges not as a primary Mesozoic center of origin but as an important Eocene refugium. Although many Mesozoic fossils from the polar region that had been identified as pine were later discredited, credible new records, mostly pollen, confirm abundant pine at many high-latitude locations in North America and Eurasia during the warm periods of the Eocene (Table 3). Pines may have been even more widespread during the early Tertiary in polar regions than indicated by the geography of present land masses. Much of the Arctic Sea is shallow, and tectonic evidence suggests that there may have been more land above sea level in polar regions in the early Tertiary than at present (Smith et al., 1981; Wolfe, 1985). Land

connections between North America and Eurasia in the North Atlantic (Tiffney, 1985a, b) would have provided high-latitude corridors for east-west migration of pines during the Eocene (Tiffney, 1985a, b).

The major limiting condition for plant growth poleward now is light. The suggestion that the Earth may have had a lower angle of inclination in the early Tertiary (Wolfe, 1978), which would allow more light at high latitudes, has been discredited (Donn, 1982; McKenna, 1983; Barron, 1984). Alternatively, geophysical and climatic conditions of the early Tertiary may have increased availability of carbon dioxide and permitted plants to photosynthesize under light regimes that were prohibitive under conditions of lower carbon dioxide concentrations that apparently followed the end of the Eocene (Berner et al., 1983; Creber & Chaloner, 1984; Ruddiman & Kutzbach, 1989, 1991; Kerr, 1991).

Low latitudes in North America and Eurasia also appear to have been refugia for pines during the warm humid periods of the Eocene. There is ample evidence that conditions in general were warmer and drier at low latitudes than at middle latitudes in the Eocene. These conditions have been documented for the southeastern United States, Central America, Taiwan (Wolfe, 1975), southern China and southeastern Asia (Guo, 1980; Hsu, 1983), and Borneo (Muller, 1966). During the Paleogene, the southern boundary of Eurasia was the Tethys seaway. Since the Indian subcontinent had not collided with Asia, the area of the present Himalayas marked the Tethys coastline in Asia. Unlike circumpolar regions, the low-latitude dry areas were disjunct and disconnected, even between the southeastern United States and Central America, and refugial populations were unlikely to have been connected by broad migration routes (Wolfe, 1975).

There is less abundant fossil evidence for pines at low latitudes than at high latitudes during the Eocene. There are few early Tertiary plant-bearing deposits in the areas of special interest, such as Mexico, Central America, and the Mediterranean, primarily due to the lack of depositional sediments (Martin & Harrell, 1957; Eguiluz Piedra, 1985). Nevertheless, Eocene pine fossils have been found at low latitudes in southeastern Asia, the southeastern and southwestern United States, and in areas of southeastern Europe that were at low latitudes during the Eocene (Table 3). In Mexico, the single specimen of pine at Chiapas (14°N) from the Oligocene (one of the earliest Tertiary plant records in Mexico), and the abundance of pines in

Veracruz (17°N) from the Miocene suggest that pines may have been present in Mexico and Central America earlier (Table 4). Similarly, pines were present in the Oligocene and abundant in Miocene deposits from southern Europe in the region of the Tethys (Palibin, 1935; Czeczott, 1954; Klipper, 1968; van der Burgh, 1973; Klaus, 1989).

Pines were not absent from middle latitudes during the Eocene. Their presence in select fossil deposits from interior western North America testifies to the presence of mid-latitude refugia. Pines in these regions more commonly date to the cool periods of the Eocene. During these times pine populations apparently expanded, whereas during the warm humid periods they contracted into narrow refugial areas where conditions were favorable. During warm humid periods, pines in interior western North America may have been fragmented into small local refugia and, therefore, poorly represented in fossil deposits.

The interior of western North America was anomalous for the Eocene world in having upland areas and centers of volcanism. Several of the pine-bearing deposits occurred at high elevations in Eocene calderas (Thunder Mountain, Idaho; Creede, Colorado), where climates were more temperate than elsewhere at middle latitudes. This region has been documented for angiosperm flora as being one of the first areas at middle latitudes in North America where climatic conditions became temperate during the Paleogene. Widespread volcanism along the cordillera added many cubic meters to the landscape in this region, building a highland that stretched from Arizona to Canada (Leopold & MacGinite, 1972; Wing, 1987; Wolfe, 1987; Ruddiman & Kutzbach, 1991).

Other middle-latitude areas such as eastern Asia may have supported pines during the warm humid periods of the Eocene, although only western North America is known to have had important upland regions. Although the early Tertiary fossil record of eastern Asia is not as complete as in western North America, pines have been found at a few middle-latitude locations in the Eocene. In Japan, the first Tertiary pines date to the last cool period of the Eocene and are not documented for the warm period at the end of the Eocene (Huzioka & Takahashi, 1970; Wolfe, 1985). These Eocene records may represent marginal populations of species that were centered farther north and expanded southward during the cool periods. Boreotropical angiosperms occurred throughout Asia in the warm humid periods of the Eocene, although they do not appear to have extended as far north as in North America (Chaney, 1940; Hsu, 1983).

## SECONDARY CENTERS OF PINE DIVERSITY

The widespread extirpation of pine populations from middle latitudes at the end of the Mesozoic is hypothesized to have led to extinction of many pine species and to have greatly depleted genetic diversity in others. Many Cretaceous fossil pines had combinations of traits not known in extant species and represent lineages that went extinct. Of two closely related pinaceous genera of the Mesozoic, *Pseudoaraucaria* fossils have not been found in rocks younger than the Late Cretaceous, and the youngest *Pityostrobus* fossils date to the early Eocene (Miller, 1976). The disappearance in these two genera of many diverse lineages closely related to *Pinus*, represents major extinctions in the pine family during the early Tertiary.

Despite this depletion of diversity in pines and taxa related to pines, the tectonic events and consequent migrations of the early Tertiary appear to have culminated in the creation of several new centers of pine diversity and the evolution of new pine lineages. This change appears to have been due in large part to increased tectonic activity. Although the period from the Mesozoic through the Paleocene had been relatively quiescent and land elevations were generally low across the continents, by the late Eocene several regions were active tectonically. In subsequent epochs, volcanism and mountain-building became increasingly important locally and globally.

The uplift of new mountain ranges and volcanic activity created environmental heterogeneity. Areas where active mountain-building coincided with Paleogene pine refugia are hypothesized to have become centers of pine radiation. Local climatic diversity was created by elevational differences, and rainshadow and other orographic effects developed. Diversity of soils evolved, with many areas having newly disturbed sites following volcanic activity. Mountain-building created new barriers to migration and gene flow, causing lineages to be fragmented and isolated. All these conditions must have favored divergence and speciation in pines. Conversely, refugial areas that did not undergo major early Tertiary mountain-building, such as the high-latitude zones, were centers from which pines migrated in the Neogene, but did not become important centers of pine speciation.

Although pines expanded and contracted from refugial areas during the fluctuating warm and cool periods of the Eocene, it was the terminal Eocene event that seemed to initiate major migrations out of refugia and to coincide with a time when pines appeared more widespread at middle latitudes. These

migrations provided further opportunities for divergence. As new environments were encountered, genetic isolation may have occurred, and possibilities for genetic drift by founder effects arose, as well as for hybridization with formerly isolated lineages.

## EVOLUTION WITHIN *PINUS* IN RELATION TO EOCENE REFUGIA

By the end of the Paleogene, all subsections of *Pinus*, with the possible exception of *Cembrae*, had evolved (Axelrod, 1986; Millar & Kinloch, 1991). The events of the early Tertiary probably gave rise to at least two subsections, speciation of lineages within several subsections, and the current biogeography of many subsections and groups within several subsections.

The hypothesis that pines were concentrated into refugial regions during the Eocene explains the current bimodal distribution and pattern of diversity of pines at low and high latitudes (see Axelrod, 1986, for maps of pine subsections). In North America three subsections, *Cembroides*, *Leiophyllae*, and *Australes*, appear to have been concentrated in southern refugia during the Eocene and radiated from them subsequently (Axelrod, 1986). Subsections *Cembroides* and *Leiophyllae* seem to have been limited to western North America and Central American refugia whereas *Australes* may have had refugial areas with a broader southern distribution, including the Gulf Coast (Tables 3, 4). The current distribution of *Australes* in both the southeastern United States and in Central America/Caribbea suggests that *Australes* may have had refugia in both regions. Although not identifiable to subsection, the abundant pine fossils of the Eocene from southern Alabama (Table 3) are from a site that is within the range of several extant species of *Australes*. Small genetic distances between taxa of *Australes* versus *Leiophyllae* (Strauss & Doerksen, 1991) suggest that these subsections were in contact or did not diverge from each other until after the Mesozoic.

Four subsections in North America appear to have been fragmented by Eocene events into several refugial regions. A division into northern and southern refugia in subsection *Sylvestres* is indicated by the extant lineages of *P. resinosa* (40°–52°N) and *P. cubensis* (restricted to Cuba, 22°N). Eocene fossils with affinities to *Sylvestres* that support a northern refugium have been found in British Columbia and northern Washington (Table 3).

Subsection *Contortae* similarly seems to have been divided into northern and southern refugia: the lineages leading to *P. contorta* and *P. banksiana* clearly had northern origins and boreal adaptations, whereas those leading to *P. clausa* and *P. virginiana* had southeastern affinities. Eocene fossils with affinities to *Contortae* have been found in northern Washington, and Oligocene fossils in British Columbia, corroborating a northern refugium (Tables 3, 4).

Subsection *Ponderosae* also may have had both northern and southern refugia. There are 10–17 species endemic or nearly endemic to Mexico and Central America, whereas wide-ranging *Pinus ponderosa* has a northern distribution and northern ecological affinities in its habitat preference and vegetation associates. Early Tertiary pines most closely allied to *Ponderosae* have been found in British Columbia (Eocene, Table 3), northern Washington, and Montana (Oligocene, Table 4). Lineages of *Ponderosae* may have been concentrated also in Rocky Mountain refugia, as suggested by Oligocene fossils from Colorado with affinities to this subsection (Table 3). A recent re-evaluation of evolutionary patterns in *Ponderosae* also indicates northern and southern division in the subsection (Lauria, 1991). *Pinus ponderosa* is considered to originate in northern latitudes, while other distinct phylads had southern origins in Mexico and Central America.

Subsection *Strobi* has northern and southern lineages in North America. Ancestral lineages of *Pinus monticola* and *P. strobus* would have migrated from northern refugia, and those of *P. strobiformis*, *P. ayacahuite*, and *P. chiapensis* (Martinez) Andresen (distinct from *P. strobus*, of which it was once classed as a variety; Andresen, 1964, 1966) would have migrated from southern refugia. Northern refugia are corroborated by Eocene fossil pines allied to subsection *Strobi* from British Columbia (Table 3). Lineages of subsection *Strobi* may also have been fragmented into middle-latitude refugia in the Rocky Mountain region, represented currently by *P. flexilis* and possibly *P. strobiformis*, and by Oligocene fossils from Idaho and Colorado (Table 4).

The small subsection *Balfourianae* is an ancient lineage (Kossack, 1989; Strauss & Doerksen, 1991; Millar & Kinloch, 1991) that appears to have been entirely concentrated in middle-latitude Rocky Mountain refugia during the early Tertiary. Present distribution of the three closely related species is in the Rocky Mountain/Great Basin/Sierra–Cascades Ranges of the western United States between 35°N and 41°N latitude. Early Tertiary fossils with probable affinities to this subsection were found in Idaho (Eocene) and Colorado (Oligocene) (Tables 3, 4).

In Eurasia, sequences of conifer-bearing deposits from the early Tertiary are not as widely distributed as in North America, but evidence for pine evolution in relation to refugia exists. Three ancient subsections, *Canarienses*, *Pineae*, and *Krempfiani*, have extant species restricted to regions that were along the Tethys seaway. Fossil evidence exists for a Tethys refugial area of pines in southeast Asia, in the region where *P. krempfii* now occurs. Pine was recorded in abundance throughout early Tertiary strata and in coastal southeast China and in northwest Borneo (Tables 3, 4). Other fossil floras for southeast Asia include temperate taxa, suggesting that pines would have found favorable habitats.

In western Europe, the boreotropical angiosperm flora was recorded abundantly from 45°N to 56°N (Chaney, 1940). Although there are no fossil records from currently low latitudes in Europe, pine fossils are known from areas of southeast Europe that were along the Tethys seaway (Chiguriaeva, 1952; Mirov, 1967). Furthermore, there is indication of dry zones in the middle Eocene along the European and north African Tethys, indirectly supporting the occurrence of pines there (Parrish et al., 1982; Parrish, 1987). Fossil pines allied to *Canariensis* and *Pineae* were widespread along the Tethys seaway in western Europe during the Miocene (reviewed in Klaus, 1989), suggesting more widespread distributions for both subsections in this region in the early Tertiary.

As in North America, in Eurasia several subsections appear to have been divided by Eocene events into northern and southern refugia. In *Sylvestres*, lineages represented by extant *P. sylvestris* most likely migrated from northern refugia. Eocene pine fossils from high latitudes in western Siberia allied to *Sylvestres* corroborate a northern refugium in Eurasia. The remaining 14 extant species in *Sylvestres*, excluding *P. densiflora*, and *P. thunbergiana*, and possibly *P. yunnanensis*, represent lineages from southern refugia. Although few Eocene deposits from southern Europe are plant-bearing, abundant fossils allied to *Sylvestres* are known from Oligocene and Miocene deposits in the Tethys region (Table 5; Palibin, 1935; Czeczott, 1954; Klipper, 1968; van der Burgh, 1973; Klaus, 1989). The exceptional three species may represent lineages from middle-latitude refugia, as documented by fossil pollen of unknown affinity from the Eocene and Oligocene of Japan and northern China (Tables 3, 4). Subsection *Gerardianae* may have been divided between a southern Tethys refugium, as represented by extant *P. gerardiana*, and a middle-latitude refugium in northern China, as represented by extant *P. bungeana*, and by early Tertiary deposits containing pine pollen in China (Tables 3, 4).

Refugia for subsection *Strobi* in Eurasia were mostly along the Tethys. Of the eight extant Eurasian species in the subsection, only *P. parviflora* seems clearly allied to lineages derived from more northerly refugia. The remaining seven modern species are all distributed along the former Tethys region. No early Tertiary fossils from Eurasia have been specifically allied with subsection *Strobi*, although Miocene fossils of the subsection testify to their presence in that region (Klipper, 1968).

The consequence of certain Eocene refugia becoming secondary centers of pine diversity is best described for Mexico and Central America. Although parts of the Mexican and Central American isthmuses were transiently under water during the Mesozoic (Kellum, 1944; Eguiluz Piedra, 1985), they were elevated during the Eocene and later Tertiary. Tectonic activity was especially great in Mexico during the late Eocene and Oligocene/Miocene. Tertiary volcanic activity significantly reshaped the Sierra Madre Occidental and created the Sierra Madre Oriental and the Transversal Neovolcanic Axis. Uplift in the early Eocene rebuilt almost the entire ranges of the Sierra Madre del Sur and Sierra Madre de Chiapas (Eguiluz Piedra, 1985).

Mexico and Central America are home to as many as 83 extant taxa of pines, including 48 species, 21 varieties, and 14 forms (Eguiluz Piedra, 1985). Within many subsections, extensive radiation and speciation are ongoing, which has been attributed to active mountain-building that began in the Eocene (Equiluz Piedra, 1985; Axelrod, 1986; Karamangala & Nickrent, 1989; Lauria, 1991). Active radiation is evidenced by closely related species clusters, with subsections *Ponderosae* and *Cembroides* the best examples. There are 10–17 species of *Ponderosae* (Eguiluz Piedra, 1985) endemic to Mexico and Central America and 10–16 species in *Cembroides* (Zavarin, 1988). The difficulty of separating the taxa of *Cembroides*, implying close genetic relationship, has led some botanists to the conclusion that *Cembroides* is a young subsection. Phylogenies based on DNA-sequence divergence indicate, however, that section *Parrya*, including subsection *Cembroides*, is ancient (Kossack, 1989; Strauss & Doerksen, 1991). Ancestral *Cembroides* lineages would have been concentrated in Mexican/Central American refugia during the early Tertiary, and the major pulse of radiations now occurring in the subsection may have begun in the early Tertiary.

Two subsections may have originated in Mexican/Central American refugia (Axelrod, 1980, 1986). Unlike other subsections, *Oocarpae* and *Sabinianae* have no Mesozoic fossil record and are not clearly documented until the Miocene. On the basis of specialized and apparently derived morphological adaptations (Shaw, 1914, 1924; Little & Critchfield, 1969; Klaus, 1980; van der Burgh, 1984), these subsections have long been considered to have originated recently. Phylogenetic analysis of DNA divergence also confirms their relative youth, especially of *Oocarpae* (Strauss & Doerksen, 1991). Using fossil and floristic evidence, Axelrod (1980) traced the origins of the northern (California/Baja California) elements of *Oocarpae* to mainland Mexico/Central America prior to the Miocene. The northern lineages appear to have diverged by the time they reached California (Millar et al., 1988), indicating that the radiation events occurred farther south in the early Tertiary. Although the systematic coherence of the extant Latin American taxa of *Oocarpae* remains uncertain, genetic relationships of some Latin American species link *Oocarpae* with *Australes* and *Ponderosae* (Critchfield, 1967), both of which have Mesozoic fossil records, appear to have had Mexican/Central American Paleogene refugia, and may have been ancestral to *Oocarpae*.

Subsection *Sabinianae* has a limited fossil record consisting of a single taxon allied to *P. sabiniana* and confined to southern California (Axelrod, 1986). Fossils are known only from the late Miocene through Quaternary, and Axelrod (1981) traced the origin of the extant species to Mexican species of *Ponderosae*. Genetic relationships of extant taxa link *Sabinianae* with *Ponderosae* on the basis of terpene affinities (Zavarin et al., 1967) and crossing evidence (Critchfield, 1966; Conkle & Critchfield, 1988). Together this evidence points to a Mexican/Central American origin of *Sabinianae* from early Tertiary *Ponderosae* lines.

## Pleistocene Versus Eocene Impacts

In this paper I document that tectonic, climatic, and biogeographic events of the Eocene had a major impact on pine distributions and evolution. The question may arise whether the effects of the Eocene were so confounded by subsequent events of the Tertiary and especially the Quaternary as to be indecipherable. I will address only the Pleistocene, since its potential was probably the greatest.

The Pleistocene was a time of profound change unprecedented in the history of the Earth. In some ways the Pleistocene was analogous to the Eocene. The Pleistocene was also an epoch with fluctuating climates, but the deviation from temperate climates in the Pleistocene was toward glacial conditions, whereas in the Eocene it was toward tropical episodes. The amplitude in average temperature between glacial and interglacial periods of the Pleistocene (5°–10°C, Bowen, 1979) was about the same as estimated for the cool and warm periods of the Eocene. The Pleistocene differed in lasting only 2 million years (cf. 20 million years for the Eocene), in having many more cycles (16–18, Bowen, 1979), and in having alternating periods of unequal duration with glacials longer than interglacials.

The events of the Pleistocene had enormous effects on vegetation, including pines. In northern latitudes, pine distributions were displaced by continental ice sheets (e.g., *Pinus contorta/P. banksiana*, Critchfield, 1985); in mountainous regions elsewhere, species migrated up or down in elevation (Miki, 1957; Van Devender & Spaulding, 1979). Along coasts and in other lowlands, pine populations shifted north and south in response to the climate cycles (e.g., *Oocarpae*, Axelrod, 1980; Millar, 1983). Concomitant to the shifts in distribution of pines were major changes in the genetic structure of species. The flux of population expansion and contraction, coupled with drastically changing selection regimes, affected the structure of genetic variation within species and allowed some species to hybridize (Critchfield, 1984, 1985; Kinloch et al., 1986; Millar, 1989).

In general, however, the Pleistocene does not appear to have completely reshuffled the genus in the way the Eocene did, and many of the Tertiary patterns and the evolutionary events that date to that period have been maintained. Notwithstanding the existence of local refugia, Pleistocene events primarily affected *Pinus* in a gradient from north to south, with the effect that species and populations shifted south then north (or down then up in elevation) following the cycle of the glacial and interglacial periods.

The impact of the Eocene, by contrast, was greatest in the latitudinal center of the genus and had the effect of dissecting the genus and concentrating pines into widely disjunct regions. Furthermore, during the early Tertiary, and unlike the Pleistocene, almost no upland regions (except in interior western North America) could offer local refuge from unfavorable climates. Whereas many pine species appear to have gone extinct in the early Tertiary, no pine extinctions in North America are attributed to the Pleistocene (Critchfield,

1984), although western Europe suffered a significant impoverishment of pine flora (Klipper, 1968). Some speciation, for example, in *Balfourianae*, *Cembroides*, and *Oocarpae*, seems to have been triggered by the Pleistocene, but no major new trends have emerged.

Insufficient time has elapsed since the close of the Pleistocene for its full impact to be felt on evolution in *Pinus*. Patterns initiated by the Pleistocene appear minor compared to the effects of the Eocene and are insufficient to erase the evolutionary impacts of the early Tertiary. Thus, many of the major evolutionary patterns of the early Tertiary can still be traced in the biogeography and relationships of extant pines.

## Validation of the Hypothesis

The arguments developed in this paper result in a working hypothesis about the effect of the Eocene on pine evolution. The hypothesis is a reconstruction of pine history based on available information from the fossil record, climatic and tectonic evidence, and biogeographic record of angiosperms and conifers. Many gaps in information exist that, if filled, would corroborate or negate this hypothesis. These gaps fall into several categories. Expanded fossil records are urgently needed, especially in regions hypothesized as Eocene pine refugia that currently have meager fossil documentation. These include Paleogene records for Central America and Mexico, low latitudes along the European Tethys, and high latitudes in eastern Asia. Technologies that allow more accurate identification of fossil affinities for macro- and especially micro-fossils at intrageneric levels would help in tracking the biogeography and evolution of these groups. These technologies need to be applied to published fossil floras, with revised taxonomic lists. Certain pine lineages have especially meager fossil records, including Cretaceous records of sections *Parrya*, especially *Gerardianae* and *Balfourianae*, and Cretaceous/early Tertiary records of section *Pinea*. Accurate dating of fossils and correlation with paleoclimatic and paleogeological events will also help to track the fine scale paths of these pines. Finally, existing and emerging genetic and molecular technologies should be applied to estimate genetic distances and divergence times among subgeneric groups. Such genetic techniques will allow tests of the hypothesized times of geographic isolation.

# PLANT LIFE-FORMS AND BIOGEOGRAPHIC RELATIONS OF THE FLORA OF LAGUNILLAS (30°S) IN THE FOG-FREE PACIFIC COASTAL DESERT[1]

*J. J. Armesto and P. E. Vidiella*[2]

## Abstract

The coastal desert of north-central Chile supports a rich but poorly known flora. Here, we document the importance of the annual and perennial habits in the flora of Lagunillas (30°S), at the southern transition from the desert to the mediterranean climate region, and discuss the origin of the desert flora by examining the geographic distribution of the taxa at the level of genus. The distribution was used to assign the species to six biogeographic elements. Annual plants represent 41% of the total flora (191 species) and are the most important life form. Excluding non-native weeds, however, decreases the importance of annuals to 33%. This value is higher than that for high-altitude deserts, but lower than for most other, less-equitable, lowland deserts both in North America and eastern Asia. Shrubs, geophytes, and other perennial herbs comprise 33%, 12%, and 21% of the native flora, respectively. The Cosmopolitan element, including weed species, accounts for 41% of the coastal desert flora. South American taxa include desert endemics (13%), Andean (12%), and Tropical American (10%) species. A large proportion (15%) of the taxa, especially shrubs, have disjunct distributions in the arid regions of North and South America. Results suggest that the present coastal desert flora derives primarily from recently diversified coastal desert and Andean taxa, most of them endemic to these areas, and secondarily from cosmopolitan weeds. The presence of a number of amphitropic xerophytes lends support to the hypothesis that arid habitats were continuous through the lowland tropics during the Glacial period.

The Pacific coastal desert of South America ranges from southern Ecuador at ca. 5°S, to about 32°S in north-central Chile (Rauh, 1985). Three major climatic and vegetational zones have been recognized within this extensive geographic region (Rauh, 1985): the narrow "tree-desert" zone of Ecuador and northern Peru, dominated by savannas and drought-deciduous forests; the "fog-loma" desert of Peru and northern Chile, with isolated patches of perennial and ephemeral vegetation maintained by permanent fog on the heights of the coastal range; and the fog-free northern Chilean coastal desert, with a predominantly ephemeral vegetation that develops on lowland areas in response to irregular rainfall events. The modern climate of the Pacific coastal desert is subjected to the desiccating influence of the Humboldt cold current, which also produces a negative thermal anomaly, resulting in temperatures 3–5°C lower than expected for the corresponding latitude, as well as highly uniform temperatures throughout the region (Ochsenius, 1982).

Arid environments developed very recently in South America (Ochsenius, 1982; Arroyo et al., 1988), in close association with geoclimatic events such as the Andean orogenesis and the onset of the Antarctic glaciation, both of which became more intense during Pleistocene–Holocene times. Tertiary climates were generally warmer and wetter than the present (Solbrig, 1976), and tropical forests covered most of the mountainless South American landscape. Climatic changes began in the mid-Eocene with a gradual decrease in temperature and an increase in the drying effect of the Andean range. Because of the rapid inception of the arid climate (Simpson, 1975; Ochsenius, 1982), the Pacific coastal desert provides a unique scenario to examine how plant and animal communities become modified by sudden environmental changes (e.g., Arroyo et al., 1988).

[1] We are grateful to G. Arancio, R. Osorio, and F. Squeo of the Herbarium of Universidad de La Serena (ULS), who played a major role in assembling and identifying the collection of plants on which this study is based. An anonymous reviewer provided valuable criticism of an earlier version of the manuscript. Partial funding for this research was provided by a grant from the OAS (1987–1988), and by the National Geographic Society (1989). This is a contribution to the Program of the Unidad de Investigación de Zonas Aridas of the Universidad de La Serena.

[2] Laboratorio de Sistemática y Ecología Vegetal, Departamento de Biología, Facultad de Ciencias, Universidad de Chile, Casilla 653, Santiago, Chile.

Although partial floristic accounts are available for certain areas, especially in the "fog-loma" region of southern Peru and northern Chile (e.g., Johnston, 1929; Ellenberg, 1959; Rundel & Mahu, 1976; Péfaur, 1982; Torres & López-Ocaña, 1982; Dillon, 1985; Rundel et al., 1991), complete systematic surveys of the local floral or fauna and their relation to other world biotas are lacking for many areas in the fog-free southern Atacama desert. This information can be relevant for refining and enhancing current paleoecological, geological, and climatic models about the Pacific coastal desert. In this paper we present the results of a survey of the vascular flora of Lagunillas (30°S), located at the southern margin of the fog-free coastal desert of north-central Chile (Fig. 1). Our goals were to assess the importance of the annual and perennial habits in the flora of Lagunillas in relation to other deserts of the world, and to examine the biogeographic relationships of the taxa in order to advance our understanding of the origins and history of the coastal desert flora.

## Study Site

Fieldwork was conducted at Lagunillas (Fig. 1), 15 km south of Coquimbo (30°06′S, 71°21′W), Chile, a field station managed by the Universidad de La Serena. Floral surveys encompassed approximately 25 km² of a gently sloping, extensive coastal terrace, traversed from east to west by an intermittent ravine up to 10 m deep and 10–20 m wide, which remains dry during most of the year. Extensive coastal terraces are a frequent feature of the coastal desert landscape between 27 and 30°S (Börgel, 1983). Altitude ranged from sea level up to 400 m on the summits of the nearby coastal hills. The terrace was covered by modern and fossil dunes, deposited over a calcareous hard-pan (caliche) layer, which extends throughout the area. The calcareous hard-pan is found at variable depths, surfacing in some places, especially on the slopes of the ravine. Further inland, closer to the coastal hills, alluvial deposits become more important, and a rocky substrate prevails on the surrounding hillsides.

The regional climate is semiarid with an average annual rainfall of 130 mm (di Castri & Hajek, 1976). Eight years of climatic records for Faro Punta Tortuga in Coquimbo (30°S) (E. Hajek, pers. comm.) indicate that annual precipitation is highly variable, with a maximum of 200 mm and a minimum of 30 mm. Records for 15 years from La Serena (29°54′S) indicate yearly totals varying between 0 and 177.5 mm (Muñoz, 1985). Rains fall mainly between April and July (winter). Air temperature rarely exceeds 22°C or falls below 10°C. For La Serena, the annual average is 14.7°C, and the mean minimum and maximum temperatures are 11.7°C and 18.4°C, respectively (Fuenzalida, 1965). Due to the accentuated influence of the ocean, air humidity remains over 80% during most of the year.

The vegetation is physiognomically dominated by evergreen and summer-dormant shrubs, except for a few months after the rains when herbs become abundant. The most common shrub species are *Encelia tomentosa*, *Haplopappus cerberoanus*, and *Flourensia thurifera*. Average shrub cover during the dry season varies between 8 and 25% (J. Gutiérrez, unpublished data). After the rainy season, plant cover increases up to 90% due to the growth of shrubs and the development of a dense cover of annuals and geophytes (Armesto, Vidiella & Gutiérrez, in press). Human impact through dry farming, and cattle and goat grazing has been important in this area as in most of the coastal desert. Before 1962, portions of the study area were cultivated in wet years mainly for wheat and potatoes, and they have been intermittently grazed since then. Nevertheless, the flora is representative of that of other less-disturbed areas of the coastal desert (unpublished data of the authors).

## Methods

Collections of plants used in this survey were conducted in Lagunillas during the growing seasons (September–December) of 1987, 1988, and 1989. No previous collections for the area were available. The number of species present in the area varies from year to year depending on the amount of rainfall. In years with low rainfall (20 mm or less), plant cover is composed mainly of shrubs and exotic weed species (Armesto, Vidiella & Gutiérrez, in press). The period of study included two years of abundant rainfall (1987: 168 mm; 1989: 80 mm), and hence we are reasonably certain that all plants potentially growing in the area have been collected. Voucher specimens of all the species collected were stored at the Herbarium of the Universidad de La Serena (ULS). Nomenclature of species follows Marticorena & Quezada (1985), except for the Nolanaceae, which follows Mesa (1981). Plants were classified by life form (annual herbs, perennial herbs, geophytes, and shrubs) according to field observations and the literature. For each genus, the number of species present in Chile (Marticorena

& Quezada, 1985), and the estimated total number of species known from all the world (Mabberley, 1987) were also compiled.

According to the modern geographic distributions of the genera, obtained primarily from Willis (1985) and Mabberley (1987), we assigned the species to the following biogeographic elements: (1) Cosmopolitan: species of genera distributed in several continents, both in temperate and tropical regions; (2) Pantropical: genera distributed within the tropics of the Old and New World; (3) Tropical American: genera primarily distributed in the lowland tropics of Central and South America; (4) Amphitropical (sensu Raven, 1963): genera occur primarily in warm deserts of North and South America, but are absent from the tropical regions in between; (5) Andean: genera mostly restricted to the tropical and/or temperate Andes of South America; and (6) Endemic: genera confined to the Pacific coastal desert of northern Chile and southern Peru.

For some genera, assignments were made based on systematic revisions. For example, the genus *Calandrinia* occurs in desert regions of North and South America and Australia. However, current evidence indicates that the genus spread and diversified in the Andes of South America (Kelley, 1973). Hence we assigned the species of *Calandrinia* to the Andean element. Although the genus *Fuchsia* has a broad distribution from North to South America, in addition to New Zealand and Tahiti, *Fuchsia lycioides* is the only member of the section *Kierschlegeria* that is restricted to the coast of north-central Chile (Berry, 1982) and related to other South American sections. We assigned this species to the Tropical American element. The genus *Tristerix* was assigned to the Andean element based on the work of Kuijt (1988). Finally, four genera (*Astephanus*, *Lastarriaea*, *Mesembryanthemum*, *Muehlebechia*) had unknown distributions, or their distribution did not fit the definitions given above.

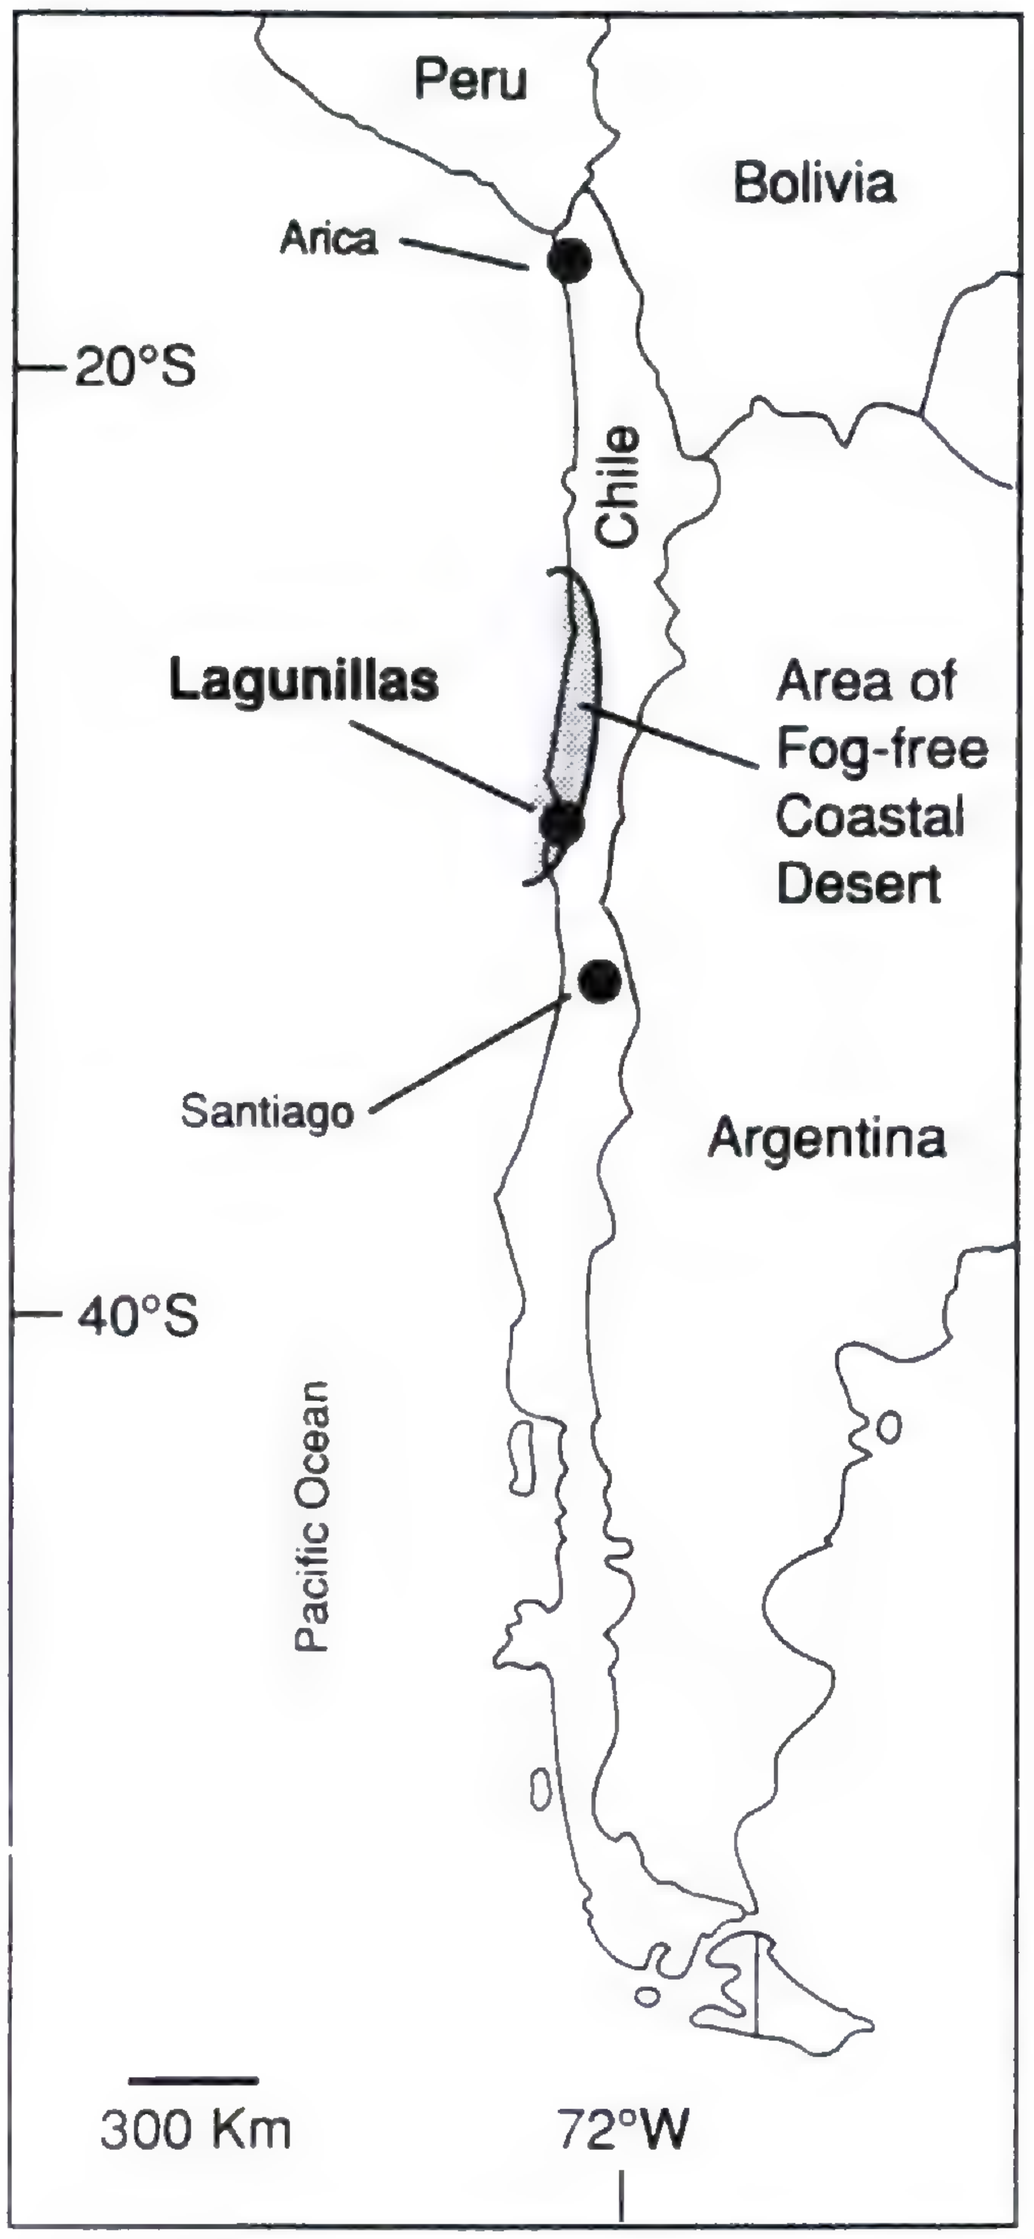

FIGURE 1. Location of Lagunillas, the study site in north-central Chile. The stippled area marks the approximate extent of the fog-free Pacific coastal desert.

## RESULTS

### FLORISTICS

A total of 191 vascular plant species, belonging to 61 families, have been collected within an area of about 25 km² in Lagunillas (Table 1). The families with the highest number of species in the flora are Compositae, Gramineae, Boraginaceae, Liliaceae, Papilionaceae, Onagraceae, and Amaryllidaceae (Table 2). Compared to the composition of the flora of a high-altitude desert in northern Chile (Arroyo et al., 1982), the coastal desert is characterized by a lower diversity of Gramineae and by the presence of bulbous monocots (Liliaceae, Amaryllidaceae). The relevance of Liliaceae and Amaryllidaceae in the coastal desert is also contrasted with the lower relative frequency of these families in the flora of Chile (Table 2). Onagraceae and Boraginaceae also seem to be better represented in the coastal desert than in the Chilean flora or in the high-Andean desert flora (Table 2).

TABLE 1. Species collected in the area of Lagunillas in the Chilean coastal desert, and their assignments to biogeographic elements based on the distribution of the genera. See text for definition of elements. * = Introduced species.

LIFE-FORMS

Annual plants represent the highest proportion of the total flora (40.8%, Table 3), followed by shrub species (28.8%). Bulbous perennials represent 10.5% of the species. All the species that are seen aboveground only after the winter rains, i.e., annuals, geophytes, and rhizomatous perennial herbs, comprise 70.7% of the total flora.

NATIVE VERSUS INTRODUCED SPECIES

Fifteen percent of the species collected are introduced (Table 3), most of them annuals. If these exotic species are excluded from the analysis, annuals decrease their representation to 33.1% (Table 3). This results from the fact that one-third of the annual species are introduced. Thus, annual and shrub species represent equivalent proportions of the native flora of Lagunillas (Table 3). There were no exotic species among geophytes, and only one shrub species was introduced.

BIOGEOGRAPHIC ELEMENTS

Cosmopolitan genera represent a high proportion (41.4%) of the total flora (Table 4), being especially common among annual (55.1% of all annuals) and perennial herbs (54.1% of perennial herbs). Some of these species belong to weedy families; probably most have life-history traits that enable them to invade recently open habitats. In contrast, only 27.3% of the shrub species belong to Cosmopolitan genera. Species that belong to disjunct genera in North and South American deserts represent 15.2% of the flora (Table 4). This disjunct element includes 21.8% of the shrubs and 16.7% of the annual species. Endemic species amount to 13.1% of the total flora. Of these endemic taxa, 18 (72.0% of all endemics and 9.4% of the total flora) are restricted to the Chilean desert. The highest proportion of endemics is found among the geophytes and the lowest among the perennial herbs. Other important biogeographic elements in the flora of Lagunillas are the Andean and Tropical American (Table 4). The Andean element is more frequent among the annuals (11.6%) and shrub species (16.4%). Tropical-American elements are more represented among the geophytes (45%) than among species of any other life form.

TABLE 3. Percentage of total, native, and introduced species by life form in the flora of Lagunillas in the Pacific coastal desert of Chile. N = number of species.

## DISCUSSION

Most species in the flora of Lagunillas are annuals (Table 3), a large proportion of which (24 out of 78, or 30.8%) are non-native weeds. These weedy species are native to Eurasia, and their presence and abundance in the study area may reflect the recent history of farming and livestock raising in north-central Chile (Bahre, 1979). All of them are also found further south in the mediterranean region of Chile (Navas, 1979), particularly in abandoned pastures or agricultural land. It seems likely that many weed species that came with the Europeans colonized the coastal desert via central Chile.

Considering native species only, the percentage of annuals in the flora of Lagunillas in the Chilean coastal desert is higher than in high-altitude Chilean and North American deserts. Annuals represent between 10 and 29% of the flora above 2,000 m in the northern Chilean Andes (10–146 species), and 19% of the flora at 1,200 m in the Great Basin, U.S.A. (322 species), where plants are subjected to low temperatures in addition to the constraints in water availability (Arroyo et al., 1988). In contrast, the proportion of native annual species (33%) in the Pacific coastal desert site is lower than in other lowland deserts with less equitable temperature regimes. Annual species may represent 40–70% of the flora in Middle-Eastern deserts (Orshan, 1986), and 52–55% of the flora in the Sonoran and Colorado deserts of California (Richerson & Lum, 1980).

Although the number of species of geophytes is often lower than the species richness of other plant life forms, they represent a high proportion of the flora in the coastal desert. The relative importance of Liliaceae and Amaryllidaceae, the major bulbous taxa, in the flora of the coastal desert is higher than in high-altitude deserts in northern Chile (Arroyo et al., 1982) or in the flora of continental Chile (Table 2). Geophytes are also important components of the flora in the deserts of Israel, Afghanistan, and Iran (Breckle, 1983). In contrast, geophytes are less important in North American deserts (Shreve, 1942).

The representation of the various biogeographic elements in the flora of Lagunillas should provide insights into the history of the Pacific coastal desert vegetation. Based on the geological evidence about the origin of this desert (Ochsenius, 1982; Arroyo et al., 1988), it is reasonable to assume that the oldest elements of its flora originated from a tropical stock of woody taxa during the Eocene. Probable relicts from that period are arid-adapted Pantropical elements such as *Prosopis*, *Acacia*, *Caesalpinea*, and *Cordia* (Table 1), which are now widespread in dry subtropical environments (Sarmiento, 1972). The past and modern geographic ranges of these woody genera, which include arid to moist tropical and subtropical regions of America and Africa, suggest that they might have originated before the breakup of Gondwana was completed (Solbrig, 1976) in the early Tertiary. The low representation of Pantropical elements today (6.3%, Table 4) indicates, however, that many old tropical elements became extinct. It is likely that most of these Tertiary tropical elements disappeared due to the rapid and strong aridization that took place during the late Pleistocene–early Holocene (Ochsenius, 1982; Simpson, 1975). Consequently, most of the modern desert flora originated more recently, in direct relation to the uplifting of the Andes and the increasing aridity of the Pacific coast of South America during the Quaternary.

We propose that some of the modern desert genera (e.g., *Adesmia*, *Chaethantera*, *Loasa*, *Mutisia*, *Porlieria*, and *Puya*) diversified in the Andean highlands and invaded the lowland desert subsequently. All of these South American genera have a large number of species (Table 1), which are mostly restricted to the Andes.

Pacific coastal desert endemics represent the third most important element in the flora (Table 4). Two subgroups can be recognized among the desert endemics. Some endemic genera appear to have diversified very recently in the coastal desert area (Mesa, 1981), exhibiting a high number of species per genus (e.g., *Cristaria*, *Malesherbia*, *Nolana*, Table 1), probably extending their ranges into the Andean environment (F. Squeo, unpublished manuscript on the genus *Malesherbia*). On the other hand, other low-diversity genera, which are often monospecific and have a geographic distribution restricted to one or a few localities in the Pacific coastal desert (e.g., *Ancrumia*, *Bridgesia*, *Llagunoa*, *Pasithaea*, *Phleocarpus*, *Reichea*) may represent remnants of a pre-aridization subtropical flora. In the latter group we could also include some Tropical American genera (e.g., *Alonsoa*, *Cestrum*, *Colliguaja*, *Oxybaphus*, *Sphacele*) that have a lower specific diversity in Chile (Table 1) than in the rest of South America.

A considerable proportion of the taxa belong to an element with a disjunct distribution in the deserts of South and North America. Because these species are presently restricted to arid lands, it is hard to explain how they may have reached their present distribution without assuming that arid habitats extended through the lowland tropics during the last glacial period or earlier (e.g., Simpson & Neff, 1985). Raven (1963) argued that most of these disjunct species could have migrated from South to North America across the Tropics, taking advantage of hypothetical subhumid sites in post-Miocene times. This hypothesis assumes that these species are capable of long-distance dispersal (Raven, 1963); however, this dispersal ability is seldom found among xerophytic species (Ellner & Schmida, 1981). For a majority of the disjunct taxa in Lagunillas (e.g., *Cardionema*, *Camassia*, *Encelia*, Table 1), it is hard to argue in favor of the long-distance dispersal hypothesis. The present distribution of these disjunct elements provides support for the hypothesis that arid environments extended through the area of the lowland Tropics during the last glacial period (Simpson & Neff, 1985). For some of the annual species (e.g., *Clarkia*, *Gilia*, *Camissonia*), dispersal associated with humans in modern times seems a more likely explanation.

An important component of the flora of the study site is the Cosmopolitan element. A major proportion of these Cosmopolitan taxa are annual and perennial herbs (Table 4). Because of their widespread distribution, it is likely that many of them could have been introduced by humans in recent times (e.g., *Erodium*, *Galium*, *Schismus*).

Because deserts are relatively open environments of recent origin (Arroyo et al., 1988), we expect that short-lived, opportunistic species, with high reproductive capacity, may contribute an important proportion of their flora.

# EVOLUTION OF REPRODUCTION IN *LAMPROTHYRSUS* (ARUNDINEAE: GRAMINEAE)

*H. E. Connor*[1] *and M. I. Dawson*[2]

ABSTRACT

*Lamprothyrsus*, a ditypic arundinoid, South American grass genus, consists predominantly of populations of exclusively female plants in which seeds are set by autonomous apospory. *Lamprothyrsus peruvianus* is a high polyploid—$2n$ = ca. 136, the highest chromosome number so far recorded in the Arundineae. The hypothesis favored here for the evolution of apospory involves a mutation for apomixis spreading through to fixation in an old, dioecious, polyploid genus resulting in generations solely of female plants. This proposal is consistent with reproductive pathways already recognized in some aposporous species of the related genus *Cortaderia*, and in some diplosporous species of *Poa* and *Calamagrostis*. It is another example of the association between apomixis and dioecism outlined by Gustafsson 45 years ago.

*Lamprothyrsus* is an arundinoid genus erected by Pilger (1906) to accommodate South American grasses with long, erect, hyaline, lateral lemma lobes and even longer, stiffer, recurved to reflexed awns; two species are now recognized: *L. peruvianus* Hitchc., primarily from Ecuador and Peru, and *L. hieronymi* (O. Kuntze) Pilger from Bolivia and northern Argentina. The genus is unique within the Gramineae in that it is the only one where almost all plants are female, and reproduction is solely from seeds set autonomously apomictically (Connor, 1979; Parodi, 1949). Because its affinity lies clearly with austral *Cortaderia* (Conert, 1961, 1987; Clayton & Renvoize, 1986), *Lamprothyrsus* might be suggested as an end of one evolutionary line of the cortaderioid facies of the tribe Arundineae. Its chromosome numbers are, therefore, of particular interest. Here we report a highly polyploid somatic number for *L. peruvianus*, and discuss its significance in the Arundineae and in the evolution of the reproductive biology of the genus.

## CHROMOSOME NUMBER AND REPRODUCTION

### THE PLANTS

One of us (H. Connor) collected seeds of tall and tussock-forming *L. peruvianus* between Tarma and San Ramon, Departmento Junín, at 2,300 m in the Peruvian Andes in August 1975; 100 plants were grown in the gardens of Botany Division, DSIR, Lincoln, New Zealand. All plants were monomorphic females—male-sterile—and of the floral form illustrated for *Lamprothyrsus* by Bernadello (1979) and Nicora & Rúgolo de Agrasar (1987), and have remained unchanged for 17 years in cultivation. All plants set seed abundantly by autonomous apospory where the embryo sac develops from the nucellus (Connor, 1979, 1987; terminology after Nogler, 1984). These seeds germinate freely.

### CHROMOSOME NUMBER

The count obtained for *L. peruvianus* is $2n$ = ca. 136 (Fig. 1); voucher CHR 449637. The chromosomes are small (0.7–2.4 μm). This is the highest reported number for the Arundineae, though it is very close to $2n$ = ca. 132 reported for *Phragmites australis*. High levels of polyploidy are already recognized in the tribe; among the highest numbers are:

1. $2n$ = ca. 132 = $11x_2$ : *Phragmites australis* (Cav.) Steudel, cited as *P. communis* Trin. in papers prior to Clayton (1968); Gorenflot, 1986)
2. $2n = 120 = 10x_2$ : *Rytidosperma indutum* (Vickery) Connor & Edgar (Brock & Brown, 1961, as *Danthonia*)
3. $2n = 108 = (18x)$ : *Arundo donax* L. (Christopher & Abraham, 1971)
   $= 12x$ : *Cortaderia jubata* (Lem.) Stapf (Connor & Edgar, 1974)

[1] Department of Geography, University of Canterbury, Christchurch, New Zealand.
[2] Landcare Research New Zealand, Lincoln, Canterbury, New Zealand.

ANN. MISSOURI BOT. GARD. 80: 512 517. 1993.

FIGURE 1. Metaphase of mitosis in *L. peruvianus*, × 3,000; $2n$ = ca. 136.

: *C. rudiuscula* Stapf, in plants raised from seeds collected (by H. Connor) at the *locus classicus*, Santa Rosa de Los Andes, Chile; voucher CHR 468718. This is the first report for this taxon.

4. $2n = 96 = 8x_2$ : *Rytidosperma* spp. (Brock & Brown, 1961)
: *Phragmites australis* (Lenoir et al., 1975; Gorenflot et al., 1984)

5. $2n = 90 = 10x$ : *Cortaderia* spp. (Hair & Beuzenberg, 1966)

6. $2n = 72 = 6x_2$ : *Rytidosperma* spp. (Brock & Brown, 1961)
: *Monachather paradoxus* Steudel (Brock & Brown, 1961, as *Danthonia bipartita*)
: *Phragmites australis* (Gorenflot et al., 1984; Lenoir et al., 1975; Pohl & Davidse, 1971)
$(12x)$ : *Arundo donax* (Christopher & Abraham, 1971)
$(12x)$ : *A. plinii* Turra (Fernandes & Queirós, 1969)
$= 8x$ : *Cortaderia* spp. (Connor & Edgar, 1974)

The basic number for *Arundo* species is uncertain; the levels of ploidy shown in parentheses are based on the assumption that $x = 6$.

The chromosome number sometimes varies among populations. Of the taxa listed above, those with variable chromosome numbers are:

*Arundo donax* $2n$ = ca. 60, 72, 108, 110 (Christopher & Abraham, 1971; Fernandes & Queirós, 1969; Larsen, 1963)
*Phragmites australis* $2n$ = 36, 42, 44, 46, 48, 49, 50, 51, 52, 54, 72, 84, 96, 132 (Gorenflot et al., 1984; Gorenflot, 1986)
*Rytidosperma indutum* $2n$ = 72, 96, 120 (Brock & Brown, 1961)
*R. caespitosum* (Gaudich.) Connor & Edgar $2n$ = 24, 48, 72 (Brock & Brown, 1961)
*R. laeve* (Vickery) Connor & Edgar $2n$ = 24, 48, 72 (Brock & Brown, 1961)
*R. linkii* (Kunth) Connor & Edgar $2n$ = 24, 48, 72 (Brock & Brown, 1961)

Even allowing that the chromosome count for *L. peruvianus* is approximate, it does not fit any of the usual arundinoid range of basic numbers indicated above, viz $x = 6$, $x = 9$, $x_2 = 12$, nor does it fit with a cytologically isolated genus such as New World *Gynerium*, $x = 11$ (Pohl & Davidse, 1971), nor with austral, Old World *Chionochloa*, $x = 7$ (Dawson, 1989).

REPRODUCTION IN HIGH POLYPLOID ARUNDINOIDS

Reproduction is sexual in high polyploid arundinoids; the exception is gametophytic apomixis in female plants in the two species of *Lamprothyrsus*, and in at least six species of *Cortaderia* (Bernadello, 1979; Connor, 1965, 1973, 1979, 1983a, b, 1987; Costas-Lippmann, 1979; Parodi, 1949; Pohl & Davidse, 1971; Philipson, 1978). Gender diversification is an uncommon evolutionary step in the tribe as a whole and, *Lamprothyrsus* and *Cortaderia* apart, is seen only in dioecism in monotypic *Gynerium*, in gynodioecism in one species of *Chionochloa*, and in andromonoecism in *Alloeochaete* and *Phragmites* (Connor, 1990).

Asexuality in females evolved in *Lamprothyrsus* and *Cortaderia* in the identical form of autonomous (nonpseudogamous) apospory after dioecism, subdioecism, or gynodioecism had become fixed as gender dimorphisms (Connor, 1987). Further, megagametogenesis is similar in both; the embryo sac, nucellar in origin, is commonly 6-nucleate, since one synergid and one antipodal are absent (Philipson, 1977, 1978; M. N. Philipson in Connor, 1987). Philipson & Connor (1984) examined the megagametophyte of eight genera of the Arundineae for haustorial synergids; they were present in *Lamprothyrsus*, *Cortaderia*, *Danthonia*, *Sieglingia*, *Rytidosperma*, and *Pyrrhanthera*, but absent from *Arundo* and *Phragmites*. There is no correlation between apomixis and haustorial synergids, because sexual reproduction is recorded in all genera except *Lamprothyrsus*.

Sexual reproduction in andromonoecious *Phragmites australis* is not very successful, as estimated from seed setting (Cartier & Lenoir, 1980; Gustafsson & Simak, 1963; Luther, 1950), even though megagametogenesis is normal (Cartier & Lenoir, 1980) and pollen fertility is high (Lenoir et al., 1975; Stoian et al., 1974). Large colonies of single, self-incompatible genotypes may be one cause, but the instability of chromosome number reported by Gorenflot et al. (1984) and Lenoir et al. (1975) could contribute in small part. Richards (1986) suggested that in northern English and Scottish populations ". . . summer temperatures are too low for seeds to ripen adequately." There is no suggestion of apomixis in *Phragmites*.

*Arundo donax* is less variable in chromosome complement than *P. australis*. All flowers are perfect. The only information we have on reproductive biology indicates that many megagametophytes fail to mature (Gustafsson, 1947; Philipson & Connor, 1984).

Sexual reproduction is usually cleistogamous in *Monachather*, and either chasmogamous or cleistogamous in *Rytidosperma* (Brock & Brown, 1961; Cashmore, 1932). *Monachather* is an extremely specialized monotypic genus of eremaean Australia; *Rytidosperma* is especially well developed in Australasia (Connor & Edgar, 1986).

*LAMPROTHYRSUS*

MALE-FERTILITY

Although there are substantial reports that *Lamprothyrsus* sets seeds exclusively on female plants in the absence of pollen, Bernadello (1979) recorded two specimens of *L. hieronymi* with polliniferous anthers: one from northern Argentina (*Fabris 3491*, 1962), and the other from Bolivia (*Steinbach 3453*, 1917). Foster (1966) had cited *Steinbach 3453* in GH without reference to its sex-form; it is male (E. A. Kellogg, in litt.). In the flowers of both, as illustrated by Bernadello (1979) and by Nicora & Rúgolo de Agrasar (1987), the anthers are large and the gynoecia small; the flowers cannot be interpreted as female flowers with male-fertile anthers. Both sex-forms are directly comparable with the dimorphic floral syndrome in *Cortaderia* (Connor, 1973).

Pollen in the male flowers of *L. hieronymi* is viable (Bernadello, 1979); we assume that it could lead to fertilization in normally reduced embryo sacs. This would necessitate strict sexuality in some plants, or the co-occurrence of sexual embryo sacs with aposporous sacs—this latter is frequent enough in gametophytic apomictic grasses. However, for the greater part plants will have produced unreduced aposporous embryo sacs; to add to the difficulty, at the time of anthesis precocious embryogenesis and endosperm formation is already well advanced. Female plants of that type would need to re-regulate the maturation of the gynoecium to allow the sequence of pollination at anthesis, pollen tube growth, and fertilization. Gynoecia in polliniferous plants are imperfectly developed as Bernadello (1979) reported, and as the Argentinian and Bolivian specimens of *L. hieronymi* show; it seems very unlikely that fertilization and seed set would occur there. Any of the benefits deriving from a generation of sexual reproduction that male plants could interpose into persistent asexuality (Lynch & Gabriel, 1983) would seem denied to *Lamprothyrsus* because the chances of males contributing genes to the next generation are very slight.

The presence of two polliniferous plants in *L. hieronymi* suggests, of course, that there may be more male plants in the populations than the herbarium collections reveal, but this needs to be es-

tablished. Should there be other male plants, explicit dioecism may be current, and asexual reproduction, though predominant, may not be exclusive. Synchronous maturation and anthesis of male and female elements would lead to sexually reproduced seeds. Nevertheless, genes for asexuality would be successfully invading the populations to the detriment of dioecism, so these two male plants could be among the last of the male remnants of that species. The count of one male plant in about 100 specimens listed by Bernadello (1979) for the whole of its Argentinian range may support this proposition.

The two male plants may only represent a low frequency sporadic mutation for the restoration of male-fertility, which brought with it the correlative changes in the gynoecium characteristic of dioecism and gynodioecism in the Arundineae. Such a mutation would be simpler if male-sterility was genetically controlled as in *Cortaderia* (Connor & Charlesworth, 1989) than if the nuclear-cytoplasmic system common to wild plants (Couvet et al., 1986) was operating.

It seems improbable that the male plants are the residue of a pseudogamous system because, as Asker (1980) has pointed out, pseudogamy is an unlikely precursor to non-pseudogamy; further, the two states never co-occur in one agamic complex. The synchrony essential to sexual reproduction would also be prerequisite of pseudogamy.

To date, polliniferous plants are unreported in *L. peruvianus*, but they are as possible in this species as in *L. hieronymi*. They would be accompanied by the same benefits, limitations, or constraints already outlined for *L. hieronymi*.

## EVOLUTION OF APOMIXIS

Pathways to the formation of populations consisting exclusively of female plants usually involve hybridism at some level; another associate is dioecism (see Westergaard, 1958). There is also a close correlation between hybridism, high levels of polyploidy, and apomixis.

*Lamprothyrsus*, with two oreophilous species, would be best interpreted as the contemporary, asexual residue of an old, austral, allopolyploid genus that had become dioecious, but which later substituted autonomous apospory in females for the sexual functions of dioecism. A mutation for apomixis spreading through females in 1M : 1F dioecious populations can readily lead to fixation (Charlesworth, 1980; Crowe, 1988; Lloyd, 1980; Marshall & Brown, 1981; Maynard Smith, 1971). Clearly, this pathway has been followed in apomictic South American species of *Cortaderia* (Connor, 1973, 1983b). Some diplosporous species of *Poa* and *Calamogrostis* have similar histories (Kellogg, 1990).

That hypothesis avoided any direct role for hybridism in the evolution of apomixis, although the high level of polyploidy indicates an amphiploid origin for taxa in *Lamprothyrsus*. Amphidiploidy itself neither assists nor hinders the development of an agamospermous system, but amphiploids will more easily accommodate occasional restoration of male-fertility.

What selection pressures would have favored the adoption of an autonomous apomixis in a dioecious taxon? It would be idle to invoke attractive ideas such as climatic conditions becoming unfavorable to the maturation and dispersal of pollen so that males became of lowered fitness; or that the sex-forms became overdispersed and exceeded pollination distances; or that sexual reproduction became limited by the ecological separation of the sex-forms as recorded by Fox & Harrison (1981) for *Festuca*, and by Freeman et al. (1976) for *Distichlis*, but undetected in *Buchloe dactyloides* (Quinn, 1991; Shaw et al., 1987) or in any of four Australian dioecious grass genera (Connor & Jacobs, 1991). Speculation about those forces should remain speculation; nevertheless, any increase in pollen fitness that was expected with the evolution of dioecism has been foregone, and with it male heterogamety. But all plants produce seeds, not half of them; and precocious embryogenesis allows the benefit of the development of seeds before both panicle emergence and anthesis.

It is evident that the maternal fitness and heterozygosity incorporated by autonomous apomixis remains high if measured in *Lamprothyrsus* by contemporary ecological versatility, and by morphological variability (Bernadello, 1979; Conert, 1961; Pilger, 1906), even though apomixis is generally not thought to be selected to increase ecological or evolutionary potentialities. Gabriel (1988) showed that apomicts, through both mutation and selection, could maintain a high level of genetic variability, and that they could be expected to perform well even in ecologically unstable environments. However, as Kellogg (1990) correctly observed, little is known of the patterns of variability in *Lamprothyrsus*, and both Conert's (1961) and Pilger's (1906) taxonomic attempts at accounting for infraspecific variation in *L. hieronymi* were unacceptable to Bernadello (1979).

*Lamprothyrsus* as a genus is predominantly autonomously apomictic in reproduction; such a state in the Gramineae is approached only by monotypic

*Nardus*, where apomixis may be autonomous; but there it is diplosporous, not aposporous, and is not exclusive (Rychlewski, 1961). All flowers are perfect and protogynous. Nogler (1984) felt that *N. stricta* L. should be reinvestigated because some critical data are unavailable.

Dioecious grasses are significantly a New World phenomenon; the greatest number of dioecious genera is in Mexico (Reeder, 1969). In none of them is there any known departure from sexual reproduction save for *Lamprothyrsus* and *Cortaderia*. It seems unlikely that there is a common ecological element, other than mountain environments, associated with the evolution of a specialized form of gametophytic apomixis, which supplanted a system already specialized in gender diversification. The explanation for the selection of this pathway must lie in reproductive efficiency, or in fitness. *Lamprothyrsus* offers an opportunity for evolutionary study as unique as itself. It is yet another example of the association between dioecism and apomixis elaborated by Gustafsson (1947).

# FIRST REPORT OF BALLISTOCHORY IN THE POACEAE[1]

*Tatiana Sendulsky*[2]

ABSTRACT

A newly described mode of fruit dispersal mechanism in bambusoid grasses of the genera *Sucrea* and *Raddia* (Poaceae: Bambusoideae: Olyreae), previously unknown, is here discussed.

Fruit dispersal in grasses (Poaceae) occurs in many different ways. The dispersal units (diaspores) mostly consist of caryopses protected by their bracts, which may be equipped with a variety of straight or twisted awns, bristles, hooks, pointed calluses, harpoonlike hairs, feathery plumes, and special tissues for buoyancy. Alternatively, they may have none of these specialized structures. In this case the dispersal unit may be composed of the whole spikelet, the caryopsis with its lemma and palea, or the naked caryopsis alone, with no protecting bracts; all three types fall as they are to the ground. There are other modes of dispersal: wind, rainwash for short distances, streams, rivers, and even the sea, termites, ants, birds, fish, and through a variety of means of transportation, intentional or unintentional, related to humans (van der Pijl, 1982; Sendulsky, 1965, 1966; Davidse, 1987; Filgueiras, 1986; Silberbauer-Gottsberger, 1984; Sendulsky et al., 1987).

These modes of dispersal in grassland grasses usually depend on one principal condition—the dry state of the mature dispersal unit. Thus caryopses, enclosed in their dry bracts with dry hairs and plumes, are light and easily carried by the wind. The awns, sharp-pointed calluses, and hooks become harder when dry and adhere better to fur or clothing. Only dry bracts let the anthecium or the caryopsis loose so that it falls easily to the ground.

A completely different condition for dispersal of diaspores is required by some genera of herbaceous bambusoid grasses. These grasses belong to the large subfamily Bambusoideae and "are not grassland grasses but are confined to warm and humid environments, within forests, usually under dense shade" (Soderstrom & Calderón, 1974).

According to Soderstrom & Calderón (1980), in 1972 and 1976 they collected about 162 different species of Bambusoideae in Brazil; of these, 80 were undescribed or new to science. At the time about 12 species of *Raddia* and a few species of *Sucrea* and of *Eremitis*, most of them still undescribed, were brought under cultivation in the Rio de Janeiro Botanical Garden by Dimitri Sucre, who accompanied Soderstrom in fieldwork in Espírito Santo and Rio de Janeiro.

In 1972, living samples of each species of these bambusoid grasses were given to me by Sucre and I started a living collection, which I still have in my office at the Instituto de Botânica in São Paulo, Brazil. Among known species there are *Raddia brasiliensis* Bertol., *R. distichophylla* (Schrad.) Chase, and the recently described *Sucrea maculata* Soderstrom. These species have revealed an unusual fruit dispersal mechanism that I could never have discovered by simply collecting, preparing, and studying the dried plant specimens.

At first I was surprised by the appearance of seedlings of different species of *Raddia* and *Sucrea maculata* in pots occupied by other plants, at a distance of 1.5–2 m from the mother plants that had produced the fruits. The mystery was explained one hot evening when I was working late in the office. Preceded by a quiet "click," a fruit flew

[1] I thank Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) for the grant that has made possible a discovery of this new dispersal phenomenon in grasses. I owe gratitude to my colleague Alasdair G. Burman for his valuable assistance and revision of the text, to Tarciso S. Filgueiras (IBGE) for helpful advice and suggestions, to L. G. Labouriau (UB) for critical review of the manuscript, and to Stanley Yankowsky, Department of Botany, Smithsonian Institution, for anatomical preparation of the spikelet section of *Sucrea maculata*, which, while this is not illustrated specifically in this paper, was used for the study and for schematical representation of the glume anatomy. I especially acknowledge the interest displayed by the late T. R. Soderstrom in this unusual and unexpected grass dispersal mechanism, and I dedicate this work to his memory.

[2] Instituto de Botânica de São Paulo, Caixa Postal 4005, 01061-970, São Paulo, S.P., Brasil.

and fell on my desk. I went to the plant, the branches of which were in slight movement, to see how it had happened; my first attempts to catch a fruit failed; the fruits were much faster than I was. Finally I caught one within its spikelet and had to hold it firmly, feeling the strong movement of the bracts between my fingers as I carried it to the microscope.

## Dispersal

Herbaceous bamboos live mainly in humid tropical forests, where there is little or no wind; anemochory, one of the common modes of dispersal in grasses, is substituted in the bambusoid grasses mentioned above by autochory, i.e., the dispersal of the diaspores by the plant itself, using ballistic movement, which depends upon the turgor or volume pressure in its cells and on the different anatomical structures of the two sides of the glume. The diaspore of the *Raddia* species and of *Sucrea maculata* is composed of the caryopsis with its lemma and palea, which wrap tightly around it and form the anthecium. At the base of the anthecium there are two green glumes, firm in texture, as long as a spikelet or longer; these glumes are responsible for the rapid ejection of the anthecium.

The irritability of the plant, and the response that produces the movement, depend on factors that may act as a stimulus. According to *Strasburger's Textbook of Botany* (Harder et al., 1967: 393), "This stimulus releases a complicated series of reactions in the living material, the energy for which comes from the organism itself and not from the initial stimulus." Thus, during an investigation of the catapult phenomenon in herbaceous bambusoid grasses, two kinds of factors were distinguished that may act as stimuli.

### External factors

*High temperature.* On hot summer days, the plant increases its ballistic activity (pers. obs.).

*Wind, drops of water, contact with insects or animals, or any mechanical touch.* The ripe diaspores are very sensitive to the slightest touch; a drop of water, an insect, or a slight breeze may trigger ballistic movement.

### Autonomous factors that are within or arise within the plant itself

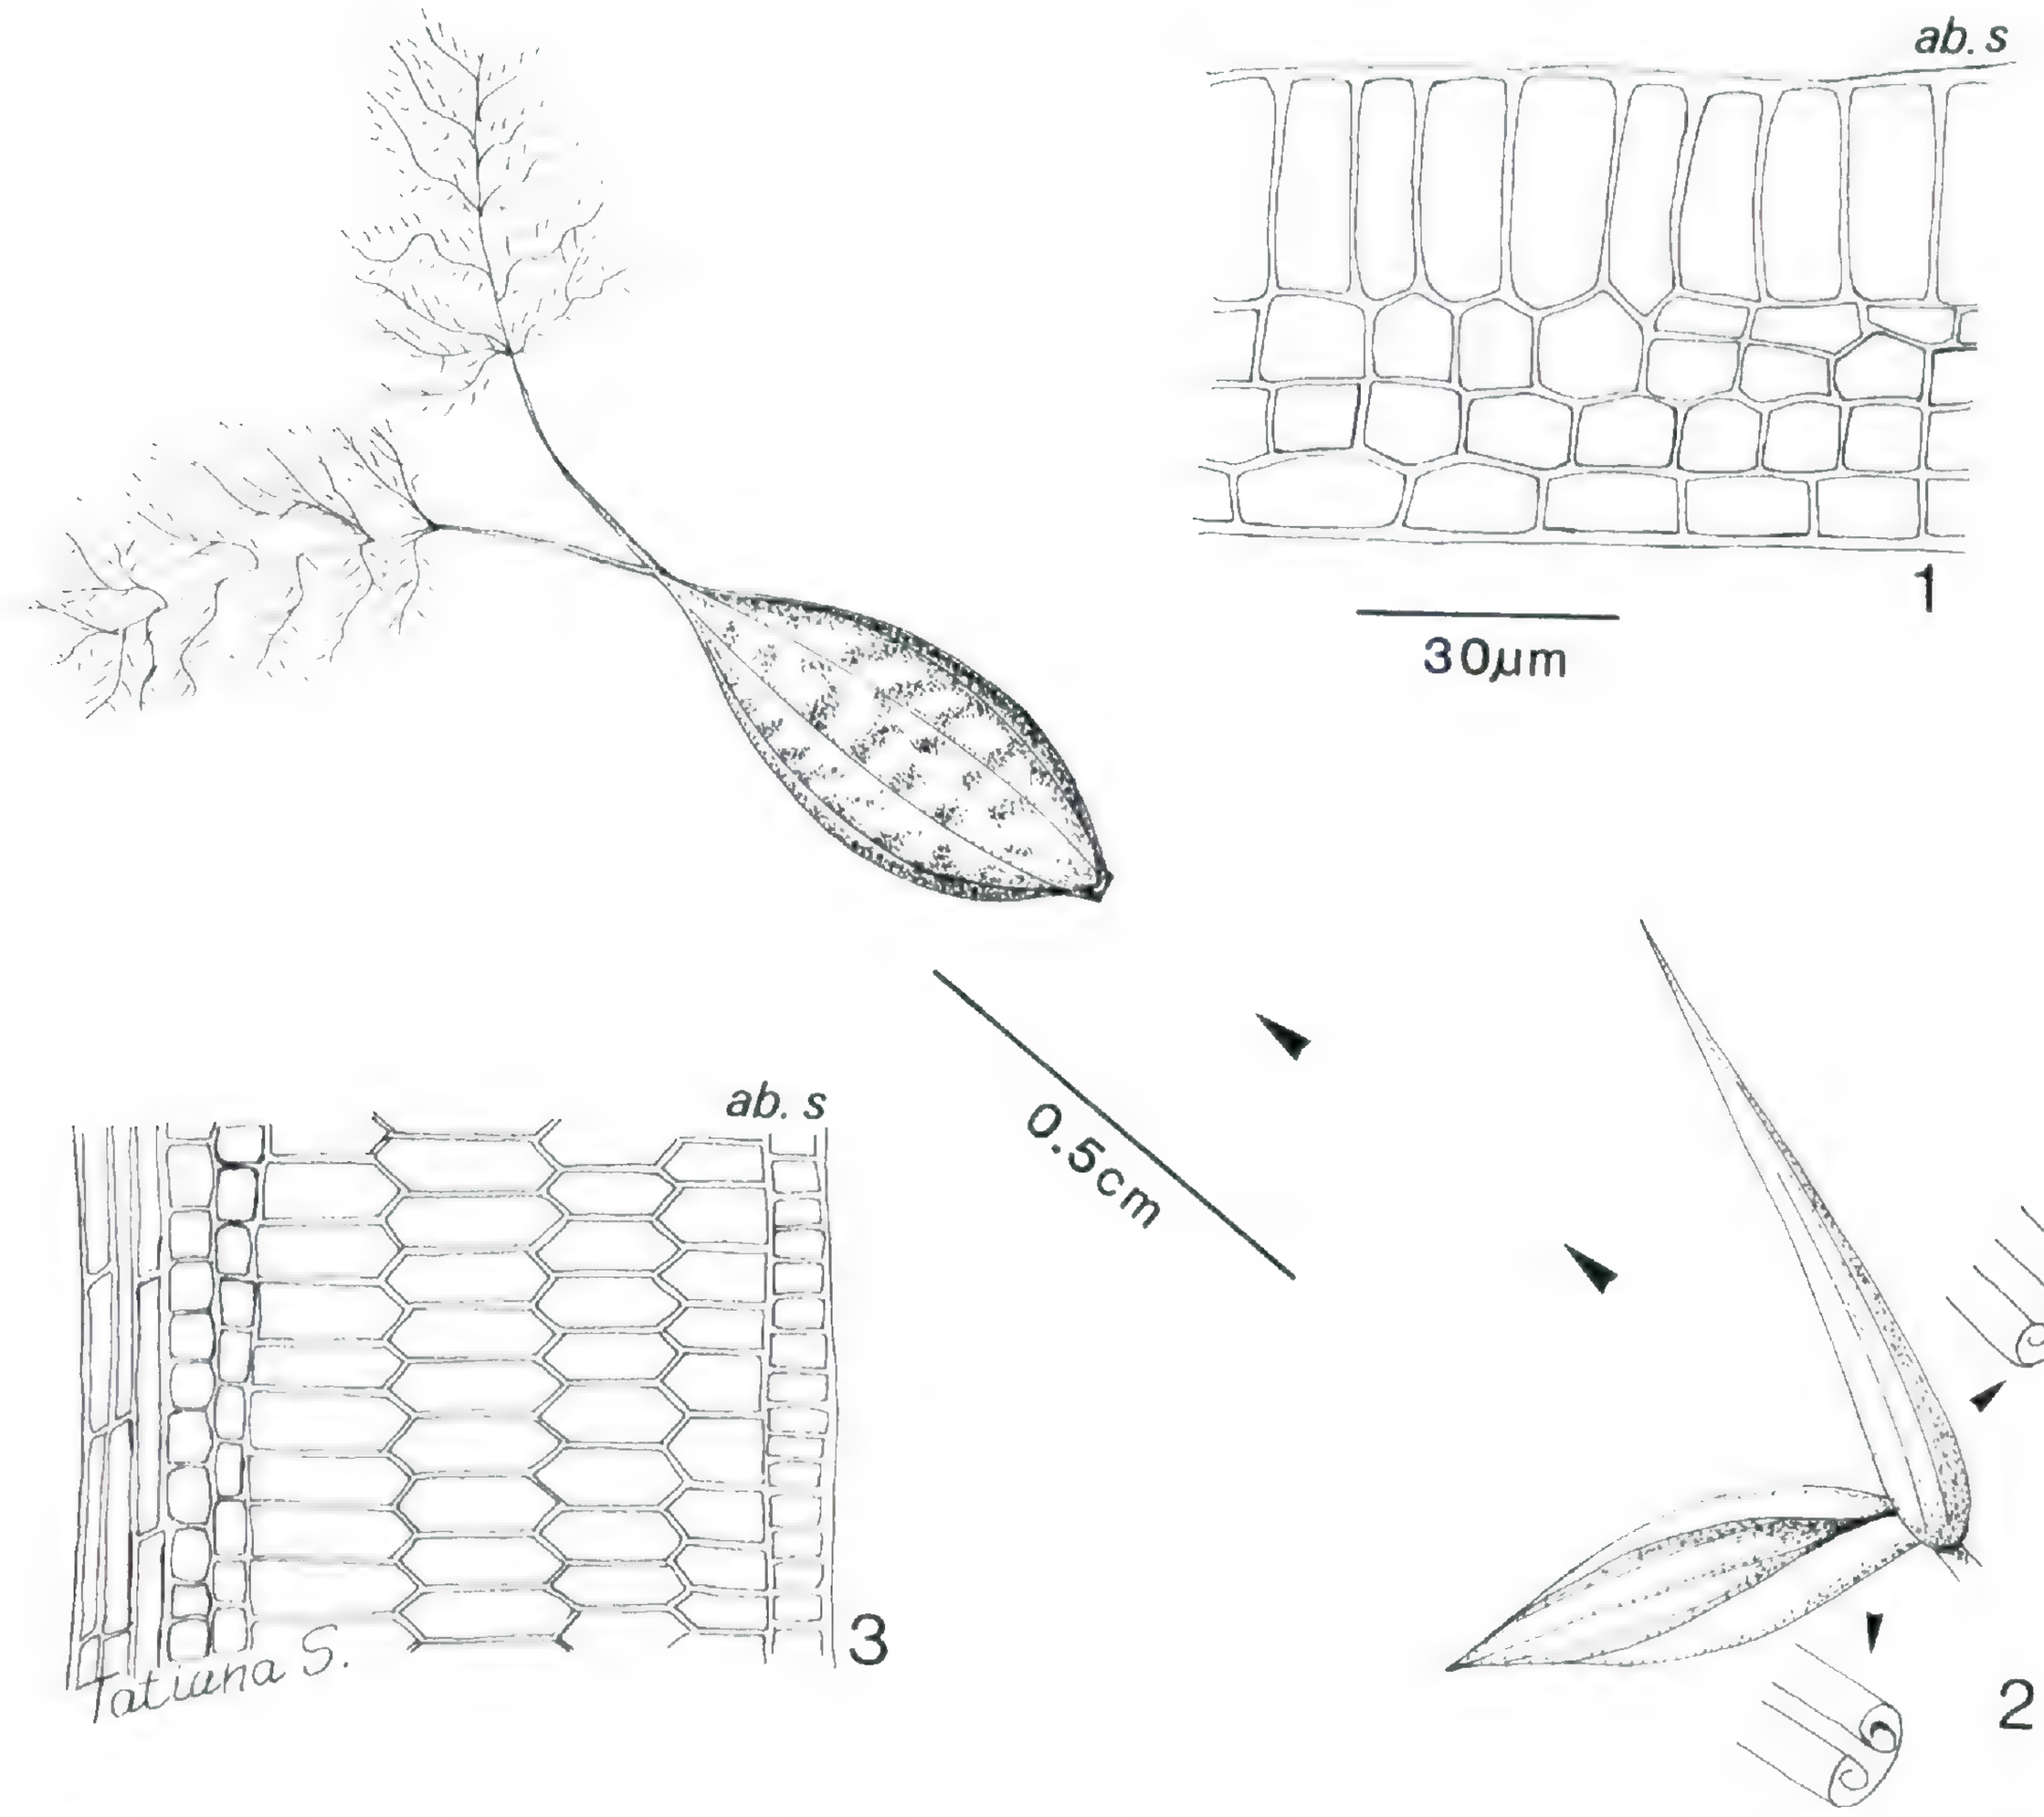
*Accelerated ripening of the fruit.* The anthecium, when being ejected, is fully formed but still bears white, fresh, plumose stigmas, which indicate the rapid development of the caryopsis from the moment of pollination to the phenomenon of ejection. The plant has to produce ripe diaspores before the glumes become dry and withered, as this will prevent them from producing the catapult process, which depends on the turgor pressure in the cells. At the moment of dispersal, the diaspore and glumes must be full of water and turgid. Here lies the main difference in conditions for dispersal in grassland grasses and in this group of herbaceous bambusoid grasses.

*Weight and surface of the anthecium.* The mature anthecium, in order to be effective, has to be heavy, while its surface is very smooth. These combined factors permit more speed, as the anthecium slips from the glumes, and increase its trajectory.

*Nyctinastic movement.* The sleep movements of the leaves, which were observed in *Sucrea maculata* and in all species of *Raddia*, often cause ejection of the diaspores. When the dense, fernlike leaves start their upward and downward movement, they sometimes get caught against each other; continuous movement causes the leaves to jerk free and the plant, or a few of its branches, swings. This sudden jerk or swaying of the branches is enough to elicit dispersal.

*Difference in anatomical structure.* The dorsiventrality of the glumes of bambusoid grasses involves inequality of the cells on the two sides of the glumes; this is necessary for nastic movement. The external (abaxial) side of the glume consists of large, uniform, narrow, uprightly arranged, thin-walled epidermal cells, twice as large as those of the internal (adaxial) side (Fig. 1). The cells of the external side tend to expand transversally because of their form, density, tightness, and turgor. The internal side consists of smaller flat cells. When the turgor in the cells of the external side reaches its maximum, the layer of the cells of the internal side resists the expansion of the external layer. But there comes a moment when, as the result of some metabolic process, or the response to a certain stimulus, the internal side cells suddenly lose tension and cease to resist. The volume of the internal side suddenly decreases, while that of the external side increases.

*Abscission of the anthecium.* The turgid ripe anthecium, clasped tightly by its turgid glumes, holds the state of tension. The moment of abscission is important; the anthecium separates from the pedicel at its base and above the insertion of the glumes. This is decisive for ejection, equal to the phenomenon of the abscission of the middle lamellae



FIGURES 1–3. Ballistic movement. — 1. Transversal section of a glume of *Sucrea maculata*. — 2. Flying diaspore of *Sucrea maculata* (glumes in lower right, anthecium in upper left). — 3. Longitudinal section of the fruit wall of the *Impatiens* species. Schematical representation, based on Strasburger (Harder et al., 1967). Abbreviation: ab. s. = abaxial side.

mellae in *Impatiens* spp., Balsaminaceae (Harder et al., 1967). As a result, the anthecium starts its slipping movement out of the tight glumes, and simultaneously the sides of the glume start from the base to roll in upon themselves forming four springs, which fling the anthecium 1.5–2 m (Fig. 2).

Ballistichory in *Impatiens* basically depends on the interaction between the thin-walled parenchyma cells of the external layer (expansion tissue) and the smaller collenchyma cells of the internal layer (resistance tissue) of the fruit wall (Harder et al., 1967; Fahn, 1974).

Comparison of the longitudinal sections of the fruit of *Impatiens* species with the cross section of the glume of *Sucrea maculata* makes clear the similarity in anatomical structures of the fruit wall and the glume. A rather fleshy fruit of *Impatiens* species (Fig. 3) presents four layers of thin-walled parenchyma cells on the external side and two or three layers of collenchyma cells on the internal side; the glume, a thin organ in *Sucrea maculata*, has only one layer of large, thin-walled epidermal cells on the external side, one layer of smaller cells on the internal side, and two layers in between, consisting of the mesophyll cells with chloroplasts.

In spite of the fact that the contraction of these dissimilar organs (fruit wall of *Impatiens*, glumes of grass) proceeds in different directions (longitudinally in the fruit wall and transversely in the glume), the catapult mechanism is the same in these plants, which thus tend to escape the shade of the mother plant.

The dispersal of diaspores by means of ballistic movements in the Poaceae was previously unknown; it is hoped that these observations on this

mode of dispersal in the herbaceous bambusoid grasses will serve as a guide for further research.

## Monographs in Systematic Botany from the Missouri Botanical Garden Number 43

# Comparative External Pollen Ultrastructure of the Araceae and Putatively Related Taxa

Michael H. Grayum

167 pp., illustrated, softcover, $30.00, plus postage.

This monograph presents the first extensive scanning electron microscope (SEM) survey of pollen of Araceae. Pollen of approximately 380 species of Araceae was studied, representing 99 of the 105 currently recognized genera. An effort was made to obtain material from all subgenera and sections distinguished in the most recent available taxonomic revisions (98 of 114 infrageneric taxa are represented in the study). Standardized, synoptic pollen descriptions are provided for all genera studied, and both whole-grain and high-magnification SEM micrographs are assembled in an atlas of 63 plates and 397 figures. An additional 12 plates and 92 figures summarizing the data accompany a detailed analysis of the polarity and evolution of pollen character states in Araceae. A discussion of the relationships of Araceae to other flowering plants features 15 plates and 104 figures depicting pollen of potential aroid relatives.

# *rbc*L SEQUENCE DATA AND PHYLOGENETIC RECONSTRUCTION IN SEED PLANTS: FOREWORD

*Gerard Zurawski*[1] *and Michael T. Clegg*[2]

When asked to write a brief foreword to this volume, we wondered what, if anything, needed to be said. Certainly the articles presented here speak for themselves about the current and future impact of comparative *rbc*L sequencing on plant phylogenetics. In the end, we felt it might be useful to describe briefly our view of the history that has led to this large and highly cooperative effort in systematics. For us at least, the history is important because it illustrates the interlocking nature of biological research.

The key players in this story include geneticists, biochemists, molecular biologists, biometricians, systematists, private industry, and national funding agencies. This diverse group laid the framework for what must surely be regarded as the most exciting effort in plant systematics in recent decades. Where did it all begin? One starting point was the discovery that some cytoplasmic organelles have their own DNA molecule. Another starting point was the suggestion by Zuckerkandl and Pauling in 1965 that the topology of branching of evolutionary trees could be inferred from the accumulation of amino acid substitutions in proteins.

The phenomenon of cytoplasmic inheritance provided the first tantalizing hints that extranuclear DNA molecules might exist in plant and animal cells. Wildman showed that an abundant protein fraction in plant cells called the "Fraction 1 Protein" was transmitted cytoplasmically in tobacco. Later, in the mid-1960s, it was established that the chloroplast and mitochondrial organelles contained DNA molecules. The Fraction 1 Protein was shown to be a component of the enzyme ribulose-1,5-bisphosphate carboxylase, responsible for fixing $CO_2$ in photosynthesis. Most work during the early 1970s was directed toward establishing the physical characteristics and size of the chloroplast DNA (i.e., that it is a closed circular molecule with an average GC content of about 38%). Beginning in the mid to late 1970s the new tools of recombinant DNA technology were aggressively applied to the study of the chloroplast genome. Because the chloroplast genome is relatively small and because chloroplast DNA constitutes an abundant fraction of total cellular DNA, most workers in the embryonic field of plant molecular biology focused on the study of the chloroplast genome. A problem

[1] DNAX Research Institute, 902 California Avenue, Palo Alto, California 94304.
[2] Department of Botany and Plant Sciences, University of California, Riverside, California 92521, U.S.A.

of nearly universal interest was the cloning and sequencing of the large subunit of ribulose-1,5-bisphosphate carboxylase (*rbc*L, the gene for Fraction 1 Protein). McIntosh, Poulsen, and Bogorad were the first to achieve this feat in 1980 by defining the *rbc*L sequence from maize.

Our involvement in this story began in 1981. One of us (M. Clegg) was a Sabbatical Visitor in the laboratory of Whitfeld and Bottomley at the Division of Plant Industry, C.S.I.R.O. in Canberra, Australia. The proposed research was to utilize RFLP analysis of chloroplast DNA to define relatedness between various modern and ancient barley cultivars. G. Zurawski was a Research Fellow in the same laboratory and had recently completed the *rbc*L sequence from spinach and was starting the pea *rbc*L sequence. A casual comment by G.Z. to M.C. expressed an opinion that "RFLP analysis is fine, but why wouldn't you want to comparatively sequence part of the barley chloroplast genomes—you would be dealing with many more base changes and they would be fully defined." This conversation prompted a determination by M.C. to learn DNA cloning and sequencing and was the beginning of our enduring collaborative friendship.

The next part of our story continued in the laboratory of G.Z. at the DNAX Research Institute of Cellular and Molecular Biology in Palo Alto, California. We spent a couple of hectic weeks together (M.C. as a Sabbatical Visitor) completing the sequence of *rbc*L and *atpβ* genes from three diverse lineages of barley. Comparisons of the maize and spinach *rbc*L sequences indicated a high degree of similarity between taxa that represented the two classes of flowering plants. However, the extent of this similarity did not prepare us for the complete absence of nucleotide differences between our hard-earned barley sequences. This result appeared remarkable in view of the moderate to high levels of nuclear gene polymorphism common in barley and most other plant taxa. Comparison of the maize and barley *rbc*L sequences established that the rate of substitution was on the order of $1 \times 10^{-9}$ substitutions per synonymous site per year, a very low value. Surprisingly, our friendship survived the hard work required to establish this low value. Soon after, comparisons of cyanobacterial and flowering plant *rbc*L sequences (with S. E. Curtis) confirmed the slow rate of evolution of this chloroplast-encoded gene over the whole sweep of plant evolution. It was clear from these initial results that the DNA sequences from slowly evolving chloroplast genes could be used to reconstruct plant phylogeny at its deepest levels.

A detailed statistical analysis of the limited number of *rbc*L sequences available in 1985 (with K. Ritland) showed that *rbc*L gene sequences could indeed be used for the reconstruction of plant evolutionary history. Despite these encouraging results, it was still a difficult and laborious task to sequence a gene from any given plant taxon. The Maxam-Gilbert method of chemical modification was the standard sequencing approach of the early 1980s. This method required detailed restriction mapping and the construction of elaborate sequencing strategies for its implementation. The time from initial preparation of DNA through to cloning a chloroplast gene and to determining its sequence frequently required six months of labor.

In parallel with work on chloroplast gene sequences, Palmer and collaborators were establishing the utility of chloroplast DNA restriction site analyses for the study of plant relationships. This work captured the attention and imagination of the systematics community and attracted a large number of imaginative, young systematists to the use of molecular data for phylogenetic analysis.

Three developments laid the foundations for the mass of coordinated data presented in this issue of the *Annals*. The first was the adoption of a sequencing protocol that utilized Sanger dideoxy-sequencing together with a standard set of *rbc*L primers. The *rbc*L primers were based on sequences that were conserved between the two distantly related taxa (maize and spinach). Preliminary work with D. E. Giannasi showed that this primer set worked well for sequencing other plant *rbc*L genes. The set of primers was made freely available to the scientific community courtesy of DNAX Research Institute of Molecular and Cellular Biology (supported by Schering-Plough Corporation). The second major development was the invention of the polymerase chain reaction method (PCR). The PCR method eliminated the cumbersome and time-consuming operations of molecular cloning. These two developments have led to a rich and exciting database that is the subject of this issue. The third parallel development was the explosive growth in computing power experienced in the 1980s and the widespread dissemination of algorithms for phylogenetic inference by Swofford and by Felsenstein. This issue is the culmination of these three developments, and in a larger sense it is the culmination of independent research trends in disciplines ranging from the chemistry of nucleic acids to systematic biology and even to computer science.

The whole exercise has been great fun for the

two of us. We could hardly have dreamed where this effort would lead when we began to work together in 1981. It has been exciting to watch a technical revolution sweep through an entire area of biology. It is also gratifying and amusing to be told by colleagues at various institutions that this is one area where the plant sciences are way ahead of the animal sciences.

# INTRODUCTION

*Douglas E. Soltis,*[1] *Mark W. Chase,*[2] *and Richard G. Olmstead*[3]

During the past several years, while *rbc*L sequences were being rapidly generated, it occurred to us that an excellent opportunity existed to conduct the first in-depth molecular phylogenetic analysis of seed plants in general, and angiosperms in particular. We therefore invited the many investigators throughout the world involved in *rbc*L sequencing studies to contribute their unpublished sequences for a broad phylogenetic analysis. The responses to our inquiries were uniformly positive. The large analysis (Chase et al.), as well as the numerous companion papers, therefore attest to the spirit of cooperation in the systematics community.

We stress to readers of the large analysis that the trees presented therein should not be viewed in some absolute way as depicting "the phylogenetic relationships" among seed plants. To the contrary, numerous most-parsimonious solutions exist, and the results presented must be viewed with this cautionary note in mind. Furthermore, we do not view this exercise as an end in itself, but rather as a stimulus for directing future research into the phylogenetics of seed plants. Undoubtedly, the large analysis could benefit from more sequences (greater taxon density) as well as more sophisticated and lengthy data analyses. We also hope that the large analysis will not only help to direct future molecular investigations, but also investigations of morphological, anatomical, chemical, and cytological characters.

In conducting a phylogenetic analysis of such magnitude as the large analysis, several important points were made clear. First, it became very difficult for individual investigators to remain isolated as students of particular groups (e.g., rosids, asterids, magnoliids, etc.). For example, in the large analysis some traditional members of Rosidae appeared within an expanded Asteridae clade, and traditional Hamamelidae appeared in lineages associated with distinct groups of rosids. Thus, investigators working on supposedly distantly related groups were frequently connected as a direct result of their *rbc*L sequencing efforts. Similarly, in many instances, the taxa under investigation in one lab became suitable outgroups for studies in other labs of other groups of plants. All of these events forged new collaborations and fostered cooperation among many, perhaps most, of the numerous co-authors of the large analysis. Second, as a byproduct of this massive collaboration, many sequences became widely available, allowing those working on companion papers to sample more thoroughly than could have been done in isolation. Third, it is possible to generate sequences much more easily and rapidly than one can rigorously analyze them. That is, our molecular methodology seems to have surpassed in speed our computer-assisted means of data analysis. Clearly, future efforts should be directed toward improved and more rapid means of data analysis. Appropriate levels of time and resources need to be dedicated to the analysis of sequence data, as well as their acquisition.

To assist readers, we have put together a large appendix at the end of this issue that lists all of the taxa for which *rbc*L sequences are reported, both in the large analysis and in the companion papers. Readers should note that the companion papers often include *rbc*L sequences for additional taxa not used in the large analysis of Chase et al. It is our hope that this appendix will assist readers in rapidly determining those taxa for which *rbc*L sequences are already available. However, it is also important to keep in mind that this appendix is already out of date: the actual number of *rbc*L sequences now available is well over 1,000.

Also provided in the appendix is voucher information for the taxa for which *rbc*L was sequenced. Although the great majority of species analyzed has been properly vouchered, vouchers were unfortunately not prepared for some of the taxa for which *rbc*L sequences are reported in the papers of this issue. This may, in part, be an unfortunate consequence of the rapidly advancing DNA technology allowing amplification of genes such as *rbc*L from DNA extracted from minute amounts of leaf material. Hence, leaf material is often obtained from botanical gardens or from collectors, and suf-

ficient material for the preparation of vouchers is often unavailable. The studies in this issue also illustrate, therefore, the critical role that botanical gardens now play as sources of living material for phylogenetic reconstruction. Unfortunately, plants grown at botanical gardens sometimes are not represented by herbarium specimens, and we would therefore urge botanical gardens to make voucher specimens for their living collections. Thus, the studies in this issue reinforce the need and importance of voucher information for all taxa used in molecular systematic studies. When vouchers are not available, the results obtained should be considered carefully, particularly in those instances in which surprising or unexpected taxonomic placements were obtained for such samples.

We hope that the large analysis and companion papers presented herein will not only act as a stimulus for future molecular and non-molecular systematic endeavors, but also will underscore what can be accomplished through the collaboration of numerous investigators. The large number of investigators cooperating in the large analysis is, as far as we are aware, unprecedented in the history of systematics. The future holds many additional opportunities for broad collaborations of similar scope as *rbc*L sequences from additional taxa and sequences of additional genes are obtained. It is our sincere hope that this issue will serve as a model and stimulus for what can be accomplished through the cooperation of numerous scientists.

We dedicate this issue to Arthur Cronquist, whose ideas and syntheses of systematic data provided inspiration, guidance, and stimulus to all botanists and whose classification provided much of the context for the papers presented. Plant systematics has benefited immeasurably not only from Arthur's hypotheses, but also from his personality and wit.

## ABSTRACT

We present the results of two exploratory parsimony analyses of DNA sequences from 475 and 499 species of seed plants, respectively, representing all major taxonomic groups. The data are exclusively from the chloroplast gene *rbc*L, which codes for the large subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO or RuBPCase). We used two different state-transformation assumptions resulting in two sets of cladograms: (i) equal-weighting for the 499-taxon analysis; and (ii) a procedure that differentially weights transversions over transitions within characters and codon positions among characters for the 475-taxon analysis. The degree of congruence between these results and other molecular, as well as morphological, cladistic studies indicates that *rbc*L sequence variation contains historical evidence appropriate for phylogenetic analysis at this taxonomic level of sampling. Because the topologies presented are necessarily approximate and cannot be evaluated adequately for internal support, these results should be assessed from the perspective of their predictive value and used to direct future studies, both molecular and morphological. In both analyses, the three genera of Gnetales are placed together as the sister group of the flowering plants, and the anomalous aquatic *Ceratophyllum* (Ceratophyllaceae) is sister to all other flowering plants. Several major lineages identified correspond well with at least some recent taxonomic schemes for angiosperms, particularly those of Dahlgren and Thorne. The basalmost clades within the angiosperms are orders of the apparently polyphyletic subclass Magnoliidae sensu Cronquist. The most conspicuous feature of the topology is that the major division is not monocot versus dicot, but rather one correlated with general pollen type: uniaperturate versus triaperturate. The Dilleniidae and Hamamelidae are the only subclasses that are grossly polyphyletic; an examination of the latter is presented as an example of the use of these broad analyses to focus more restricted studies. A broadly circumscribed Rosidae is paraphyletic to Asteridae and Dilleniidae. Subclass Caryophyllidae is monophyletic and derived from within Rosidae in the 475-taxon analysis but is sister to a group composed of broadly delineated Asteridae and Rosidae in the 499-taxon study.

Current assessments of higher-level relationships in seed plants are based largely on informed judgments of the relative value of various reproductive and vegetative characters (including secondary chemistry) and to some extent on historical precedent. Authors of recent taxonomic schemes (for example, Dahlgren, 1980; Takhtajan, 1980, 1987; Cronquist, 1981; Thorne, 1983, 1992) have synthesized an enormous amount of information. Nevertheless, their taxonomic decisions have been guided by estimations of which characters are reliable indicators of relationships. These differing judgments are responsible for radical differences in delimitation and relative ranks of taxa in each system of classification. Recently, a number of explicit, cladistic hypotheses have been developed at inclusive hierarchical levels (e.g., Crane, 1985, 1988; Dahlgren & Bremer, 1985; Dahlgren et al., 1985; Doyle & Donoghue, 1986, 1992; Bremer et al., 1987; Donoghue & Doyle, 1989; Loconte & Stevenson, 1991; Martin & Dowd, 1991; Hamby & Zimmer, 1992; Hufford, 1992; Olmstead et al., 1992; Taylor & Hickey, 1992). Such cladistic studies have previously been limited in scope; some data matrices contain significant taxonomic gaps, and in others characters for some taxa are missing. Both of these factors may have unpredictably misleading effects (Nixon & Davis, 1991; Platnick et al., 1991). Despite a great deal of investigation and analysis, seed-plant phylogenetics is, at best, in a preliminary stage of investigation and knowledge.

Molecular data, specifically DNA sequences, have received a great deal of attention as a potential source of "phylogenetically informative" characters that are putatively less ambiguous than nonmolecular characters. Such pronouncements suffer from the limitation that, at higher taxonomic levels, no extensive sampling and phylogenetic description of DNA sequence variation has taken place. The most taxonomically comprehensive analysis of nucleic acid sequences published so far on plants (rRNA; Hamby & Zimmer, 1992) used only 60 taxa, and a number of these were partial sequences. Martin & Dowd (1991), using nucleic acid sequences of the small subunit of RuBisCO (*rbc*S) inferred from amino acid sequences, studied 335 taxa from 135 families, still less than a third of angiosperm families. If insufficient sampling of taxa or characters (i.e., sequence length, acknowledged as a problem with the *rbc*S data studied by Martin & Dowd, 1991) are indeed factors, then no valid investigation of the "informativeness" of a given gene sequence exists for seed plants. Thus we are left with only an unfounded assessment of sequence data as having the *potential* to aid in estimating higher-level relationships.

Suggestions that the chloroplast gene *rbc*L, which codes for the large subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO or RuBPCase), was an appropriate locus to use in phylogenetic studies began with Ritland & Clegg (1987) and Zurawski & Clegg (1987). Initial attempts to evaluate relationships used only a dozen or so sequences representing all land plants (Palmer et al., 1988; Giannasi et al., 1992). Other recent studies have been restricted to single families (Doebley et al., 1990; Kim et al., 1992) or putatively closely related families (Soltis et al., 1990; Les et al., 1991; Donoghue et al., 1992; Olmstead et al., 1992; Rettig et al., 1992). Most of the latter studies began the process of incorporating significantly greater sampling to enhance their phylogenetic perspective. The use of *rbc*L was spurred by G. Zurawski, who generously made available a set of internal sequencing primers. The advent of temperature cyclers and high-temperature-resistant DNA polymerases (sometimes termed Polymerase Chain Reaction or PCR) has greatly enhanced rates at which gene sequence data are accumulating, so that effects on phylogenetic estimates of more intensive sampling of sequence variation can now be investigated.

We wish to examine here the degree to which a representative sampling of sequence variation for *rbc*L contains evidence of the evolutionary history of seed plants. In this study, we address the quality of evidence present in *rbc*L sequences for all major seed-plant lineages (roughly 265 families, the exact number depending on the taxonomic scheme followed). To a limited extent, we will compare our phylogenetic hypotheses with recent schemes, but such comparisons are difficult and must be considered heuristic because sister-group relationships ex-

from the DGAPA, Universidad Nacional Autónoma de México, Mexico, to LEE. We also thank David L. Swofford and John M. Mercer for assistance and advice in running the parsimony analyses; William S. Alverson, Michael T. Clegg, Julie Dowd, E. Allen Herre, Peter G. Martin, and James E. Rodman, for access to their unpublished sequences; Jeffrey J. Doyle, Robert F. Thorne, Peter Westin, Michael J. Donoghue, and several anonymous reviewers for their helpful suggestions; and the Royal Botanic Gardens, Kew, for support in the final stages of the preparation of the manuscript.

pressed in cladograms are difficult to relate directly to diagrams and statements of progenitor/descendant relationships used in many taxonomic schemes. Dahlgren et al. (1985) and Dahlgren & Bremer (1985) have published analyses most similar to the ones presented here but they are not of a similar scope. Although some specific topological components can be compared to other cladistic studies (Conti et al., 1993; Rodman et al., 1993; Qiu et al., 1993; and several of the other studies in this issue), morphological phylogenetic studies at this level with similar, broad taxonomic sampling do not exist. The computational difficulties of evaluating internal support (e.g., the bootstrap, Felsenstein, 1985; decay analysis, Bremer, 1988) or departure from matrix randomness (Archie, 1989; Faith & Cranston, 1991; Källersjö et al., 1992) for such large numbers of taxa likewise prevent us from addressing extensively these issues here. We do present an analysis of families traditionally referred to Hamamelidae as an example of how internal support for specific clades might be examined. (See also other papers in this issue that address internal and external support for subsets of the general results.) Thus, the broad relationships described here can be used to focus more restricted (with fewer taxa), and therefore more rigorous, investigations.

We expect that patterns presented here will change somewhat as sequences of more species are added or if methodological improvements permit exact solutions (for a discussion of progress, see Penny et al., 1992). These results nonetheless have great value, both from heuristic and methodological perspectives, although the preliminary nature of these studies precludes a detailed examination of implications for seed-plant taxonomy and character evolution, as well as investigations of gene and protein evolution.

We have generally followed the taxonomic circumscriptions of Cronquist (1981) for dicots because this system conforms closely to those used in most textbooks and floras. For monocots, we have adopted the system of Dahlgren et al. (1985) but have changed the superorder ending "-iflorae" used by Dahlgren to the more appropriate "-anae" (Thorne, 1992).

## Materials and Methods

Selection of taxa for this study was not guided by a specific plan. Close examination of genera included in the analysis will reveal an uneven taxonomic distribution; some groups are well represented (e.g., Asteraceae and Asteridae in general, Cornaceae, Ericales, Magnoliaceae, Zingiberanae), whereas others are poorly sampled (e.g., dilleniid orders, especially Violales and Theales). Despite lack of a coordinated effort, all subclasses and orders have at least some representatives. All species that are used in this issue of the *Annals of the Missouri Botanical Garden* are listed alphabetically by family in a final Appendix along with other information concerning voucher status, sequence gaps, literature citations for published sequences, and figures of this paper in which each taxon occurs. Some taxa that were included in the 475-taxon data set were excluded from the 499-taxon matrix. Thus, in the second analysis certain families have fewer representatives, but the overall representation of lineages is greater.

Due to the large number of laboratories that contributed unpublished sequences, no standardized procedure was used to produce the sequences analyzed here. A generalization would be the following: a fragment containing *rbc*L was amplified from a total DNA extract using primers that flank or are near the ends of the coding region; this fragment was then directly sequenced using one of several different procedures or was cloned using standard recombinant DNA techniques; dideoxy sequencing generally included both strands for at least ⅘ of the minimally 1428-bp gene. Some workers used more closely spaced primers to sequence only one strand of DNA; either strategy appears to provide reasonably error-free sequences. Most extraction protocols relied on fresh or freshly dried leaf samples, but some samples were amplified from DNA extracted from herbarium specimens as old as 20 years.

Amplification of *rbc*L from some taxa produced two different products. Some of these products were different enough in size to observe on an agarose gel, whereas others were detected initially because multiple bands occurred at the same points in autoradiograms, indicating that more than one template was present. Nearly all cycads produced two loci (Hills & Chase, unpublished), which were separately cloned and sequenced to characterize both copies. In cycads examined, one copy contained deletions that disrupted the reading frame, an indication that this copy may represent a "pseudogene." In Convolvulaceae, Olmstead (unpublished) detected two copies of *rbc*L, one copy of which contained deletions. In *Canella* (Canellaceae; Qiu et al., 1993) and *Galphimia* (Malpighiaceae; M. W. Chase, H. G. Hills & W. R. Anderson, unpublished), two size-conserved copies of *rbc*L were also encountered. In *Galphimia*, one copy clearly contained substitutions at numerous sites otherwise conserved among angiosperms, suggesting that this

copy was a pseudogene. In *Canella*, no such unusual substitutions were observed in either copy. Two, reading-frame-intact copies of *rbc*L are also reported in Ulmaceae (E. Conti & K. J. Sytsma, unpublished). For *Canella*, we included both sequences in all analyses, but because the two sequences are always each other's sister we show only the position of "*Canella*" (in fact, there are two terminals here; the complete matrix used in Search II thus has 500 terminals but only 499 taxa).
